Cases "*c*" and "*d*" of Fig. 4 represent the same heat and power requirements as "*b*," but part of the power is produced by a Diesel engine. Case "*c*" shows the ideal case where all of the heat load is supplied by the steam-engine exhaust, and, conversely, all of the steam-engine exhaust is utilized. The daily steam-power output is 50 per cent of the total power. In this case all of the steam produced is used doubly.

Case "*d*" shows the practical case for the joint Diesel and steam plant, corresponding to case "*b*" for the all-steam-power plant. The steam-power plant produces 57 per cent of the daily power output and the Diesel plant the remaining 43 per cent. The exhaust-use factor of the steam plant is increased to 75 per cent (from 43 per cent in "*b*"). By-product steam power still constitutes 43 per cent of the total power, the same as in "*b*." Case "*d*" corresponds to the daily steam-load curves of Fig. 5, to which further reference will be made.

Heat Recoverable From Diesel Engines

In the foregoing no account has been taken of the low-pressure steam or hot water that can be obtained by utilizing the heat rejected by the Diesel engine in its water jackets and exhaust gases. The recoverable heat per kilowatt hour of power output is much less than the heat discarded by a steam engine or turbine, being about 4500 B.t.u. per kw-hr. for a four-stroke cycle air-injection Diesel. Nevertheless it is of considerable value if it can be used. Over two-thirds of this recoverable heat is in the form of warm water discharged from the jackets. This costs nothing to recover and may often be used for boiler feed. Warm water is also useful in many factory processes or for faucet service in buildings.

The value of the Diesel exhaust heat is more debatable; whether its recovery is justified depends upon the cost of recovering it (including investment charges) and upon the cost of the heat it displaces. In all-Diesel plants with small heat load the exhaust heat may be highly valuable because it greatly simplifies the problem of heat supply. On the other hand, in combination steam and Diesel power plants such as are now being discussed, the availability of low-cost exhaust steam at all times minimizes the value of the Diesel-exhaust heat.

In any case, the heat recoverable from Diesel engines is too small in comparison with the heat demands in the sort of problems here under consideration to have any important influence upon the economic balance.

Cost Comparisons

Up to this point the analysis has been a thermal one. It now becomes necessary to give it practical meaning by considering the costs involved, rather than the B.t.u. The major cost variables are fuel costs and fixed charges; the minor ones are such items as attendance, maintenance, lubrication, supplies, ash removal, make-up water, and feedwater treatment. It is not implied that attendance is a minor item of power cost, but that the difference in attendance cost between steam and Diesel units is small. Furthermore, the various minor cost variables offset each other to such an extent that they do not appreciably affect the results of a preliminary study, and may therefore be ignored here.

It does not seem necessary in this paper to discuss the reliability and maintenance cost of Diesel engines. The intelligent steam operating engineer has no difficulty in learning to handle Diesel equipment. The records of modern Diesel plants show that their reliability is satisfactory and that their maintenance costs do not exceed those of a high-grade steam plant.

The relations of fuel cost and fixed charges will now be considered for combination plants consisting of uniflow steam engines operating noncondensing and Diesel engines without heat recovery. For the steam power plant the following conditions are assumed:

Boiler pressure, 165-lb. gage
Superheat, 100 deg. fahr.
Back pressure, 2-lb. gage
Boiler evaporation, 8 lb. steam per lb. coal
Engine economy, 30 lb. steam per kw-hr.
Heat delivered in steam, 1069 B.t.u. per lb.
Heat lost in engines, 4100 B.t.u. per kw-hr.
Price of coal, $6.25 per ton
Initial cost of steam engine plant, $80 per kw. capacity (500-kw. units)
Fixed charges, 12 per cent.

Then:

Fuel cost, by-product steam power	=	0.15 cents per kw-hr.
Fuel cost, prime steam power	=	1.17 cents per kw-hr.
Annual fixed charges	=	$9.60 per kw. capacity.

By-product steam power is understood to mean steam power the exhaust of which is fully utilized for heating, and which is therefore charged only with the heat actually abstracted in passing through the engines—i.e., 4100 B.t.u. per kw-hr. Prime steam power is steam power whose exhaust is not utilized.

For the Diesel part of the power plant the following conditions are assumed:

Fuel economy, 10 kw-hr. per gal.
Price of fuel, $0.05 per gal.
Initial cost of Diesel plant, $100 per kw.
Fixed charges, 12 per cent.

Then:

Fuel cost, Diesel power	=	0.50 cents per kw-hr.
Annual fixed charges	=	$12 per kw. capacity.

In estimating the initial cost of the Diesel power plant, it is planned to use combination steam and Diesel units consisting of the usual horizontal steam-engine generating unit with crankshaft extending beyond the outboard bearing and connected through a flexible coupling to a Diesel engine. The usual speeds of uniflow and four-valve steam engines match those of heavy-duty Diesel engines close enough to permit this common drive. In the summer time, when the steam ends of some of the combined units are not needed, the steam connecting rods can be disconnected. On the other hand, in the winter time, some of the Diesel engines can be disconnected from the generators by removing the flexible pins in the couplings. During the mild seasons when part steam and part Diesel power are required, both prime movers can be utilized on the common generator, the load being distributed between them according to the demand.

A combination steam and Diesel unit will effect a considerable saving in initial cost by reducing the installed generator capacity, the wiring from generator to switchboard, and the switchboard itself. It will also reduce foundation size and cost, inasmuch as the Diesel engine will have the benefit of the steam-engine foundation. Furthermore, there will be a considerable saving in space occupied. If the steam engine is of the vertical multicylinder type, the space saving will be still greater; in this case

TABLE 2 ESTIMATED INITIAL COST OF 750-HP. DIESEL-ENGINE INSTALLATION (To drive 500-kw. generator of steam unit)

Engine and erection	$37,500
Foundation (additional)	2,000
Fuel tank	1,000
Freight and carting	1,700
Piping	1,000
Pumps, air compressor, oil reclaimer, flexible coupling, etc.	1,500
Building space, additional	1,500
Contingencies	1,300
Engineering	2,500
Total	$50,000

the common generator might have its own shaft and bearings, with flexible couplings on both sides.

Table 2 is an estimate of the initial cost of a 750-hp. Diesel engine to drive a 500-kw. generator mounted on a steam-engine shaft. It will be noted that the additional cost of the Diesel end is $100 per kw.

Steam Power Plant Need Not Be Full Size

When a joint Diesel and steam power plant is planned there is no need to make the steam-power capacity sufficient to handle the entire power load. This holds true even when the winter heat load greatly exceeds the exhaust steam that such a full-size steam plant would produce. At first thought this statement seems illogical in view of the fact that with the part-size steam plant less by-product power can be produced and its place must be taken by the more expensive Diesel power. But though the fuel cost is thus increased, the fixed charges will be reduced to a greater extent. In other words, reducing the size of the steam power plant will avoid investment in steam plant used to generate by-product power for only a short time during the winter. This point is brought out in the following simplified examples.

Diesel Power Added to Full-Size Steam Plant (Case IV)

In case IV, Diesel power is added to a full-size steam plant. During the winter, the heat load is large, as per case III (Fig. 2), the daily heat consumption being 150 per cent of the exhaust-steam output. During this period the Diesel power is not used, and the steam units supply the same amount of by-product power as in case III, with only 10,000 lb. of unused exhaust steam per 24 hr.

During the summer, however, the heat load is less, as per case I (Fig. 2), where the daily heat consumption is only one-third that of case III. This is the time to use Diesel power, and in case IV it is assumed that sufficient Diesel-engine capacity is installed to reduce the maximum exhaust output from the steam plant from 24,500 lb. per hour to 12,500 lb. per hour. As will be shown later, this corresponds to a Diesel-plant capacity of 49 per cent of the total power demand. These conditions are illustrated in Fig. 5.

Here D is the reduction in exhaust output by substituting Diesel power.

Then $\frac{D}{A + D}$ = proportion of daily power output generated by Diesel power.

Table 3 shows the changes in heat-use factors accomplished by the joint use of Diesel power, case IV, as compared to the simple steam plant, case I. It should be noted that during the summer:

1 The exhaust use factor C/A is improved from 0.43 to 0.75.

2 The proportion of heat load supplied by exhaust steam C/B remains the same, viz., 0.87.

3 The unused exhaust steam is reduced from 136,000 lb. per day to 34,000 lb. per day.

These figures may be converted to dollar values by considering fuel costs and fixed charges as follows:

(*A*) *Fuel Cost, Summer.* The reduction in unused exhaust steam is 102,000 lb. per day. Dividing this by 29 (lb. of exhaust steam per kw-hr.), the reduction in steam-generated power is 3520 kw-hr. per day. Inasmuch as the saving in fuel cost per kilowatt hour between Diesel power and prime steam power is 0.67 cents per kw-hr., the saving in daily fuel cost is $23.60.

(*B*) *Fixed Charges.* In order to accomplish this saving the capacity of the Diesel installation must be 12,000 ÷ 29 = 414 kw. The steam-plant capacity, which in this case is sufficient to carry the entire power load, is 24,500 ÷ 29 = 845 kw. The additional fixed charges on account of the Diesel installation are 414 kw. × $100 × 12 per cent = $4970. Therefore, in order to offset these additional fixed charges, the Diesel power plant will have to operate under the summer-heat-load conditions (Fig. 5), for $4970 ÷ $23.60, or 210 days per year.

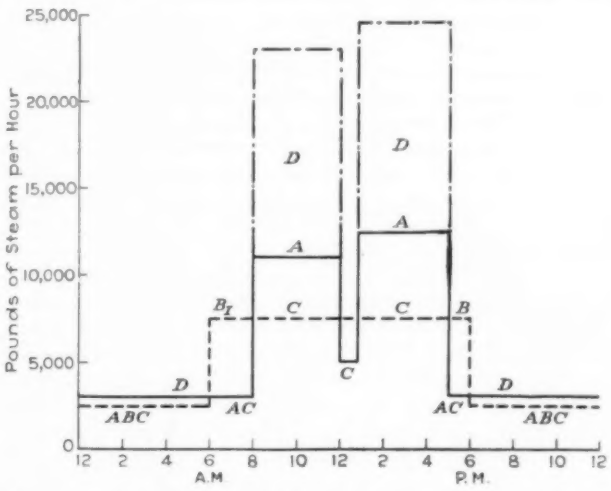

Fig. 5 Steam-Load Curves, Joint Diesel and Steam Plant, Summer Conditions

Diesel Power With Part-Size Steam Plant (Case V)

The effect of using Diesel power in conjunction with a part-size steam plant may now be investigated. This will be designated as case V, which is based upon the same Diesel capacity as in case IV (i.e., 414 kw.), but upon only 600 kw. of steam-power capacity (instead of 845 kw.). The total power demand remains, as before, 845 kw.

During the summer, the heat load being light, the Diesel plant is used at full power during the hours of maximum power load, and therefore the reduction in size of the steam plant does not affect its output. Consequently, the heat-use factor remains the same as for the previous case, as shown in Fig. 5 and in Table 3, case IV.

TABLE 3 EFFECT OF DIESEL POWER UPON HEAT-USE FACTORS IN JOINT POWER PLANTS

	All-steam power		Case IV		Case V	
Total power load	845		845		845	
Steam-power capacity	845		845		600	
Diesel-power capacity	0		414		414	
Season	Winter	Summer	Winter	Summer	Winter	Summer
Heat load, B	III	I	III	I	III	I
Ratio of heat load to exhaust output, B/A	1.50	0.50	1.50	0.87	1.90	0.87
Exhaust-use factor, C/A	0.96	0.43	0.96	0.75	1.00	0.75
Proportion of heat load supplied by exhaust, C/B	0.64	0.87	0.64	0.87	0.53	0.87
Reduction in exhaust output by substituting Diesel power, 1000 lb. per 24 hr., D	0	0	0	102	50.8	102
Proportion of daily power output generated by Diesel, $\frac{D}{A + D}$	0	0	0	0.43	0.21	0.43
Unused exhaust steam, 1000 lb. per 24 hr., A-C	10	136	10	34	0	34

In the winter, however, when the heat load is large (*B*-III) less by-product power is generated, and the thermal relations are as shown in Fig. 6. The reduction in by-product power occurs during the hours of maximum power demand; in this case between 8 and 12 a.m. and between 1 and 5 p.m. However, this thermal loss is partly compensated by the substitution of Diesel power for some prime steam power during the same hours. During these hours the full-size steam plant (845 kw.) would have exhausted 190,000 lb. of steam, of which 180,000 lb. would have been used for heating, while 10,000 lb. would have been wasted. In the present case, however, the 600-kw. steam plant exhausts during the same hours only 139,200 lb., all of which is used for heating. The reduction in by-product power is therefore 180,000 — 139,200 ÷ 29 = 1410 kw-hr., and the reduction in prime steam power is 10,000 ÷ 29 = 345 kw-hr.

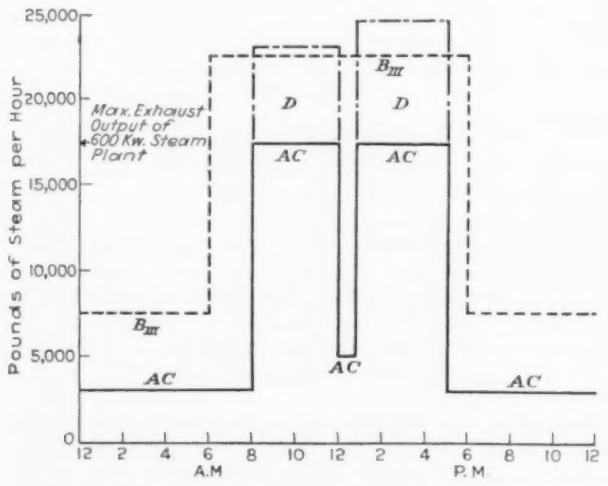

FIG. 6 STEAM-LOAD CURVES, DIESEL WITH PART-SIZE STEAM PLANT, WINTER CONDITIONS

Table 3 shows the heat-use factors corresponding to case V. It will be noted that the exhaust-use factor is raised to unity during the winter period; also that 21 per cent of the daily power output is generated by Diesel in the winter and 43 per cent in the summer.

Converting these thermal figures into costs give the following:

(*A*) *Fuel Cost, Winter.* Increased fuel cost by substituting Diesel power for by-product power = 1410 × 0.35 cents = $4.93. Decreased fuel cost by substituting Diesel power for prime steam power = 345 × 0.67 cents = $2.31. Net increase in fuel cost per winter day = $2.62.

Inspection of the load curves, Fig. 6, shows that the increase in fuel cost per winter day diminishes as the season becomes warmer. This is because the heat-load curve *B* drops in warmer weather, causing an all-steam-power plant to produce less by-product power and more prime power. Accordingly it is fair to assume for the present example that the reduced size of the steam plant will increase the fuel cost for the entire winter by 60 times the maximum daily increase, or $157.

(*B*) *Fuel Cost, Summer.* As already explained, the heat-use factors during the summer will be the same as in the previous case, and the fuel cost saving will also be identical, i.e., $23.60 per day.

(*C*) *Fixed Charges.* The additional fixed charges for case V as compared with the simple steam plant may be computed as follows:

Diesel installation, 414 kw. × $100 × 12 per cent...	$4970
Less reduction on steam installation, 245 kw. × $60 × 12 per cent.....	1760
Net additional fixed charges.....	$3210

TABLE 4 RESULTS OF TWO STUDIES FOR HEAT AND POWER SUPPLY

	Large loft building			Large department store		
Type of service.....						
Annual consumption of low-pressure steam.....	33,000,000 lb. per year			90,100,000 lb. per year		
Annual consumption of electricity.....	4,200,000 kw-hr. per year			7,576,000 kw-hr. per year		
Maximum demand for low-pressure steam..	25,000 lb. per hr.			47,500 lb. per hr.		
Maximum demand for electricity.....	1,500 kw.			2,419 kw.		
Type of plant considered.....	Purchased power	All-steam power	Joint steam and Diesel	Purchased power	All-steam power	Joint steam and Diesel
Steam power plant capacity.....	0	1700 kw.	1000 kw.	0	3000 kw.	1200 kw.
Diesel power plant capacity.....	0	0	700 kw.	0	0	1800 kw.
Annual overall cost including fixed charges[1].....	$127,500	$113,260	$105,460	$143,650	$123,600	$98,190

[1] Items common to all types of plants omitted.

In order to effect a net saving, the Diesel installation must more than offset by means of its summer fuel savings not only its additional fixed charges but also its additional winter fuel cost of $157; these items total $3367 per year. Therefore the Diesel power plant must operate under the summer conditions of Fig. 5 for 143 days per year.

PART-SIZE STEAM PLANT, WITH DIESEL POWER, IS JUSTIFIED

Comparing cases IV and V, it appears that the combination of Diesel power with a part-size steam plant accomplishes the following:

1 It substitutes Diesel power for expensive prime steam power during the hours of maximum power demand.

2 Even in the coldest weather, when the reduced size of the steam plant causes the greatest loss in by-product power, the increased daily fuel cost is only $2.62 as compared with a reduction of $23.60 in the daily fuel cost during warm weather.

3 The saving in warm-weather fuel cost will offset the extra fixed charges of the Diesel plus its extra winter fuel cost, if the small heat-load conditions exist for 143 days per year, as compared with 210 days in the case of the full-size steam plant with Diesel power.

Similar computations for an all-Diesel plant with the same power and heat conditions show that its annual cost would greatly exceed that of the combination plant. It is evident, therefore, that the part-size steam plant joined with Diesel power will produce the foregoing heat and power requirements at a lower annual cost than an all-steam plant, an all-Diesel plant, or a combination of Diesel power with a full-size steam plant.

RESERVE POWER

No attempt has been made here to decide the best total capacity for a practical power plant to meet the assumed load conditions, nor to determine the best relative proportions of Diesel and steam power, as these questions depend upon too many extraneous factors. One of these is the necessity for reserve power. The capacity of the combined steam and Diesel plant must, of course, exceed the maximum power demand. Generally it should exceed it by one spare unit, either steam or Diesel. There is certainly no need of planning to have both a steam and a Diesel spare unit, as one or the other, depending upon the season, will serve the purpose. In the cold season, when the steam plant is operating at full capacity, the Diesel equipment will provide reserve capacity. In the warm season, when the Diesel plant is in steady operation, the steam plant

will provide the necessary reserve. Some of the steam plant, in any event, will be running during the summer; consequently boilers and piping will be under pressure, and the remaining steam equipment can be put into service quickly.

In this connection it is well to keep in mind the unusual value of a Diesel engine for breakdown service. The Diesel unit, so far as the power end is concerned, is entirely independent of the steam plant; it therefore is available for use even if the entire steam plant is out of service. A spare steam-power unit, of course, does not enjoy this advantage.

Other Factors

Some other factors entering into a study of the joint use of Diesel and steam power deserve general comment, such as the following:

1 All of the preceding examples have been based upon noncondensing steam equipment. If it is feasible to install condensing equipment, the steam plant's fixed charges will be increased, but the fuel cost of prime steam power will be much lower, particularly in large plants; the resulting smaller differential with respect to Diesel-fuel cost will reduce the possible benefits of installing Diesel power.

2 In noncondensing steam plants using Diesel engines, good steam economy is not nearly as important as in all-steam plants, because less prime steam power is generated. Consequently, the steam plant may be simpler and less expensive. The four-valve steam engine deserves careful consideration in joint power-plant projects, as its lower initial cost may easily offset its slightly increased fuel consumption, under conditions of moderate steam pressure and atmospheric exhaust. To a smaller degree this also applies to the use of steam turbines.

3 In the numerical examples just computed, no account has been taken of the heat recoverable from the Diesel-engine water jacket and exhaust. This would obviously lead to still greater thermal economy, but would have to be offset against the additional fixed charges.

4 If the conditions are such that the power capacity of an existing steam plant must be increased, it is often easier to install a relatively compact Diesel unit rather than to enlarge the steam plant. If, as is frequently the case, the power load already exceeds the heat load, an increase in the steam power-plant capacity would necessitate installing not only additional steam engines but also boilers.

Plant Design

After the heat balance analyses have been concluded, the design of the joint power plant demands careful study. If new steam-power units are required, they must be carefully selected and due consideration be given to uniflow engines, four-valve engines, and turbines. The selection of the Diesel-power equipment involves questions of two-stroke cycle or four-stroke cycle, air injection or mechanical injection, running speed, governor control, and many others. The answers depend upon the kind of service required, the nature of the fuels available, and similar factors. In addition, the engineer must carefully consider the differences in power ratings of engines offered by various manufacturers and also their servicing facilities. He must design proper foundations, devise suitable water-supply arrangements, dispose of the exhaust gases without occasioning objections from noise or smoke or odor, and prevent the transmission of engine vibrations or noise to the surroundings. In many cases these are real engineering problems the successful solution of which depends upon the application of competent engineering skill and experience.

A number of refinements can be contrived for joint Diesel and steam power plants; for instance, the automatic division of load between the steam engines and the Diesels. This is desirable during periods when the heat load is less than the maximum exhaust-steam output and is fluctuating. At such times the best balance is obtained by loading the steam engines to the point where they will supply just enough exhaust steam to meet the heat requirements. In a direct-current installation this load distribution between steam and Diesel could be maintained automatically by controlling the voltage of a steam unit according to the exhaust back pressure. (This is predicated, of course, upon the steam unit having its own independent generator.)

Practical Examples

Several studies of heat and power balance involving the joint use of Diesel and steam engines have recently been made. Full details cannot be given, but the conclusions in two cases are presented in Table 4.

An actual application of Diesel engines in an existing steam power plant was recently made in the department store of R. H. Macy & Co., New York City. Here two 800-kw. Diesel generating units were installed in a steam power plant containing Corliss engines of 3350 kw. total capacity. The power load had grown faster than the heat demand because of the installation of escalators, electric elevators, additional lighting, and an air-conditioning system, so that even in the winter a large amount of the steam used for power generation had been wasted to the atmosphere. It is expected that the Diesel engines will go far to stop this waste. It is notable, too, that because of the compactness of modern Diesel engines sufficient space was found in a crowded engine room for two 800-kw. units in the space formerly occupied by pumps and tanks used for hydraulic elevators.

Another recent installation of a Diesel engine in conjunction with a steam power plant is that in the new Hotel New Yorker, in New York City. Here a 350-kw. Diesel unit was installed in conjunction with 2200 kw. of uniflow steam engines. In this case, however, the primary purpose of the Diesel installation was not to improve heat balance, but to provide breakdown protection. No matter what trouble may occur in the steam plant, the Diesel engine is always available for service, and even if the steam plant should be completely shut down, the Diesel engine has sufficient capacity to supply emergency power and light requirements. However, as far as the Diesel engine's effect upon the heat balance is concerned, its influence will be small, as the Diesel power is too small in comparison with the steam power.

Conclusion

It is hoped that this paper has brought out the following salient points:

1 Diesel engines can be effectively used in conjunction with certain types of steam power plants to produce power and heat at low over-all cost. Their utility consists in enabling the steam plant to produce the optimum quantity of by-product power from space-heating and process steam, while the Diesel units generate the remaining power at lower cost than a steam plant would.

2 In such joint steam and Diesel power plants the total plant capacity need not exceed that of a corresponding all-steam power plant. Despite some loss in thermal economy, the decreased investment results in lower over-all costs.

3 In any study of the use of power steam for heating purposes, the exhaust-use factor must be determined with the utmost care. Detailed analyses of power and heat requirements at all hours of the day and at all times of the year must be made; otherwise the amount of exhaust steam utilized may be greatly overestimated and erroneous conclusions be reached.

Discussion

S. B. Daugherty.[4] In one of the plants of the United States Steel Corporation, in their later installations of large gas engines, they provided (some six or seven years ago) for the installation of waste-heat boilers to recover the heat from exhaust gases. They had not at that time made the installations.

L. F. Burger.[5] The writer has in mind a plant that he installed in Pittsburgh some years ago. The party wanted only one generator, but wanted to operate it with two engines. It therefore was arranged to install the generator between the two engines. Sliding clutch couplings were mounted on both ends of the generator shaft and on one end of each engine's crankshaft. This installation was so arranged that one could operate the generator with both engines at the same time or either one of the engines could be cut off. This proved to be a very satisfactory installation. As the changes from one engine to the other engine could be made without throwing off the load on the generator, providing it was not greater than the capacity of one of the engines, this change could also be made without a noticeable flicker in the lights operated by current from the generator.

R. L. Sackett.[6] The paper emphasizes the importance of careful analysis of heat loads, peaks, and seasonal demands. Such papers serve to point out new fields where the Diesel engine may be used in parallel with other forms of prime movers.

Dr. Schweitzer, in his paper before the A.S.M.E. last December, directed attention to the possibility of peak loads in large steam-generating plants being carried with economy by oil engines.

There is still another field which has not yet received much attention before this Society. Hydroelectric plants are subject to fluctuations in output due to low flow and restricted storage. Steam has usually been employed as an auxiliary either to carry the peak or the base load, depending on conditions. Where the hydro power is a small factor on a large interconnected steam system, Diesel power may not be economy, but where a plant auxiliary is necessary, an analysis of the peak and base loads may show Diesel power to be advantageous. It is even possible that enlarging an existing hydro-steam plant may best be done by installing a Diesel unit.

Data of costs are now available, and careful analysis supported by sound judgment will show that Diesel power is an increasingly valuable base or auxiliary source of energy.

E. W. Hammond.[7] This paper clearly defines proper methods for the selection of Diesel and steam engines to balance heat and power. A similar study has recently been made at a refinery showing that Diesel engines had a wide field of application in this industry, even though refineries are large users of process steam as well as power.

After determining that Diesels are the economical prime movers, and the first study indicates a six-month operation is justified, a further survey should be made to compare costs of producing power with the steam units to include for these machines all fixed and operating charges. Since the first study assumes only six months' operation of the Diesel, all annual fixed charges have been applied against the Diesel. Additional operating time beyond six months for the Diesel requires only consideration of the operating charges, which may be lower than cost of producing power in the steam units, in which case these should be omitted and the heating or steam load carried on the boilers.

There is a proposed arrangement of a Diesel and a steam engine to drive a common generator with disconnecting couplings. This is a treacherous proposition, because with such an arrangement torsional vibrations are very likely to be present, and the danger of these is well known to every one. Likewise, there will be considerable difficulty in getting the governors of the steam engine and the Diesel engine set so that they will hold the same speed variation with changes of load.

Likewise it will be difficult to arrange for placing both units in service. The writer believes the better arrangement would be to have a separate generator direct-connected to each engine to eliminate all of these difficulties as well as to provide flexibility and continuity of power supply.

Edward J. Kunze.[8] Use of a steam accumulator as a heat exchanger in a Diesel system, as has been proposed, is not feasible. The steam accumulator is not intended to be used as a heat-recovery apparatus. It is designed to even the steam load over short periods of time, thus avoiding rapid fluctuations in pressure during such short periods.

Steam accumulators function by holding large quantities of water under a pressure and temperature considerably higher than those of the boilers they serve, so that on demand of a boiler some of this highly compressed water, passing through a reducing valve to the boiler, is flashed into steam at boiler pressure.

Obviously, high cost and large size, which are inherent in this system, eliminate the steam accumulator for use as a heat exchanger such as may be useful in a Diesel system.

Author's Closure

The recovery of Diesel-engine waste heat is not an important factor in joint steam and Diesel power plants, which are the subject of this paper. If such plants are designed for best dollar economy, the installed Diesel-engine capacity is less than the power load, and therefore steam engines are operating at all times. Thus cheap heat in the form of engine-exhaust steam is always available. (See Fig. 5 in the paper.)

During a few months of the year, when the heat load is a maximum, the steam-engine exhaust is inadequate (see Fig. 6), and the Diesel engine's heat would be useful. However, this condition of affairs is so brief that it would seldom pay to install Diesel exhaust-heat reclaimers, as their fixed charges and maintenance would generally exceed the cost of the same amount of live steam from the fuel-fired boilers. The situation here is quite different from the case of an all-Diesel power plant; in the latter the value of the exhaust heat is much greater and often fully justifies the installation of the heat exchangers necessary to reclaim it.

As for the warm water discharged from the Diesel-engine jackets, this low-temperature heat is available at no extra expense and should be utilized if it is at all possible. Furthermore, utilizing the jacket water not only saves heat but also water, and sometimes also eliminates a jacket-water recooling system.

Several of the discussors have cited objections to the suggested use of a combination generating unit consisting of a common generator driven by both a Diesel and a steam engine. The bugbear of torsional vibrations can be eliminated by mathematical analysis such as is now being successfully applied to many similar problems. The problem of governing is not difficult; the conditions for speed regulation of a steam engine and

a Diesel engine connected to a common shaft are practically the same as when separate steam-engine units and Diesel-engine units drive alternating-current generators in parallel, and this of course is quite common.

One is not compelled to resort to combination generating units in order to make practical applications of Diesel engines in steam-power plants. However, the attractive features of such a combination unit, i.e., reduced investment in foundation, generator, wiring, and switchboard, and a great saving in space, would seem to justify its development.

Research of the National Advisory Committee for Aeronautics on Aircraft Diesel Engines

By CARLTON KEMPER,[1] HAMPTON, VA.

The National Advisory Committee for Aeronautics has studied the theoretical performance possible with a Diesel engine operating upon a dual-combustion cycle. It has investigated the great number of factors which control the injection characteristics of fuel sprays, and coordinated and applied results from test information on fuel injection and combustion to the design of combustion chambers. Considerable progress has been made.

THE AIRCRAFT Diesel-engine research of the National Advisory Committee for Aeronautics is a part of a general program having for its object the investigation of the factors involved in improving the safety and economy of aircraft. The high-speed Diesel engine is attractive as a power plant for aircraft, because its use results in the following advantages: First, a reduction to a great extent of the fire hazard in aircraft; second, the elimination of radio interference without a system of ignition shielding; third, the reduction of fuel consumption; and fourth, the use at present of a cheap fuel. In its broadest aspect the problem of developing the aircraft Diesel engine is one of obtaining fundamental information on the characteristics of fuel sprays and air turbulence which affect combustion. Until the effect on the rate of combustion of such factors as drop size, rate of injection, spray dispersion and distribution, temperature, and air density and turbulence are known, it will be difficult to increase greatly the performance of the aircraft Diesel engine above the present values obtained with high-speed oil engines.

The research of the committee may be divided into three main parts. The first is a study of the theoretical performance possible of attainment with this type of engine operating upon a dual-combustion cycle. This work includes the determination of the effect on cycle, combustion, volumetric, mechanical, and cooling efficiencies of such factors as maximum cylinder pressure, compression ratio, and quantity of excess air. The only practical method for investigating these factors at the present time is to develop methods of calculating their theoretical effect. The results of this investigation serve as a guide to indicate the maximum performance possible of attainment. The second investigation is concerned primarily with the great number of factors which control the injection characteristics of fuel sprays. It is the demand in this investigation for more information on spray penetration and dispersion which produced the N.A.C.A. spray-photography equipment with which it is possible to take 25 consecutive pictures of a single spray at rates of from 2000 to 4000 pictures per second (reference 1). The third investigation has for its object the coordination and application of the results of all available test information on fuel injection and combustion to the design of combustion chambers which will give increased engine performance.

During the past year considerable progress has been made along the lines of obtaining information which will permit the successful prediction of the injection characteristics of a given design of fuel-injection system, and in increasing engine performance without appreciably increasing the maximum cylinder pressure. This paper will briefly review some of the results obtained in the various investigations conducted at the Langley Memorial Aeronautical Laboratory during the past year.

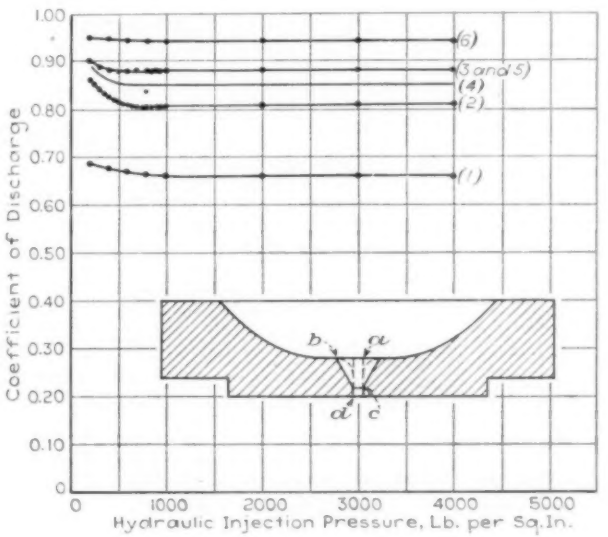

FIG. 1 EFFECT OF HYDRAULIC INJECTION PRESSURE ON COEFFICIENT OF DISCHARGE

Orifice diameter 0.015 in., back pressure atmospheric.)

COEFFICIENT OF DISCHARGE INVESTIGATION

The present work of determining the coefficients of discharge for small-diameter orifices under high injection pressures is an extension of that undertaken by W. F. Joachim, and was conducted with the same equipment (reference 2). In this work the factors which have been investigated are the diameter and length-diameter ratio of the orifice, the injection pressure, and the shape of the approach to the orifice. Fig. 1 shows the effect of injection pressure and change in orifice approach on the coefficient of discharge for a 0.015-in. diameter orifice. At the start of the tests, the nozzle had sharp edges and gave a coefficient of discharge of about 0.65. The first change consisted in round-

[1] Associate Mechanical Engineer, Langley Memorial Aeronautical Laboratory, National Advisory Committee for Aeronautics. Mr. Kemper was graduated from the University of Pennsylvania with the degree of B.S. in Mechanical Engineering in 1923. He was with the Packard Motor Car Company until September, 1924, and since that time he has been with his present connection.

Presented at the Third National Oil and Gas Power Meeting, State College, Pa., June 12 to 14, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

ing the leading edge to approximately $^1/_{64}$-in. radius. This single alteration increased the coefficient from 0.65 to 0.80. The experiment was then tried of rounding the leading edge to approximately a $^1/_{32}$-in. radius. This change increased the coefficient to 0.88. The leading edge of the orifice was then beveled to 60 deg., leaving the edges sharp. A small decrease in the coefficient was obtained, but by slightly rounding the sharp edges *b*, *c*, and *d*, the coefficient was increased to 0.94. This represents an increase of 42 per cent in the value of the coefficient obtained by changing the shape of the orifice approach and in rounding the edges of the orifice. In this series of tests the orifice length-diameter ratio has been changed, and might be thought to have some effect on the coefficient of discharge. The curve

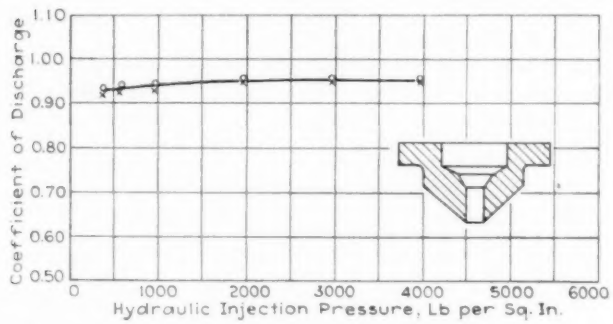

FIG. 2 EFFECT OF HYDRAULIC IGNITION PRESSURE ON COEFFICIENT OF DISCHARGE

(Orifice diameter, 0.014 in.; length-diameter ratio, 1, 2, and 3; back air pressure, atmospheric.)

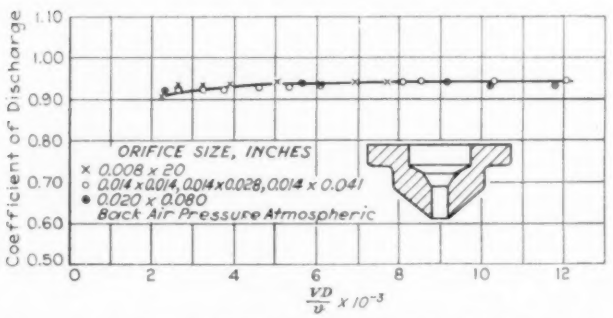

FIG. 3 VARIATION OF COEFFICIENT OF DISCHARGE WITH REYNOLDS NUMBER

of Fig. 2 shows that the length-diameter ratio is relatively unimportant, provided the same geometrical shaped nozzle is used. In the tests made with this 0.014-in. diameter orifice the length-diameter ratio was varied in successive steps of 3, 2, and 1. The results show that except at the lower injection pressures where there was a slight decrease, the coefficient remained constant at 0.94, the same value that was obtained with the orifice illustrated in Fig. 1.

If it is true that the orifice length-diameter ratio and orifice size have no effect on the coefficient of discharge providing the same geometrical shape of orifice is used, then the values of the coefficient of discharge plotted against the Reynolds number should give constant values. Fig. 3 shows the curve obtained when the data are plotted in this manner. It may be noted that the value of the Reynolds number investigated varies from 2000 to 12,000. The curve shows results obtained with orifices having diameters of 0.008 in., 0.014 in., and 0.020 in. for orifice length-diameter ratios of 1, 2, 3, and 4. The large values of the Reynolds number obtained even with the low injection pressures indicate that the flow in the orifice for all test conditions is within the range of turbulent flow.

In using the coefficient-of-discharge apparatus the nozzles to be tested are assembled in a special holder. Sufficient tests were made, however, with the nozzles mounted in an automatic injection valve having a low valve-opening pressure, to show that the spring-loaded stem above the orifice had no effect on the value of the coefficient.

Although the angle of 60 deg. was chosen arbitrarily because nozzles made at the laboratory have used this angle, the work by Zucrow (reference 3) has shown that this angle gives the maximum value of the coefficient.

The values of the coefficient of discharge have been used in determining the variation in oil pressure during the injection period of an injection system consisting of an injection pump having a constant-velocity cam and an automatic spring-loaded injection valve. The valve opening pressure was taken as 500 lb. per sq. in., and the orifice diameter as 0.020 in. The calculations were made for a pump speed of 750 r.p.m.

If no leakage past the pump plunger is assumed, the displacement of the plunger does two things; it compresses the fuel in

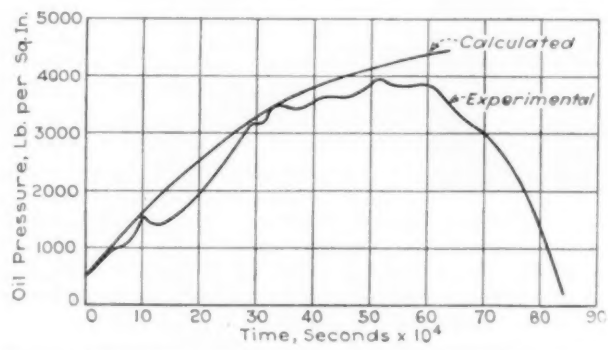

FIG. 4 COMPARISON OF CALCULATED AND EXPERIMENTALLY DETERMINED PRESSURES IN AN INJECTION PUMP

(Orifice diameter, 0.02 in.; valve-opening pressure, 500 lb. per sq. in.; pump r.p.m., 750.)

the injection system, and discharges fuel through the injection valve. By equating the rate of displacement of the pump to the rate of discharge through the orifice plus the rate of compression in the injection system, the instantaneous pressure at the discharge orifice can be computed. The decrease in volume of the fuel with pressure may be calculated from the information contained in reference 4. Knowing the diameter and coefficient of discharge of the orifice, the flow through the injection valve can be calculated by the familiar hydraulic formulas,

$$Q = A\ V\ t, \text{ where } V = C\ \sqrt{2g\ P/\rho}$$

The calculated injection pressures have been plotted in Fig. 4, for comparison with the experimental values of oil pressure determined from the stem-motion diagram of an automatic injection valve (reference 5). The agreement of the curves during the injection stroke of the pump plunger is good. The calculations have not been extended above 0.006 sec., since at about this time the bypass on the fuel pump opens. The curves indicate that for the period of injection during which the bypass valve is closed the instantaneous pressures may be calculated with a fair degree of accuracy.

INVESTIGATION OF SPRAY PENETRATION

At the same time that the work is being continued on the coefficient-of-discharge apparatus, the effect of injection pressure and chamber pressure on the spray penetration and spray shape

is being determined with the spray-photography equipment for the same orifices. The effect of injection pressure, chamber pressure, and orifice length-diameter ratio on fuel-spray penetration after 0.001 sec. is shown in the curves of Fig. 5.

The data were obtained for a 0.014-in. diameter orifice having length-diameter ratios of 2, 3, and 4. The valve-opening pressure was 2000 lb. per sq. in. The range of injection pressures investigated was from 2000 to 8000 lb. per sq. in., and the chamber pressures were varied from 65 to 250 lb. per sq. in. An examination of the surfaces which represent the data obtained for each orifice length-diameter shows that for any given injection pressure and chamber pressure increasing the orifice length-diameter ratio increases the spray penetration. At the low chamber, pressures increasing the length diameter from 3 to 4 results in

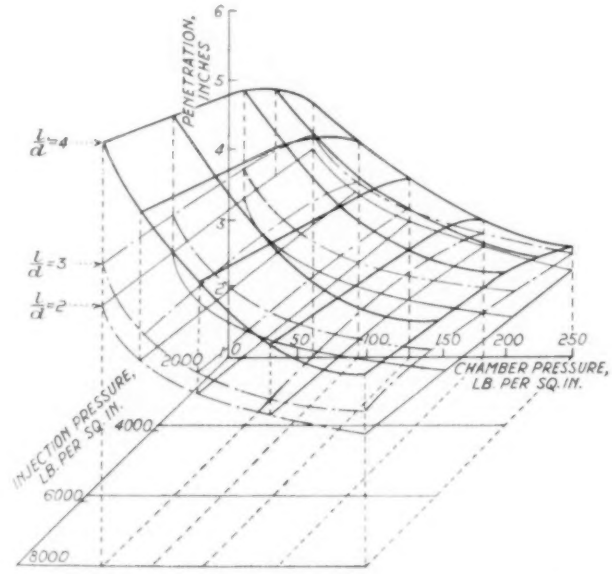

FIG. 5 EFFECT OF INJECTION PRESSURE, CHAMBER PRESSURE, AND ORIFICE LENGTH-DIAMETER RATIO ON SPRAY PENETRATION (Orifice diameter, 0.014 in.; valve-opening pressure, 2000 lb. per sq. in.; penetration, after 0.001 sec.)

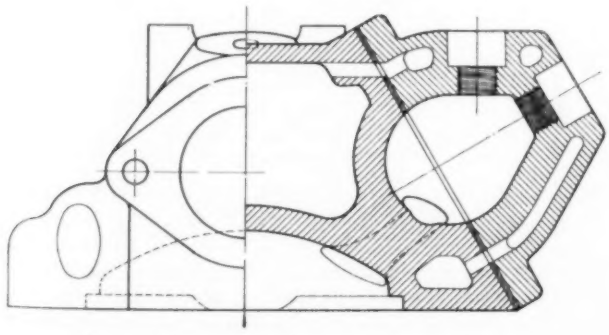

FIG. 6 COMBUSTION-CHAMBER DESIGN NO. 3

a greater increase in penetration than is obtained by increasing the length-diameter ratio from 2 to 3. As the chamber pressure is increased, however, this difference in penetration for equal increments of change in the length-diameter ratio decreases, until at a chamber pressure of 250 lb. per sq. in., the increase in penetration for a change in length-diameter ratio of 2 to 3 is about equal to that obtained by increasing this ratio from 3 to 4. Previous tests have shown that with centrifugal stems the maximum spray dispersion is obtained with orifice length-diameter ratios of 1.5 to 2 (reference 6). With the higher length-diameter ratio the spray angle is less, and the jet maintains a compact stream for a greater distance into the chamber before breaking down. This work will include similar information for a range of orifice sizes from 0.005 in. to 0.040 in., and for injection times of 0.001 sec., 0.002 sec., and 0.003 sec. Both plain- and centrifugal-injection valve stems will be used.

INVESTIGATION OF VALVE-STEM MOTION

Although it has been impossible to obtain a commercial indicator capable of indicating the instantaneous pressures obtained in the fuel-injection line during injection, a method has been developed which permits the determination of these instantaneous pressures from the photographic records obtained of the motion of the injection valve stem. By an analysis of these records, it has been possible accurately to determine the injection characteristics of a common-rail fuel-injection system.

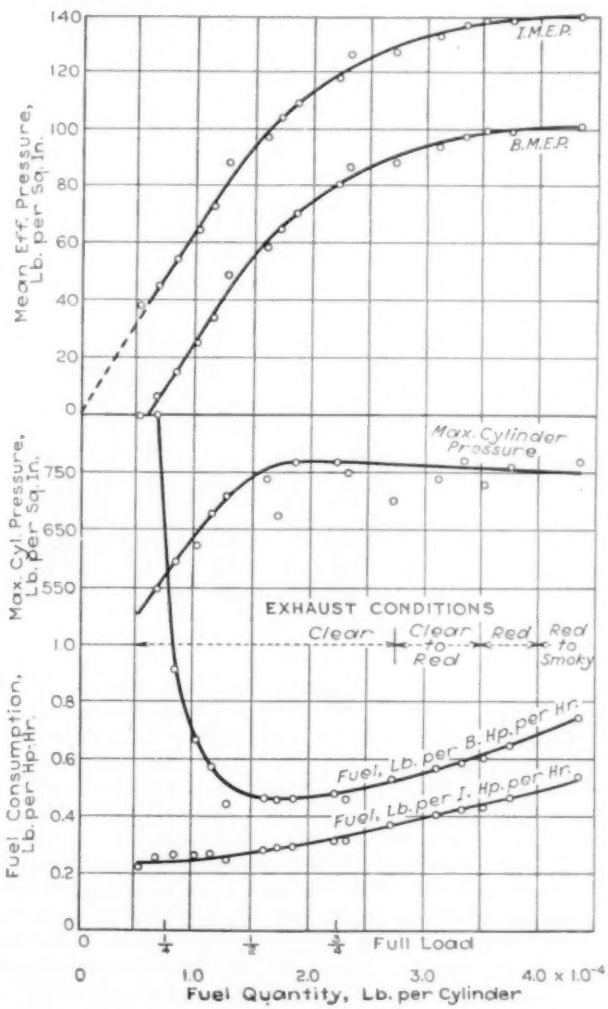

FIG. 7 EFFECT OF LOAD ON ENGINE PERFORMANCE WITH COMBUSTION-CHAMBER DESIGN NO. 3
(Bore, 5 in.; stroke, 7 in.; engine speed, 1500 r.p.m.)

COMBUSTION CHAMBER INVESTIGATION

There are two general methods for obtaining an intimate mixture of fuel and air in the cylinder of an aircraft Diesel engine. The fuel may be distributed throughout the air in the combustion

chamber by so proportioning and directing the fuel-injection orifices as to obtain the desired mixing, or a high velocity of air flow in the combustion chamber may be used to distribute the fuel. At present, research work is being conducted upon a combustion chamber representative of each of these methods of fuel-spray distribution.

The laboratory has stressed low maximum cylinder pressures for this type engine. The figure of 800 lb. per sq. in. has been arbitrarily taken as the maximum permissible cylinder pressure. It is advantageous to operate at low maximum cylinder pressures, because of the great increase in structural and maintenance difficulties which arise when higher pressures are used. It has been noted that all attempts to operate these test engines on a constant-volume cycle have usually resulted in decreased power.

A complete description of the cylinder head designed to investigate the effect of high air turbulence on fuel-spray distribution has been previously given in reference 7. A sketch of the cylinder head is shown in Fig. 6. This cylinder head consists of a pear-shaped bulb directly connected with the main cylinder through a $^9/_{16}$-in. diameter orifice set at an angle so as to give a high velocity of air flow within the bulb on the compression stroke of the piston and within the cylinder on the expansion stroke.

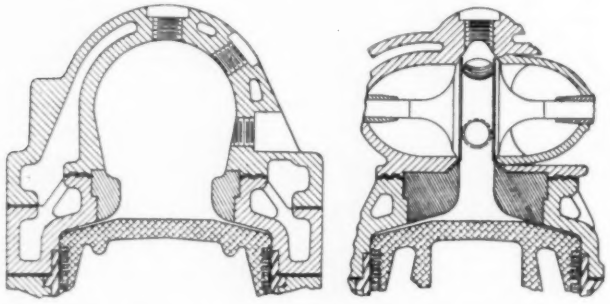

FIG. 8 COMBUSTION-CHAMBER DESIGN NO. 4

The fuel-injection valve is located along the center line of the bulb. With the present arrangement, the percentage of air within the bulb at the end of the compression stroke is 50 per cent. The increased engine performance over that previously reported has been obtained by using a cam-operated fuel-injection pump, a fuel-injection valve having a single 0.050-in. diameter orifice, and by using low valve-opening pressures.

Fig. 7 shows the engine performance obtained at a speed of 1500 r.p.m. with the cylinder head mounted on a 5-in. bore by 7-in. stroke test engine. The performance is plotted against fuel quantity in pounds per cycle. Full-load fuel quantity has been taken as the weight of fuel per cycle giving 15 per cent excess air. The outstanding point is the high indicated mean effective pressure obtained of 140 lb. per sq. in. with a maximum cylinder pressure of approximately 750 lb. per sq. in. The indicated power has been obtained by adding to the brake power the power required to motor over the engine with the dynamometer maintaining the same speed, water, oil, and air temperature as in the power run. The maximum cylinder pressures recorded have been indicated and checked by "trapped" pressure readings of a balanced-pressure disk-type indicator. The balanced condition of the disk is indicated by the flash of a neon lamp. The full-load performance of the engine gives an indicated mean effective pressure of 133 lb. per sq. in., and a fuel consumption of 0.40 lb. per i.hp. per hr. The corresponding brake mean effective pressure is 94 lb. per sq. in., and the fuel consumption 0.55 lb. per b.hp. per hr. The low mechanical efficiency of the engine at full load of 70 per cent is due in part to the high friction power necessary to force the air charge through the small-diameter orifice and the number of auxiliaries driven by the engine. The condition of the engine exhaust within 4 in. of the exhaust valve is also indicated on the performance curves. It may be noted that a clear exhaust is maintained from idling to 91 per cent of the full-load fuel. The maximum brake mean effective pressure obtained with a colorless exhaust is 91 lb. per sq. in., and the corresponding fuel consumption 0.52 lb. per b.hp. per hr. With increase in load the exhaust changes to dull red and finally becomes smoky. The maximum cylinder pressure increases with increase in fuel quantity until the maximum power with a colorless exhaust is reached. As the fuel is increased above the

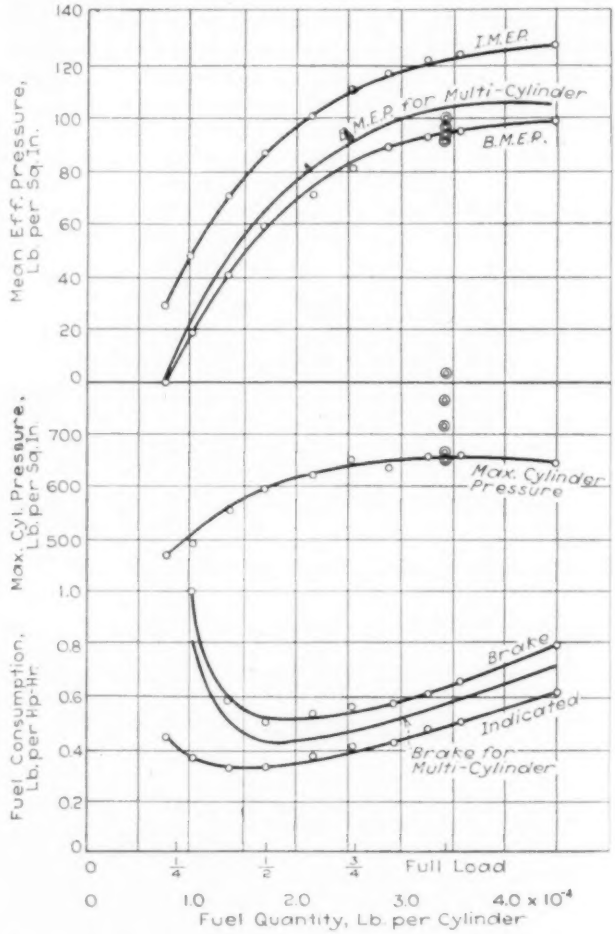

FIG. 9 EFFECT OF LOAD ON ENGINE PERFORMANCE WITH COMBUSTION-CHAMBER DESIGN NO. 4
(Bore, 5 in.; stroke, 7 in.; engine speed, 1500 r.p.m.)

full-load value, the maximum cylinder pressure remains practically constant, although the power continues to increase.

Although this type of combustion chamber is usually associated with relatively slow engine speeds, recent tests have shown that it is possible at 1500 r.p.m. to obtain a rate-of-pressure rise in the bulb of 1,080,000 lb. per sq. in. per sec. This rate-of-pressure rise is more than three times greater than that giving optimum performance in high-speed carburetor engines (reference 8).

COMBUSTION CHAMBER DESIGN NO. 4

The effect of fuel-spray distribution on engine performance has been determined for the combustion chamber design No. 4 shown in Fig. 8. This design is a vertical disk-type combustion chamber formed between horizontally arranged inlet and exhaust valves.

The cylinder head has been made with removable orifices between the upper part of the combustion chamber and the cylinder proper. The fuel-injection valve is mounted in the top of the combustion chamber. The engine performance shown in Figs. 9 and 10 was obtained with a cam-operated fuel-injection pump and an automatic spring-loaded fuel-injection valve. A uniform distribution of fuel throughout the air in the combustion chamber was obtained by varying the size, number, and direction of the orifices in the valve nozzle.

Fig. 9 shows the variation in engine performance with load for this cylinder head mounted on a single-cylinder test engine having

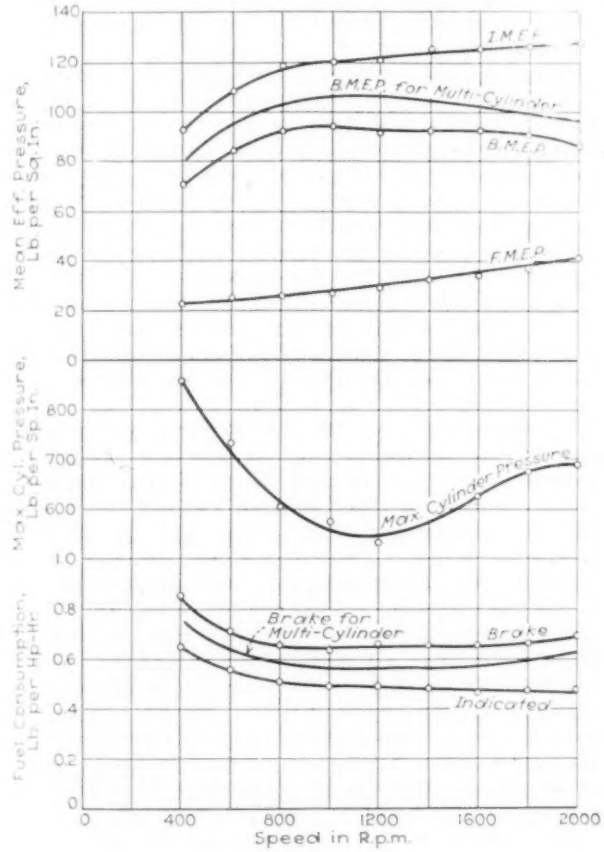

Fig. 10 Effect of Engine Speed on Performance at Full Load With Combustion-Chamber Design No. 4
(Bore, 5 in.; stroke, 7 in.)

5-in. bore by 7-in. stroke, and operated at a speed of 1500 r.p.m. The outstanding characteristic of this combustion chamber is the high brake mean effective pressure obtained with low maximum cylinder pressures. Since this engine has a higher volumetric efficiency than the No. 3 cylinder head, the full-load fuel quantity per cycle is increased. The full-load fuel quantity of 3.45×10^{-4} lb. per cycle in this case gives no excess air in the cylinder. The full-load mechanical efficiency of this test engine is 77 per cent, which may be compared with the value of 70 per cent recorded for the bulb-type cylinder head. Using the same values of indicated power and fuel consumption, the brake performance has been calculated for an assumed mechanical efficiency of 85 per cent. This value of mechanical efficiency is readily obtainable in multi-cylinder engines. The full-load brake mean effective pressure is then increased from 94 to 104 lb. per sq. in., and the corresponding fuel consumption decreased from 0.63 to 0.56 lb. per b.hp. per hr.

The effect on the full-load engine power of increasing the injection-advance angle so as to operate with higher maximum cylinder pressures is shown by the concentric circles. It may be noted that increasing the maximum cylinder pressure from 650

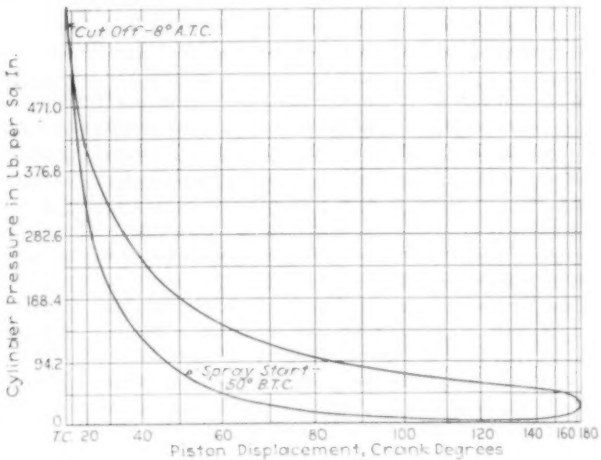

Fig. 11 Indicator Card Using Low Rate of Injection
(Bore, 5 in.; stroke, 7 in.; compression ratio, 13.5; engine speed, 1500 r.p.m.; brake horsepower, 19.5.)

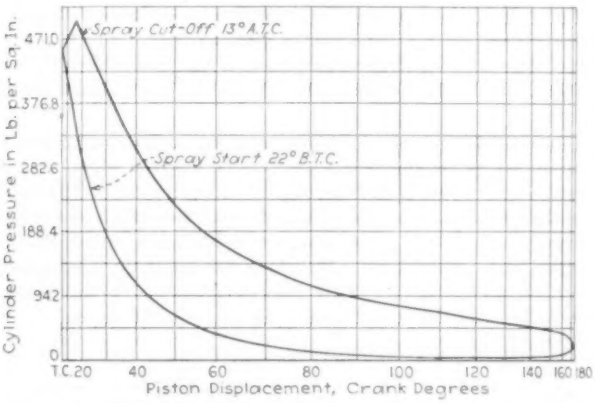

Fig. 12 Indicator Card Using High Rate of Injection
(Bore, 5 in.; stroke, 7 in.; compression ratio, 13.5; engine speed, 1500 r.p.m.; brake horsepower, 22.8.)

to 815 lb. per sq. in. increased the b.m.e.p. from 95 to 101 lb. per sq. in. The increase in injection advance angle necessary to obtain this increase in maximum cylinder pressure was only 8 deg. greater than the advance angle giving normal operation.

The effect of variation in engine speed from 400 to 2000 r.p.m. on the performance of the engine with the No. 4 cylinder head is shown in Fig. 10. The curve of maximum cylinder pressures shows a pressure of 850 lb. per sq. in. at an engine speed of 400 r.p.m. With increase in engine speed, however, the maximum cylinder pressure falls rapidly until a speed of 1200 r.p.m. is reached. Above 1200 r.p.m. the curve rises and reaches a value of approximately 700 lb. per sq. in. at a speed of 2000 r.p.m. The maintenance of a flat fuel consumption curve for a range of engine speeds from 800 to 1800 r.p.m. is of particular interest. The operation of the engine for the complete range of speeds is smooth and regular. No difficulty has been experienced in coking of the multi-orifice injection nozzles even when the engine is idled for several hours at a speed of 200 r.p.m.

Engine Indicators

Work is in progress on the design of a satisfactory optical-

type indicator for the aircraft-type Diesel engine. While this indicator is being developed, the work on the test engines has been greatly assisted by indicator cards obtained with a modified Farnboro indicator. The alterations made to the commercial indicator, which have improved its performance, have been an 80 per cent reduction in the weight of the operating disk, the reduction in the movement of the disk from 0.015 in. to 0.005 in., the elimination of the sliding contact between the disk and the central spindle, and the use of a new paper which permits a reduction in the primary voltage. The maximum cylinder pressures for the same engine-operating conditions have been determined from the indicator card and checked by the maximum-pressure indicator. The indicated power checks within 4 per cent the sum of the brake and friction power determined by motoring. The disadvantage of this type indicator is that it does not give the variation in pressure for each cycle.

Figs. 11 and 12 show indicator cards plotted from pressure-time records obtained with this indicator. The two different rates of combustion were obtained in the same engine under the same operating conditions by changing the rate of fuel injection. Fig. 11 shows a full-load indicator card obtained at an engine speed of 1500 r.p.m. when operating with the No. 4 cylinder head and a low rate of fuel injection. The time of spray start and cut-off has been determined with the oscilloscope and is indicated on the cards. This low rate of fuel injection gave a fast rate of pressure rise in the engine and a maximum cylinder pressure of 620 lb. per sq. in. The indicator card shown in Fig. 12 was obtained using a high rate of fuel injection. For this rate of fuel injection, the type of combustion and maximum cylinder pressure obtained is comparable to that of slow-speed Diesel engine.

The laboratory work of this research has yielded considerable information as to the characteristics of various types of fuel sprays when injected into air at low temperature. The next investigation will be the determination of the effect of various kinds and amounts of air flow on the combustion characteristics of these same fuel sprays. With this fundamental information available, the design of aircraft Diesel engines can be undertaken with far greater chances of producing a successful engine.

Discussion

P. H. Schweitzer.[2] The investigations carried out by the N.A.C.A. constitute the most important source of knowledge on high-speed compression-ignition engines. Each of the three divisions of research fills a useful purpose. A fourth division, however, would have the object of testing Diesel engines in airplanes. No organization is more qualified than the N.A.C.A. to undertake such investigation and a lot of good should come out of it.

It is surprising that the value of the coefficient of discharge is so high for small orifices and that it is so constant over a wide range of pressures and length-diameter ratios. It shows the importance of the entering edge. Wherever it is true that the length-diameter ratio has no effect on the coefficient of discharge, it must be equally true that the viscosity has no effect on same. It would be interesting to check that with the respective orifices by heating the oil.

The writer would like to know the viscosity of the oil used in the tests. The high Reynolds numbers given would indicate that the oil used was extremely thin (one-tenth as viscous as water). For the Gulf black oil, which is one of the oils used, with a Saybolt viscosity of 1000 sec. at 80 deg. fahr., when flowing under 4000 lb. pressure through a 0.015-in. diameter orifice, the Reynolds number is 210. In this case there is a decidedly laminar flow and the Bernoulli formula should not be used without a viscosity correction which is 15 per cent at an l/d ratio of 2, 25 per cent at an l/d ratio of 5, and 37 per cent at an l/d ratio of 10. The writer recommends the use of a viscosity correction whenever the Reynolds number divided by the length per diameter ratio is below 100. This is likely to occur when the orifices are longer than four diameters.

Referring to Fig. 4, the writer would like to ask the author how the injection pressures have been calculated. To calculate the instantaneous injection pressures from the discharges by the hydraulic formula, the rate of discharge has to be known. Was this experimentally determined for the various phases of the injection?

The data given for the spray penetration are true apparently for very thin liquids only. Using ordinary Diesel oil of, say, 100 Saybolt viscosity, the increase of the length from 3 to 4 diameters will hardly result in a greater increase in penetration than is obtained by increasing the length-diameter ratio from 2 to 3; it is probable that the penetration will not increase at all when the length is increased beyond three times the diameter. The viscosity has a decided effect on all these characteristics, and the viscosity of one Diesel fuel oil is sometimes 100 times greater than the viscosity of another Diesel fuel oil.

The committee is to be complimented on the high mean effective pressures obtained with the experimental engines, which are frequently coupled with moderate explosion pressures.

The author mentions that all attempts to operate these test engines on a constant-volume cycle have usually resulted in decreased power. To what engines does the author refer? Does this mean that an advance in injection timing generally resulted in lower m.i.p.? That is contrary to common experience.

The writer has confidence in the no-turbulent type of combustion chambers for aviation purposes and is pleased to see the investigation which is promised in this direction.

Leigh M. Griffith.[3] In actual engine operation engineers are concerned with getting the fuel into the combustion chamber at the correct rate and with the proper degree of atomization and penetration. With a given fuel pressure, the desired rate of injection can be secured from a large orifice of low discharge coefficient, or from a small orifice of high coefficient, but one has little idea of the relative atomization and penetration. This would be a fruitful question to study. On the face of the matter,

[2] Professor of Engineering Research, Pennsylvania State College, State College, Pa. Mem. A.S.M.E.

[3] Vice-President and General Manager, Emsco Aero Engine Co., Bell, Calif. Mem. A.S.M.E.

the large orifice of low coefficient would be preferable. It is less likely to clog, and is easier to drill accurately, inspect, and clean. Moreover, the rounding or countersinking operation at the entrance of the high-coefficient orifice may seriously complicate the nozzle design.

The engine test results reported for the two forms of cylinder head are somewhat discouraging, when compared to other recently reported results. At the speed of 1500 r.p.m. (1750 ft. per min.), the bulb-head gave 0.40 lb. per i.hp. per hr. at 133 lb. i.m.e.p., the maximum pressure apparently being about 750 lb. The No. 4 head gave an even poorer result of 0.455 lb. per i.hp. per hr. at 131 lb. i.m.e.p. and a maximum pressure of 815 lb. Such high indicated fuel consumptions show that the injection or combustion conditions were far from correct.

Some eight years ago, the British 8-in. by 11-in. laboratory Diesel engine gave about 0.36 lb. per i.hp. per hr. at 130 lb. i.m.e.p. and 1200 r.p.m. (2200 ft. per min.), with maximum pressure limited to 650 lb. When the maximum pressure was raised to 800 lb., the fuel rate dropped to 0.33 lb. and the i.m.e.p. rose to 136 lb. In fact, the N.A.C.A. research laboratory itself about the same time reported 0.36 lb. at 116 lb. i.m.e.p. and 1750 r.p.m. (2040 ft. per min.), while in 1925 it obtained a fuel rate of 0.33 lb. at 132 lb. i.m.e.p. at 1500 r.p.m. (1750 ft. per min.), the maximum pressures being described as "excessive" but not evaluated in either case.

It is interesting to compare the above figures with those recorded by H. R. Ricardo in *Automobile Engineer* for April, 1930. Working with a 5.5-in. by 7-in. engine, he obtained a fuel rate of 0.285 lb. per i.hp. per hr. at 122 lb. i.m.e.p. and 2200 r.p.m. (2570 ft. per min.), with a maximum pressure of 850 lb. Taking a mechanical efficiency of 85 per cent, this corresponds to 0.334 lb. per b.hp. per hr. and 104 lb. b.m.e.p. The Junkers two-stroke opposed-piston aircraft Diesel is reported to give under 0.38 lb. per b.hp. per hr. at 91 lb. b.m.e.p. and 1500 r.p.m. (2070 ft. per min.), but neither the maximum pressure nor the mechanical efficiency was stated. Assuming a mechanical efficiency of 80 per cent, which is reasonable for such a complicated mechanism, the indicated fuel consumption becomes 0.30 lb. and the i.m.e.p. is 114 lb.

It is pleasing to note that the development of a single-cycle indicator for high-speed Diesel-engine work is in hand. Although the writer's experience with the Farnboro indicator in high-speed Diesel development has been most satisfactory, he fully appreciates that a good single-cycle indicator would be of undoubted value for research work.

All of the essential requirements peculiar to the aeronautic Diesel engine have already been met separately, most of them several years ago, so that the development of other and larger aircraft Diesels awaits only the required engineering effort adequately financed.

Author's Closure

Referring to Dr. Schweitzer's discussion, the viscosity of the oil used in these tests is about 0.048 poises at 80 deg. fahr. and at atmospheric pressure. This corresponds to 45 Saybolt seconds. Data on the variation of the viscosity of this oil with temperature and pressure are given in N.A.C.A. Technical Note No. 315. Dr. Schweitzer's conclusion regarding the thinness of this oil was no doubt drawn from the curve of coefficients versus Reynolds' number given in the advance copy of this paper, which unfortunately was incorrect. The correct values are given in the final paper. The author agrees with the writer in the corrections applied to the Bernoulli formula; not only for the friction loss, if any, but also a correction to the basic formula. Bernoulli's equation assumes the kinetic energy of flow to be $V^2/2g$, whereas this can be true only when the velocity is uniform over the cross-section. For water and the normal distribution of velocity with turbulent flow the kinetic energy is known to be approximately 1.05 $V^2/2g$, and that for a laminar flow about $V^2/2g$, which is twice that given by Bernoulli's equation.

Results recently obtained at this laboratory confirm the writer's opinion that as the length-diameter ratio is increased a length may be reached at which a maximum penetration may be obtained. Increasing the length of the orifice beyond this point would probably result in either no further increase or, what is more likely, a decrease in the penetration. The length at which the maximum penetration is obtained during the first few thousandths of a second after the start of injection varies with the injection and chamber pressure and with the diameter

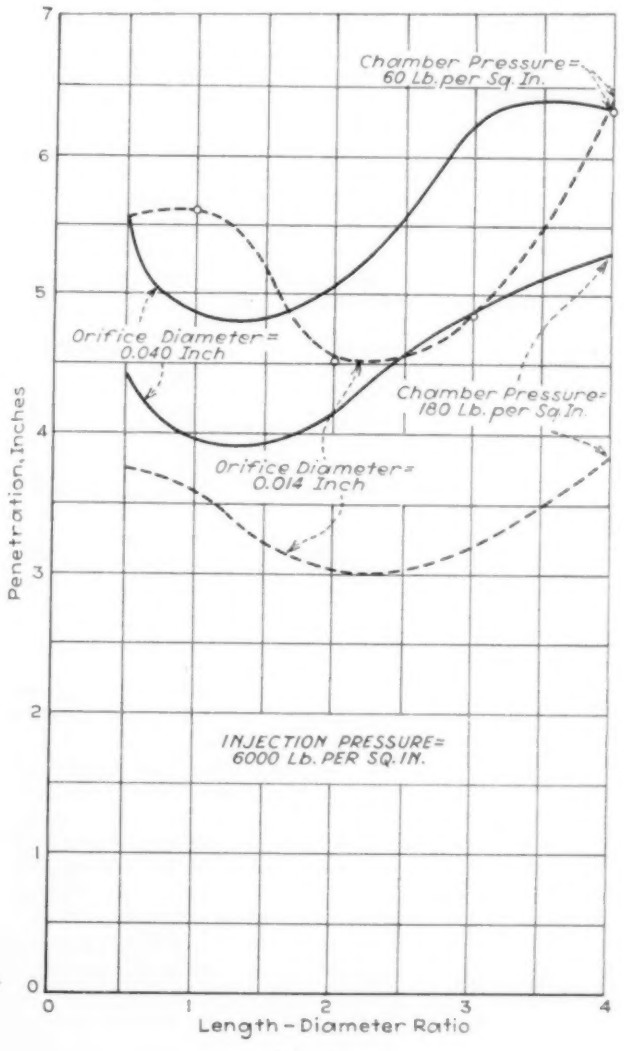

Fig. 13

of the orifice. Fig. 13 shows a set of curves obtained with two sizes of orifices for an injection pressure of 6000 lb. per sq. in. and chamber pressures of 60 and 180 lb. per sq. in. From these curves it will be seen that a maximum was reached at about a $1/d$ ratio of 4 for the 0.040-in. orifice. With the 0.014-in. orifice, however, the penetration appears to increase at a higher rate of the ratio between 3 and 4 with the smaller orifice, especially for the lower back-air pressure. The committee has

included in its program further tests with an 0.008 and 0.020 in. diameter orifice for $1/d$ ratios up to 10 which it is hoped will give the form of curves of penetration versus $1/d$ ratio after a maximum is reached. The author agrees with the writer that the viscosity has a decided effect on spray characteristics, and not only this, but also with the operation of the pump and injection valve when oil with a high viscosity is used.

Figs. 11 and 12 show the performance obtained when operating on the constant-volume cycle and the dual-combustion cycle. Advancing the time of injection does not necessarily change the combustion cycle of the engine. The effect on full-load performance of increasing the injection-advance angle is shown in Fig. 9. With this type of combustion chamber the increase in power is not proportional to the increase in maximum cylinder pressure, since a point can be reached beyond which the intensity of the engine knock increases with no further increase in engine power.

The injection pressures given in Fig. 4 were calculated from the known curve of plunger movement and the coefficients of discharge as experimentally determined. The assumption was made that there was no leakage past the pump plunger.

As to Mr. Griffith's discussion, a review of the report by H. B. Taylor entitled, "High-Speed Compression-Ignition Engine Research," which appeared in the July, 1928, issue of *The Journal of the Royal Aeronautical Society*, gives the following performance figures for the 8-in. bore by 11-in. stroke single-cylinder test engine designated as T-20:

Engine	Excess air	Speed	Maximum cylinder pressure	I.m.e.p.	I.f.c.	B.m.e.p.	B.f.c.	Mechanical efficiency
T-20	0.29	1200	650	121.4	0.396	107	0.45	0.881
Cylinder head No. 4	0.30	1200	650	117.8	0.386	88	0.51	0.748
Cylinder head No. 4	0.30	1500	650	112.5	0.390	85	0.55	0.750

These performance values may be compared with that of cylinder head No. 4 at a speed of 1500 r.p.m. and a fuel quantity of 2.65×10^{-4}, which gives an excess air coefficient of 1.30, as obtained from Fig. 9. The performance with this same cylinder head at 1200 r.p.m. and for the same excess-air coefficient has also been tabulated. The indicated mean effective pressure and fuel consumption obtained with the No. 4 cylinder head certainly compare favorably with those reported for the T-20. No mention is made in this report of the performance of 130 lb. per sq. in. indicated mean effective pressure and a fuel consumption of 0.36 lb. per indicated horsepower per hour under the conditions of engine speed and maximum cylinder pressure given by Mr. Griffith. The performance reported by H. R. Ricardo for a sleeve-valve engine using his "swirl type" combustion chamber is admittedly superior to any that has been obtained with a poppet-valve engine. In spite of the high performance quoted in laboratory tests, however, it is necessary to rate the Ricardo-Brotherhood engine at a brake mean effective pressure of only 83 lb. per sq. in. and a low speed of revolution. The low engine speed is necessary because of the high inertia forces of the sleeve and operating mechanism.

OGP-52-6

Diesel Power-Plant Records

By M. J. REED,[1] NEW YORK, N. Y.

The advice to keep records of Diesel-engine power-plant operation has been given often, but the author here states the kinds of records that should be kept and the inferences and conclusions that may be drawn from them. No attempt is made to draw up a general or standard power-plant log, but informative data are listed so that individual operators may decide how far they may wish to go in the recording of the performances of their plants.

THE advice to keep more and better records has been given often to Diesel power-plant operators. Not so frequently, however, have the preceptors stated what kind of records should be kept and what inferences can be drawn from these. In trying to detail this general advice no attempt will be made in this paper to draw up a standard power-plant log which could apply to any plant, under any conditions, anywhere. It is enough to try to point out what data are informative and what are not, and what deductions can be drawn from the former. With data so classified, individual operators can decide how far they wish to go in the recording of the performances of their plants.

Some data indicate how the Diesel plant is being operated at the moment only, but give no index of a permanent trend of affairs. Of such are circulating-water temperatures, injection-air pressures, etc. These could be called "operational" data. Other data apply to the actual condition of engines and point to a time when replacements will be needed. These could be called "maintenance" data. A third kind of data fixes the basis for the determination of the cost of the unit produced; these are "cost" data. The plan of this paper is to take up the various systems—i.e., the circulating-water system, the inlet and exhaust system, the lubricating-oil system, the fuel-oil system, and the output system—in turn to determine what information really tells a story and into what class of data it falls.

Fig. 1 is a diagram of a typical double-circuit water-circulating system with soft water for engine cooling and raw water for soft-water cooling. In this diagram the temperatures which are informative are indicated by T, with an identifying subscript. The engine inlet-water temperature T_a is important in relation to the discharge temperatures T_b, T_c, T_d, T_e, T_f, T_g. The spread, or rise, should not exceed 30 deg. fahr. for any system and preferably not 15 deg. fahr. for a double circuit such as is illustrated. The discharge temperature T_b to T_g should not fall below 100 deg. fahr. or climb above 130 deg. fahr. for best results. Higher discharge temperatures may cause the cylinder lubrication to break down from overheating; lower discharge temperatures are not favorable to the best combustion. The one case calls for more soft-water circulation or more raw-water circulation, or both; the other calls for less circulation.

The diagram shows a bypass connection between the discharge of the soft-water pump and the soft-water reservoir. A bypass connection of this sort should be installed in all cases where very cold circulating water is available. Even for systems of the type illustrated, it is better to adjust for temperatures by means of such a bypass than by throttling the circulating pump.

Discharge temperatures from 100 to 130 deg. fahr. should be maintained throughout the load range. In fact, it is most important that these temperatures be not lowered at low loads, for it is at these loads that combustion would suffer most from low cylinder temperatures.

The temperatures T_b, T_c, and T_d should be approximately alike. The same specification holds for T_e, T_f, and T_g. Unequal temperatures indicate unequal water distribution, which should be corrected by throttling the lines to the cold cylinders (or pistons, as the case may be). Of course, the exhaust pyrometer should be first consulted to see if cylinder loadings are alike before concluding that water distribution is responsible.

The only benefit obtained by requiring these temperatures to be recorded hourly is a sort of insurance that the shift engineer is reading the thermometers and making the indicated adjustments. The readings cannot indicate anything about carbonization or scale, since the amount of water being circulated is unknown, nor would it be practical to meter it accurately. If an owner wishes to be sure his engineer is on the job, the shift report should call for hourly entries of these temperatures. It would be foolish, however, to clutter up a monthly report with this kind of information.

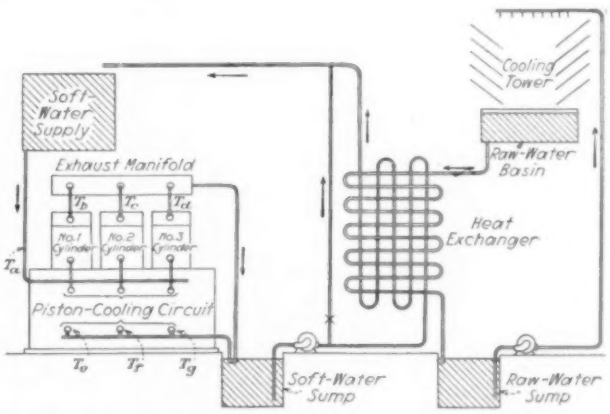

FIG. 1 TYPICAL DOUBLE-CIRCUIT WATER-CIRCULATING SYSTEM

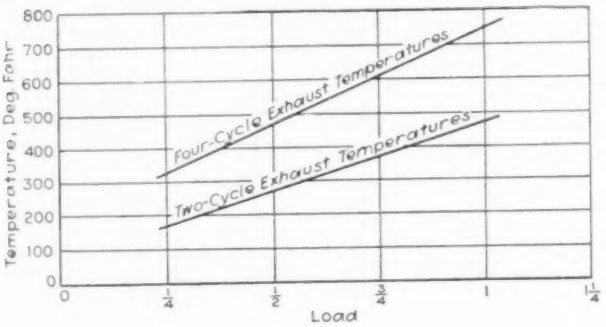
Raw water conditions—i.e., the outside wet- and dry-bulb temperatures, and the temperatures in and out of the heat exchanger—are very important considerations when a plant is being designed, but become entirely secondary after it is put in operation. The raw-water system does not matter so long as the soft-water temperatures are satisfactory. Should trouble show up in the soft-water system, the raw-water system may be adjusted, but the soft-water thermometers tell whether the adjustment has been satisfactory. The temperature of the soft water as it leaves the exhaust manifold is not important unless it climbs high enough to effect T_a.

Circulating water should be supplied to an engine by gravity from an elevated tank. An alarm operated by a float in the tank is usually provided to give warning of low water level. Therefore the pressure of the circulating water at the engine is not of interest; it is either sufficient or the alarm is sounding.

Fig. 2 illustrates an inlet and exhaust system as applied to one cylinder. Air at atmospheric pressure and temperature P_a and T_a is led to the cylinder through the inlet piping. Here it is compressed to pressure P_b, supports combustion, and ex-



[1] Research Engineer, Diesel Engine Manufacturers' Association.

Presented at a meeting, November 26, 1929, of the Oil and Gas Power Section of the Philadelphia Section of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

hausts at temperature T_c. Variation of 1 in. in barometric pressure P_a will account for approximately 0.01 lb. variation in the fuel rate per brake horsepower hour, the higher barometer corresponding to the better fuel rate. A variation of 20 deg. in inlet temperature corresponds to a similar variation in the fuel rate, the lower temperature corresponding to the better fuel rate. Plant operators who insist upon this degree of fineness in their records should read and record intake pressure and temperature once per shift. Intake temperature should be read at or near the actual intake, however; not in the engine room for an outside intake, nor outside for an engine-room intake.

The compression pressure P_b is highly important. Poor compression means poor combustion; poor combustion brings about poorer compression; and so on in a vicious circle. Compression pressure should be read from a pull card once per month, or at least four times per annum. It is a good idea to plot these compression readings against time, or hours of operation. The resulting curve will indicate the progressive condition of the piston rings.

The exhaust temperature T_c is not so important in itself as in

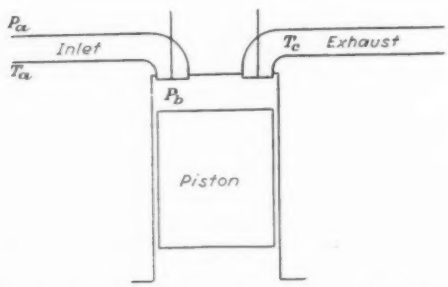


FIG. 2 INLET AND EXHAUST SYSTEM AS APPLIED TO ONE CYLINDER

relation to the exhaust temperatures of the other cylinders. An appreciable difference in exhaust temperatures means unequal cylinder loadings. If piston rings and valves are in proper shape, such inequalities can be reduced by regulating the amounts of fuel delivered by the injection pumps.

Too much reliance should not be placed on pyrometer readings unless the elements are inspected occasionally. A dirty element may cause a low reading. Increased fuel injection in that case would tend to foul the element all the more, thus depressing the reading still further.

Exhaust temperatures should be read every hour. Therefore if a record is considered desirable, entries should be made hourly. Once the record has been gone over to see that cylinder temperatures are roughly equal and that the average is not abnormal, the information has served its purpose and should not be transferred to monthly records. The curves in Fig. 2 show what exhaust temperatures are normal over the load range.

This completes the inlet and exhaust system for mechanical-injection engines. Air-injection engines, however, have injection-air pressures to be observed in addition. For best combustion the injection-air pressures at various loads should be approximately as shown in Fig. 3. This diagram also shows the normal variation of intercooler pressures. An intercooler pressure much above the amounts shown indicates valve trouble in the stage drawing from the intercooler, whereas a subnormal intercooler pressure points to the stage delivering to the intercooler. These pressures, including the injection pressure, should be observed every hour, and, if recorded, should be recorded once per hour.

A typical lubricating-oil system is illustrated in Fig. 4. The

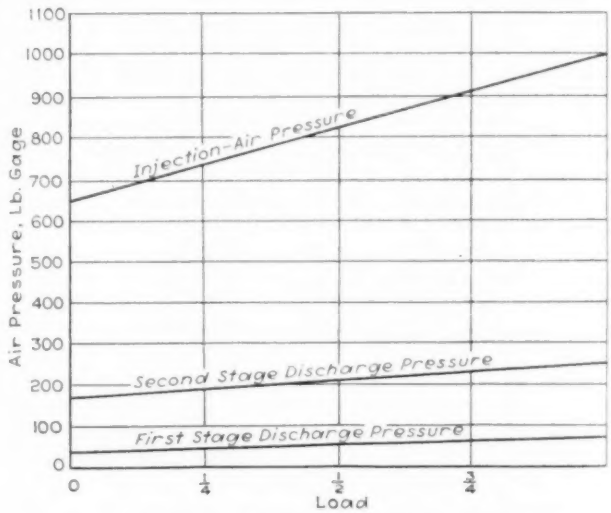

FIG. 3 RANGE OF INJECTION-COMPRESSOR PRESSURES

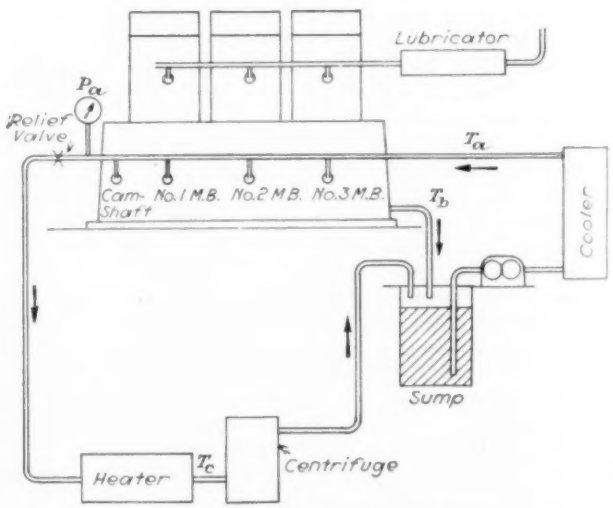

FIG. 4 TYPICAL LUBRICATING-OIL SYSTEM

engine cylinders are served with oil by drop feed. Force-feed lubricates the main bearings, connecting rods, and camshaft bearings. A part of the oil in circulation is bypassed continuously through a centrifuge. All of the oil in circulation passes through a cooler.

The only observable information of the drop-feed system is the number of drops per minute. The force-feed pressure P_a varies for different makes of engines. Whatever is normal for the engine is what should be held. A gradual fall in pressure in-

dicates bearing wear or pump wear. A sudden fall in pressure means a burnt-out bearing or a broken load. An increase in pressure may mean a clogged load.

If the crankcase temperature T_b does not exceed 135 deg. fahr. without cooling, no cooling is necessary. However, cooling the oil to a temperature of 90 to 100 deg. fahr. at the force-feed header will improve the lubricating-oil economy. The header temperature with a cooler should be not over 100 deg. and the crankcase temperature T_b should not be over 135 deg., with or without a cooler. Before the oil enters the centrifuge it should be heated to 160 deg. for effective purification. An increase in crankcase temperature may mean a hot bearing. The temperatures and pressure of the lubricating oil system should be read once each hour and, if recorded, should be set down as often.

The amount of new lubricating oil added to the system of each engine is data that should be logged in every plant without fail. Not only should the gallons added to each engine (not the amount added to all engines as a whole) be logged in the shift report and transferred to the monthly report, but an independent check should be made by recording the total amount of unused oil on hand on the first of the month being reported, the amount of oil bought during the month, and the amount of unused oil on hand the first of the month following. The monthly report should show the net amount of lubricating oil used per engine as calculated by the first method and the total net amount used for the plant as calculated by the second method.

When operated at a constant speed, an engine will use a constant amount of lubricating oil per hour no matter what the load may be. Therefore, the engineer should multiply the engine rating in horsepower by the number of hours operating and divide by the number of gallons used during the month to arrive at the number of rated horsepower hours per gallon for his monthly report. If the average speed of the engine was below the full rated speed, the rating should be scaled down in proportion for this calculation. This chart gives a good index of the efficiency of lubrication. One gallon of oil per 2000 rated horsepower-hours is fair; one gallon per 3000 rated horsepower-hours is good (in both cases without centrifuging).

Of course, the office should record the price paid for lubricating oil and should calculate and record the lubricating oil cost per unit generated. The office should also keep a record of the brands used and the economy reached with each brand. Manufacturers will recommend satisfactory brands of oil, but they cannot draw too fine a line between good oils and excellent oils. The user must do this by consulting his records.

The temperature of the fuel oil at the engine-injection pump is of importance only when using a heavy oil which must be heated. In that case, there will be a temperature below which the oil can be pumped but will not atomize satisfactorily. An hourly record of the fuel-oil temperature will tell whether the engineer is maintaining this minimum temperature. The oil company supplying the oil in question can advise what the minimum temperature should be.

The amount of fuel oil used is a figure of even more importance than the same information for lubricating oil. It should be reported by each shift engineer for each engine in gallons per shift. The determination should be based upon day tank readings—meters are not accurate enough. The total for the plant per month should be independently checked in the same manner as outlined for lubricating oil. Both the total for each engine for the month as arrived at from the shift reports and the total for the plant as determined by the independent check should be entered on the monthly report.

It is well to have the shift engineers report the number of units generated per gallon in their shifts. The office can easily prepare a curve showing at a glance the number of units that would be generated at any load factor with normal fuel economy. Such a curve as worked out for a given test performance and a given generator efficiency and a given fuel is shown in Fig. 5. Should the actual performance be poorer than the curve indicates, the engineer knows he should look for trouble in the engine valves, rings, spray nozzles, etc.

The office should record the price paid for all fuel oil and should reduce the total cost to the cost per unit generated during the month. In addition, the office should make a record of the following fuel-oil properties for each shipment:

Gravity in degrees A.P.I.
B.t.u. per pound
Viscosity in seconds Saybolt Universal at 100 deg. fahr. or other standard
Conradson carbon, per cent by weight
Sulphur, per cent by weight
Ash, per cent by weight
Water and sediment, per cent by volume
Flash point

Any reliable company can supply this information for the oil it sells. Gravity and B.t.u. per pound are necessary in calculating the number of pounds per gallon and the relation of the oil bought to the oil used as a basis for engine guarantees. Viscosity is important for its bearing upon heating. Flash point must be a certain figure to meet local insurance requirements.

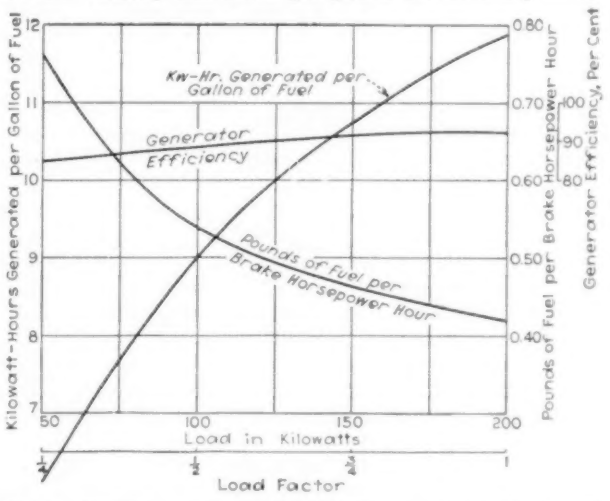

FIG. 5 NUMBER OF UNITS GENERATED AT ANY LOAD FACTOR

The carbon content has a pronounced influence upon combustion if appreciable. Both carbon and ash are believed to contribute to liner wear. The only method of determining how poor an oil (and, of course, how cheap an oil) can be profitably used is to watch the engine performance in respect to fuel consumption and liner wear and the balance against oil price. Engine manufacturers cannot help much to strike this balance; they cannot operate individual engines for long enough periods.

Before leaving the subjects of fuel oil and lubricating oil, emphasis might well be given to the necessity of laying out the plant in such a way that the consumption of fuel and lubricating oil can be ascertained per engine. The average of one good engine and one poor one is two fair engines. The good one misses well deserved credit; the poor one escapes a needed investigation.

Each shift should report the number of gallons of make-up water added to the soft- or raw-water systems and the number of pounds of treating compound used if water is treated. These amounts should be totaled in the monthly report and the cost should be recorded by the office. Any other supplies should be described in the shift report as used. The office should total the

cost of all supplies used during the month and reduce the figures to the cost per unit generated. Each shift should report the men on duty and the number of hours worked by each. The office should total the attendance cost for the month and reduce the figures to cost per unit generated. Whenever extra labor is required to assist in making repairs, the cost of the extra labor should be considered a part of repair cost, not a part of regular attendance costs.

Repair parts should be listed in the shift report when used. The reason for the repair should be set down briefly. If an accident has occurred, the cause should be outlined. Repairs fall generally into three classes: (1) Repairs to correct wear (normal). (2) Repairs to rectify accidents (abnormal). (3) Repairs to modernize design (betterments).

Repair costs, to be fully illuminating, should also be broken down along these lines. In any case the office should keep accurate costs covering all repairs and extra labor required to make them.

Table 1 is a maintenance log prepared by a manufacturer of four-stroke cycle, mechanical-injection engines. The only criticism the author has to offer is that the form should call for the liner wear. This should be recorded in thousandths whenever observed for any type of engine. The figures should be reduced to wear per 1000 hours of operation per inch of piston diameter. One manufacturer stated that a wear of 0.0002 in. per inch is normal at the top of the piston travel for 1000 hours. Another manufacturer believes that normal wear is somewhat less than this.

Diesel engines vary so widely in type and design that it would be impossible to draw up a standard maintenance log. Fortunately, it is not necessary to attempt this. Manufacturers of engines are very glad to furnish users with detailed advice along this line and many have printed forms applying particularly to their engines.

Next is the measurement of the unit produced by the plant. In the case of generating units it is kilowatt-hours. Every generating plant should have integrating watt-hour meters, one for each engine and one for the net plant output. A similar allocation of recording indicating watt-meters is desirable, although not quite so essential as the watt-hour meters. The shift engineer should read the integrating meters each hour and report the kilowatt-hour production per engine per shift and the net plant output per shift. He should also report the fifteen-minute peak load for his shift for each engine and for the plant. This peak load should be read from the record of the indicating meters. The monthly report should show the total kilowatt-hours per unit per day, the total for the plant per day, and the totals in each case for the month.

The shift report should state the number of hours each unit was operated. From this the load factor for the unit should be calculated—the ratio of the kilowatt-hours generated to the number that would have been generated had the unit been operating at full load while running. This load factor is useful in connection with the number of units generated per gallon of fuel, as was explained previously. The monthly report can show the average load factor per month for comparison with the average number of kilowatt-hours generated per gallon of fuel.

There are a number of items of information which have no bearing on Diesel operation, as distinct from steam operation, but which are required for their bearing on the electrical operation. For instance, amperes per phase and voltage are needed to discover the power factor. Speed, constant enough not to affect lubricating-oil consumption in the case of generator units, is needed to determine cycles. The feeder-circuit-current distribution does not affect Diesel economy, but can be very important to the plant as a producer of electrical energy.

Diesel-operated pumping plants should record the integrating venturi-meter reading hourly. The monthly report should set down the gallonage by days and the total for the month. Hourly readings should be taken for both suction and discharge heads. These should be averaged for days and for the month in the monthly report. Many pumping plants are very particular about capacity, but make no effort to arrive at the average total pumping head. This is like measuring amperes, but not volts. Pumping costs should be reduced to the unit of 1,000,000 ft-lb. of water pumped.

The final unit in an ice plant is of course a ton of ice. However, there are so many conditions outside of the Diesel engines which can influence the cost per ton of ice that more data than the number of tons of ice are desirable. The average suction pressure and the average head pressure compiled from hourly readings, together with the average revolutions per minute, will fix the number of tons of refrigeration, assuming saturated gas in the suction line. A ton of refrigeration is a better unit than a ton of ice because it is more independent of other factors and, in addition, takes account of storage. The engineer of a Diesel-driven ice plant should also keep a record of condensing-water temperatures and ice-making-water temperatures to check up on his general plant operation as distinct from the purely Diesel end of operation.

The data discussed in this paper are presented herewith in itemized form, with the conclusions set down opposite.

Item	Engineer's reports: Daily	Monthly	Office record
Circulating-Water System:			
Temperature at engine inlet	Yes, hourly	No	No
Temperature at cylinder outlets	Yes, hourly	No	No
Temperature at piston outlets	Yes, hourly	No	No
Cost of make-up and treatment	(See supplies)		
Inlet and Exhaust System:			
Air temperature at engine inlet	(?), once per shift	(?), daily average	(?), monthly average
Barometer	(?), once per shift	(?), daily average	(?), monthly average
Compression pressure	No	Yes, once per month	Yes, once per month
Temperature, each cylinder exhaust	Yes, hourly	No	No
Injection air pressure:			
Final	Yes, hourly	No	No
Each cooler	Yes, hourly	No	No
Lubricating-Oil System:			
Force-feed pressure	Yes, hourly	No	No
Crankcase oil temperature	Yes, hourly	No	No
Temperature to centrifuge	Yes, hourly	No	No
Temperature from cooler	Yes, hourly	No	No
Gallons of new oil added for each engine	Yes, by shifts	Yes, per day	Yes, per month
Gallons on hand, 1st of month	No	Yes	Yes
Gallons bought during month	No	Yes	Yes
Gallons on hand 1st of following month	No	Yes	Yes
Total gallons used by plant during month	No	Yes	Yes
Cost of each shipment	No	No	Yes
Cost of oil used per month	No	No	Yes
Lubricating-oil cost per kw-hr. (or other unit)	No	No	Yes
Rated hp-hr. per gal. each unit	No	Yes	Yes
Fuel-Oil System:			
Temperature at injection pump	Yes	No	No
Gallons used per unit	Yes, per shift	Yes, per day	Yes, per month
Gallons on hand, 1st of month	No	Yes	Yes
Gallons bought during month	No	Yes	Yes
Gallons remaining 1st of following month	No	Yes	Yes
Total gallons used in month	No	Yes	Yes
Price paid, each shipment	No	No	Yes
Total cost of oil used in month	No	No	Yes
Fuel cost per kw-hr.	No	No	Yes
Gross kw-hr. per gal. each unit	Yes, by shifts	Yes, daily average	Yes, monthly average
Characteristics of fuel (see text)	No	No	Yes
Supplies:			
Gallons make-up water added	Yes, per shift	Yes, per day	Yes, per month
Pounds of treating compound used	Yes, per shift	Yes, per day	Yes, per month
Cost of make-up water	No	No	Yes, per month
Cost of treating compound	No	No	Yes, per month
Other supplies used, description	Yes, by shifts	No	No
Cost of other supplies	No	No	Yes, per month
Total cost of supplies	No	No	Yes, per month
Cost per kw-hr. of supplies	No	No	Yes, per month
Repairs:			
Description of parts	Yes, by shifts	Yes	Yes
Cost of parts	No	No	Yes
Cost of repairs to renew wear, parts	No	No	Yes, monthly
Extra labor	No	No	Yes, monthly
Cost of repairs to renew breakage, parts	No	No	Yes, monthly
Extra labor	No	No	Yes, monthly
Cost of repairs to modernize design, parts	No	No	Yes, monthly
Extra labor	No	No	Yes, monthly
Total cost of repairs, material, and extra labor	No	No	Yes, monthly
Repair cost per kw-hr.	No	No	Yes, monthly
Cause of any accidents	Yes	Yes	Yes
Attendance:			
Men on duty	Yes, by shifts	Yes, man-hours per day	Yes, man-hours per month
Hours for each man			
Extra labor for repairs	Yes, man-hours	Yes, man-hours	Yes, man-hours
Cost of extra labor	No	No	See under "Repairs"
Cost of attendance	No	No	Yes, monthly
Cost per kw-hr.	No	No	Yes, monthly
Load Data (Electrical):			
Kw-hr. generated per unit	Yes, readings each hour	Yes, per day	Yes, per month
Net kw-hr. station output	Yes, readings each hour	Yes, per day	Yes, per month
Peak load for 15 min.:			
Per unit	Yes, per shift	Yes, per day	Yes, per month
Per station	Yes, per shift	Yes, per day	Yes, per month
Amperes per phase, each unit	Yes, hourly	No	No
Volts	Yes, hourly	No	No
Power factor	Yes, hourly	Yes, daily average	Yes, monthly average
Feeder distribution, kw-hr. per circuit	Yes, per hour	Yes, per day	Yes, per month
Hours of operation, per unit	Yes, by shifts	Yes, per day	Yes, per month
Load factor, per unit	Yes, per shift	Yes, per day	Yes, per month
Auxiliary load (unit totals minus station net), kw-hr.	Yes, by shifts	Yes, per day	Yes, per month
Revolutions per minute (cycles)	Yes, per hour	Yes, daily average	Yes, monthly
Load Data (Pumping):			
Venturi meter	Yes, hourly	Yes, daily capacity	Yes, monthly capacity
Suction pressure	Yes, hourly	Yes, daily average	Yes, monthly average
Discharge pressure	Yes, hourly	Yes, daily average	Yes, monthly average
Total head	Yes, hourly	Yes, daily average	Yes, monthly average
Million foot-pounds	No	Yes, daily	Yes, monthly
Million foot-pounds per 100 lb. fuel	No	Yes, daily	Yes, monthly
Auxiliary power generated, kw-hr.	Yes, per shift	Yes, per day	Yes, per month
Hours operating, each unit	Yes, per shift	Yes, per day	Yes, per month
R.p.m., each unit	Yes, hourly	Yes, daily average	Yes, monthly average
Load Data (Refrigeration):			
Suction pressure	Yes, hourly	Yes, daily average	Yes, monthly average
Head pressure	Yes, hourly	Yes, daily average	Yes, monthly average
Condensing water temperature	Yes, hourly	Yes, daily average	Yes, monthly average
Ice-making water temperature	Yes, hourly	Yes, daily average	Yes, monthly average
R.p.m. each unit	Yes, hourly	Yes, daily average	Yes, monthly average
Hours operating, each unit	Yes, per shift	Yes, per day	Yes, per month
Tons refrigeration	No	No	Yes, per month
Tons ice made	Yes, per shift	Yes, per day	Yes, per month
Auxiliary load, kw-hr.	Yes, per shift	Yes, per day	Yes, per month
Maintenance Data:			
(See form for maintenance record attached)			
Also liner wear in thousandths	Enter as observed		Yes, total and per 1000 hr.
Recapitulation:			
Fuel cost per unit	No	No	Yes, monthly
Lubricating-oil cost per unit	No	No	Yes, monthly
Attendance cost per unit	No	No	Yes, monthly
Supply cost per unit	No	No	Yes, monthly
Repair cost per unit	No	No	Yes, monthly
Total cost per unit	No	No	Yes, monthly

Results of Some Tests by Industry of Sample Diesel Fuel Oil[1]

Progress Report No. 2 of the A.S.M.E. Special Research Committee on Diesel Fuel-Oil Specifications[2]

THIS committee delivered a Progress Report at the Annual Oil and Gas Power Convention at Penn State in June, 1929, in which its tentative specifications as recommended for Diesel engines were reported for the first time.

Oil engines in this country were divided into two classes and designated as "heavy duty" and "light high speed." The specifications advanced at that time for the two classes were as follows:

	Heavy duty	Light high speed
Viscosity at 100° F. (Saybolt Universal)	Max. 200 sec.	Min. 45 sec. Max. 100 sec.
Sulphur	Max. 3% by wt.	Max. 2%
Conradson	Max. 4%	Max. 1%
Ash	Max. 0.08%	Max. 0.02%
Flash	Min. 150 ° F.	Min. 150° F.
Moisture and sediment	Max. 1%	Max. 5%

NOTE: *Specific Gravity or A.P.I.* Gravity is of no importance as it pertains to the burning qualities of an oil. It should be given, however, by the supplier in order that weight per gallon can be computed.

The committee also qualified these specifications and explained the reasons for the adoption of each item and the relative merit of the various qualities. It is not within the jurisdiction of a research committee to set standards. Our function is to recommend to a standards organization what we consider acceptable Diesel specifications after a thorough investigation of types and classes of engines, conditions among the users of oil engines, and limitations and qualifications of oil refiners and distributors. After this information has been correlated, it is then necessary to proceed with the research and development work to a point where the committee can advise as to the practical application of such specifications in actual commercial Diesel-engine installations. To this end the committee sent out an appeal to the manufacturers of Diesel engines requesting that they run actual tests in engines of their design on oil meeting the maximum specifications as tentatively submitted for the two general types in order to supply it with complete information on the function of such oils. A form was drawn up for the reporting of test information in order that the data could be readily correlated and submitted to the committee for its information.

To date oil has been supplied to the Electric Boat Company, the Ingersoll-Rand Company, Fairbanks, Morse & Co., Nordbert Manufacturing Company, Cooper-Bessemer Corporation, I. P. Morris & De La Vergne, Inc., International Harvester, and also to the Zenith-Detroit Corporation for test in Diesel-engine fuel-oil filters. Captain Dinger, chairman of this committee, has at his disposal three Diesel engines on test blocks and several small units installed in motor boats. Oil was also submitted to him for operation of these units. We have received to date some detailed reports from companies testing this oil and have included some of the pertinent data in this report. It must be remembered that these tests are not conclusive nor is information contained herein sufficient proof to the committee that the specifications which have been recommended are either failures or successes. Any discussion or general comment on the part of the general public will be of valuable assistance to the committee in determining its next move as to advancing an acceptable specification to the interested industries.

It will readily be seen that it would be impossible to fabricate oils for these tests which would meet the maximum specifications in every particular. Therefore the committee decided that the governing limit should be the maximum viscosity specification—200 sec. Saybolt Universal at 100 deg. fahr. for heavy-duty engines and 100 sec. for the light high-speed units. The other qualities of the oil were allowed to fall where they would. For instance, various samples at the maximum viscosity had carbon and ash contents in excess of the committee's recommendation. Members of the committee from the oil industry advised that it would be practically impossible to guarantee the Conradson carbon content in oils of this viscosity at the specified maximum of

[1] Presented at the Oil and Gas Power session at the Annual Meeting, December 2 to 6, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

[2] The personnel of this committee is as follows:

Henry C. Dinger, Capt., *Chairman*, in charge of Engineering Experiment Station, U. S. Navy, Annapolis, Md.

Wiley H. Butler, *Secretary*, Standard Oil Company of New Jersey, New York, N. Y.

James C. Barnaby, Assistant to Chief Engineer, Worthington Pump and Machinery Corporation, New York, N. Y.

R. J. Broege, Buda Company, Harvey, Ill.

Harte Cooke, Engineer, McIntosh & Seymour Corporation, Auburn, N. Y.

Thomas G. Delbridge, Supervisor, Process Division, Atlantic Refining Company, Philadelphia, Pa.

Herbert W. Dow, Sales Engineer, Nordberg Manufacturing Company, Milwaukee, Wis.

Louis R. Ford, Consulting Engineer, Brooklyn, N. Y.

H. E. Gehres, Vice-President and Chief Engineer, Cooper-Bessemer Corporation, Mt. Vernon, Ohio.

Lester M. Goldsmith, Consulting Engineer, Atlantic Refining Company, Philadelphia, Pa.

H. C. Hallings, United States Representative, Burmeister & Wain Ltd. (Copenhagen), New York, N. Y.

Charles B. Jahnke, Chief Engineer, Fairbanks, Morse & Co., Beloit, Wis.

Charles Legrand, Consulting Engineer, Phelps-Dodge Corporation, Douglas, Ariz.

Kenneth G. MacKenzie, Chief Chemist, Texas Company, New York, N. Y.

John T. McCoy, Assistant Technologist, Tidewater Oil Company, Bayonne, N. J.

Lester G. Metcalf, Assistant Manager of Refineries, Union Oil Company of California, Los Angeles, Calif.

B. E. Meurk, Superintendent Engineer, Isthmian Steamship Lines, New York, N. Y.

G. H. Michler, Standard Oil Company of New Jersey, New York, N. Y.

Ernest Nibbs, Chief Engineer, Electric Boat Company, Groton, Conn.

Ralph Miller, Chief Engineer, Oil Engine Department, Ingersoll-Rand Company, Phillipsburg, N. J.

M. J. Reed, Research Engineer, Diesel Engine Manufacturers Association, New York, N. Y.

Lee Schneitter, Plant Betterment Engineer, Electric Bond and Share Company, New York, N. Y.

Benjamin C. Smith, President, Standard Motors Construction Company, Jersey City, N. J.

George N. Somerville, Atlas-Imperial Diesel Engine Company, Oakland, Calif.

4 per cent. Consequently, it was deemed advisable to procure as much information as possible with fuels at 200 sec. viscosity and note the difference, if any, between the product falling within the Conradson specification and that which did not.

Manufacturer No. 1. Oil submitted in this case was made up under the following analysis:

A.P.I. gravity	23.0 deg.
Flash point (closed cup)	210° F.
Viscosity at 100° F. (Saybolt Universal)	200 sec.
Sulphur (bomb)	1.144%
Pour	Zero and lower
Ash	Trace
Moisture	None
B. S.	0.05%
Conradson carbon	3.33%

This manufacturer has not had an opportunity as yet to conduct a thorough test, but during a preliminary run on his 11-in. by 14-in. engine he found that the load could be maintained only by dropping the speed from the standard 350 r.p.m. to 325 r.p.m. At this condition the exhaust contained a considerable amount of smoke. This manufacturer hopes to present a more conclusive report in the very near future.

Manufacturer No. 2. This manufacturer has not yet had an opportunity to test the sample of heavy fuel which he obtained, but expects to be able to report in the very near future.

Manufacturer No. 3. Oil tested by this manufacturer had the following analysis:

Viscosity at 100° F. (Saybolt Universal)	193 sec.
Sulphur	1.543%
Conradson carbon	5.76%
Ash	0.042%
Flash point (closed cup)	210° F.
Moisture and sediment	0.05%
A.P.I. gravity	22.1 deg.

The engine used for the test had the following characteristics:

Cycle	Four
Acting	Single
Number of cylinders	Two
Bore	12½ in.
Stroke	18 in.
Rate of speed	280 r.p.m.
Brake horsepower	115 b.hp.
Piston cooling	None
Type of spray valve	Multihole nozzle
Condition	100%
Compression pressure	380 lb.
Timing	28 deg. before top center to 8 deg. after top center

Two series of tests were conducted, one with standard uncooled spray nozzles and one with water-cooled spray nozzles. In each case the engine was calibrated by running a preliminary test on a light fuel oil of 28 deg. B. and low viscosity. The tests run using the sample oil and the uncooled nozzles showed very little difference from the performance on the light oil at the start. In each case, however, after the engine ran for about 1½ hours the exhaust became quite smoky and the engine had to be shut down to clean the spray nozzles. Until this happened, however, the fuel consumption, exhaust temperature, and the appearance of the exhaust were about equal to the corresponding performance on light fuel at loads from 25 to 110 per cent of rating.

When using the cooled nozzles the performance was again practically the same with the sample oil as with the light oil. The trouble with smoking after a period of running, however, was not so serious. An analysis of this smoking trouble showed that the injection nozzles were being fouled with the formation of small carbon craters. This formation in the case of the uncooled nozzles was more serious than in the case of the cooled nozzles. In the latter instance the cone seemed to form to a certain point and then break off to pass out the exhaust.

After the tests were completed, the engine was run with cooled nozzles at shop load until the balance of the fuel was consumed. During this time the performance was as good as with the light fuel with the exception that considerable trouble was once experienced in starting with the outside temperature at 45 deg. and a certain amount of difficulty at starting was experienced every day, although this difficulty was only slight.

It was the manufacturer's opinion that the extent to which these objectionable carbon cones were formed is not sufficiently serious to call the fuel unsatisfactory, and he felt that perhaps improvement in design might entirely get rid of this cone-forming feature in the near future.

Manufacturer No. 4. Oil tested by this manufacturer had the following analysis:

Viscosity at 100° F. (Saybolt Universal)	193 sec.
Sulphur	1.543%
Conradson carbon	5.76%
Ash	0.042%
Flash point (closed cup)	210° F.
Sediment and moisture	0.05%
A.P.I. gravity	22.1 deg.

The engine used for this test was as follows:

Cycle	Two
Acting	Single
Number of cylinders	One
Bore	14 in.
Stroke	17 in.
Rate of speed	257 r.p.m.
Brake horsepower	65 b.hp.
Piston cooling	None
Type of spray valve	Uncooled
Type of injection	Precombustion or direct

The engine used is an experimental engine which can be arranged to operate with a precombustion chamber or with injection directly into the main combustion chamber. Tests using the sample oil were conducted for either system of injection, and results were noted at full, three-quarter, half, and no-load.

Before the runs on sample oil the engine was operated on the light fuel oil used for shop testing. The results indicated that the engine was in first-class condition.

The sample oil runs with the engine arranged with a precombustion chamber showed exhaust temperatures approximately 15 deg. higher than on the shop oil. The exhaust was dark and cloudy, all of which indicated incomplete combustion and fuel consumption considerably increased.

The sample-oil runs with direct injection showed exhaust temperatures approximately 15 deg. higher than with shop-test oil, indicating a tendency toward incomplete combustion. The exhaust was cloudy.

An examination of the engine after running with precombustion showed carbon deposits on the nozzle and cylinder head. After running on direct injection, a crater was found around the nozzle orifice, and the top of the piston was found to be covered with soft, fluffy carbon. The engine could not be started from cold, using the sample oil with either system of injection, but had to be first warmed up on light oil.

This company concludes that the sample oil is unsatisfactory for general use in Diesel engines of this type because of its high viscosity and low gravity.

Manufacturer No. 5. Oil used for this test had the following analysis:

Ash	0.36%
Water	0.50%
Sediment	0.11%
Sulphur	2.36%
B.t.u. (high)	18,520
Baumé (60° F.)	15 deg.
Flash point (p.m. closed cup)	270° F.
Fire point (open cup)	329° F.
Conradson carbon	3.90%
Viscosity at 100° F. (Universal)	198 sec.

The engine used for this test was as follows:

Cycle	Four
Acting	Single
Number of cylinders	Four
Bore	14½ in.
Stroke	18 in.
Rate of speed	277 r.p.m.
Brake horsepower	260 b.hp.
Type of spray valve	Solid injection; Price system; single orifice, uncooled
Condition	New engine
Compression pressure	340 lb.

The engine was first operated for 4½ hours under full-load conditions with fuel temperature at 81 deg. fahr. The exhaust was light brown, slightly darker than the previous run with shop-test oil. The engine was then operated for 2½ hours at 18 per cent of full load. The exhaust during this light-load operation showed a very dense, yellowish smoke. Quite frequently fuel charges failed to fire in the engine, causing unsteady operation. After this test full load was again applied, and after a few minutes of full-load operation the previous full-load conditions were re-established. The oil was then heated from 81 deg. fahr. to 141 deg. fahr., but no changes were noted in the operation at full load. Furthermore, with heated fuel, the light-load operation was no less erratic.

Manufacturer No. 6. Oil tested by this manufacturer had the following analysis:

A.P.I. gravity	14.7 deg.
B.t.u.	18,565
Viscosity at 100° F. (Saybolt Universal)	178 sec.
Sulphur	0.931%
Conradson carbon	6.0%
Water and sediment	0.9%
Ash	Trace

The engine used by this manufacturer in this test had the following characteristics:

Cycle	Four
Acting	Single
Number of cylinders	One
Bore	17 in.
Stroke	19 in.
Rate of speed	257 r.p.m.
Brake horsepower	110 b.hp.
Type of spray valve	Single orifice; double check, uncooled, Price system
Condition	New engine
Compression pressure	335 lb.
Timing	21 deg. before top center

This engine was operated on the sample oil for 2½ hours at loads from 25 to 110 per cent of rating. The fuel oil was consumed more efficiently at 100 and 110 per cent loads than on the shop-test oil, but considerably less efficiently at loads from 25 to 75 per cent. The exhaust on the sample oil was quite smoky in comparison with the shop-test oil. After the run the engine was examined, and the exhaust valve, seat, and stem were found to be gummed. There were also gummy deposits of carbon in the exhaust manifold. The temperature of the sample oil at the engine was 70 deg. fahr., but no trouble was experienced in starting.

The opinion of the manufacturer was that the sample oil was unsatisfactory for this type of engine in view of the very poor performance at low load.

Naval Experimental Station, No. 7. Operating tests of a special Diesel oil were conducted at this station in connection with the standardization of Diesel fuel-oil specifications. The analysis of the special Diesel oil was as follows:

A.P.I. gravity	20.8 deg.
Flash point (closed cup)	200° F.
Sulphur content	1.45%
Conradson carbon	5.41%
Ash	0.1%
Sediment	0.21%
Viscosity at 100° F. (Saybolt Universal)	200 sec.

The M.A.N. engine of 350 hp. was run 72 hours at 100 per cent load and operated very satisfactorily when the oil was heated to at least 145 deg. fahr. Attempts to start this engine with the oil at room temperature of about 60 deg. fahr. were unsuccessful. The operation of the engine with the oil below 145 deg. fahr., after the engine had been started by other oil, was not satisfactory. It was found advisable to have the heater within a few feet of the fuel-metering cylinder. The apparent difficulty in using this Diesel oil seems to be in the flow to the fuel pump through the metering chamber. The design of the M.A.N. engine, with a small metering chamber, greatly restricted openings to the fuel pump, and pump plunger of ⅜ in. diameter by 1-in. stroke does not allow the use of the more viscous fuel. It is believed, however, that after the fuel is delivered by the pump at high pressure to the cylinder and vaporized by the means of high-pressure air, the actual combustion of the more viscous fuel is nearly equal to that of the present Navy standard Diesel oil. This engine operates very satisfactorily on Navy Diesel fuel without any heating. It also operated on Bunker "A" fuel that has been centrifuged and heated to about 140 deg. fahr. This engine, built in Germany 11 years ago, has very small and intricate oil passages. It is necessary that the fuel be fluid enough to flow readily through these passages. Apparently if the oil is heated to between 3 and 4 Engler (approximately 90 to 130 Saybolt Universal), which corresponds to 130 deg. fahr. for the A.S.M.E. standard Diesel fuel, the oil will function with apparent satisfaction.

The Fairbanks-Morse 50-kw. engine was run 48 hours at 35 hp. with this special fuel at 60 deg. fahr. However, due to the fact that less viscous fuel is handled more easily by the service pump, the operation of the engine was more satisfactory and reliable with fuel at 120 deg. fahr. The Fairbanks-Morse engine is of the semi-Diesel solid-injection type previously made by the manufacturer and is more likely to give inefficient results when using the heavier fuel, due to the fact that the compression pressure above the piston and the corresponding temperature are not as high as with the full-Diesel-type engine. In addition, the solid injection of fuel at a considerably lower pressure does not tend to give as complete vaporization of the fuel as obtained in the full-Diesel engine. This engine can be operated on A.S.M.E. standard fuel, but it will give more satisfactory operation on Navy Diesel, which is the oil ordinarily used. However, this engine also will operate on Bunker "A" when heated to 140 deg. fahr.

The Nelseco 150-kw. Diesel engine was run 36 hours at 85 hp. and operated very satisfactorily with this special fuel, starting and operating very well at room temperature of 58 deg. fahr. The design of the Nelseco Diesel engine is such that a more

viscous oil can be used. The engine has large fuel lines to the fuel metering chamber, and a fuel pump with plunger $^5/_8$ in. diameter by $^3/_8$ in. stroke, in connection with high-pressure air atomization. The standard A.S.M.E. fuel appears to function about as well as Navy Diesel in this engine.

The Cummins (motor boat) 50-hp. Diesel engine is a six-cylinder, four-cycle, full-Diesel solid-injection engine, rated at 50 b.hp. at 850 r.p.m., for use in driving motor boats. While the time of running the special Diesel oil in this engine was only one hour, it was determined that the engine would start and operate satisfactorily with the special Diesel oil at ordinary room temperature of about 70 deg. fahr., although when load was put on, the exhaust was somewhat smoky. It is believed that with the installation of a heater, using circulating water to heat oil to about 130 deg. fahr., this engine would operate in a generally satisfactory manner. A lighter oil would of course be somewhat better, especially for starting or for operating in cold weather.

From the short trials on Diesel engines at the Experiment Station, the indications are that proper fluidity is the essential matter, and then when this is obtained by heating, much heavier fuel can be used on the small engines than is generally supposed. The difficulty with heavy oil seems to be largely due to failure of the oil to flow properly through the small passages that are met with on some engines.

The determination of the proper temperature to which to heat Diesel fuel is as follows:

It has come to the notice of this station that the M.A.N. engineers have recommended that Diesel fuel be brought to the proper liquid state by heating so that the viscosity at the atomizing nozzle is brought to about 5 deg. Engler (approximately 170 Saybolt Universal). This information seems to be more or less substantiated by the experience in heating Diesel fuel for the various engines at this station. The following comment in regard to this matter may suggest a field of investigation:

The proper viscosity at the oil pump is a very important matter in proper operation of Diesel engines. From a limited number of runs at the Experimental Station on four engines—the M.A.N. German submarine 250 kw., Nelson four-cycle 100 kw., Fairbanks-Morse 50 kw., and Cummins solid injection—it would appear that the viscosity at the pumps should be approximately 4 Engler (approximately 130 Saybolt Universal).

Light oils such as Navy Diesel require no heating even in cold weather. In this case 4 Engler (approximately 130 Saybolt Universal) corresponds to about 45 deg. fahr. However, the design of the oil passages will affect the ability of the engine to operate.

The A.S.M.E. committee's sample Diesel fuel will work on most American engines without heating, but in engines of German design a more fluid oil is necessary. Apparently impossible oils if heated to 4 Engler will operate on most any engine. The fact is significant that the Cummins 50-hp. 850-r.p.m. solid-injection will operate on the sample fuel without heating, while the M.A.N. 350-hp. will not. Additional experiments should be made by engine builders in an effort to establish the proper viscosity Saybolt at which any Diesel gives complete satisfaction. In the case of mechanical oil-burning apparatus this has been found to be 2 to 4 Engler (approximately 50 to 130 Saybolt Universal). It is probably near the same point for Diesel engines.

If there could be obtained the results of tests on heavy Diesel fuel heated to a temperature at which it gives satisfaction, this point could be determined for practical purposes.

It is suggested that builders and users be asked to make such tests and to report the temperature at which fuels seem to give most satisfaction.

Light Oil Specifications

The committee has been concentrating on the specification for heavy-duty oils and has this work well under way. It is now making arrangements to test the oils meeting the tentative specification for light high-speed engines. The oil companies which are represented on this committee will be in a position to supply fuels in order that these tests might be conducted. Consequently, it is requested that the engine builders that are producing motors of the aforementioned type procure sufficient quantities of this oil to conduct tests in a manner similar to those that have been made with the heavier oil and to advise the committee of the results. Several builders of light Diesels have already received samples, but information on the tests has not been submitted.

Conclusion

Although the results so far disclosed on the proposed specification for Diesel have not given entire satisfaction in some medium-sized engines when the oil was not heated at the fuel pump, the committee is not inclined to accept those results as final and will modify the specification. As the purpose in establishing a Diesel fuel for general distribution is a question of price and as any change would stipulate a lower viscosity or a more stringent Conradson, it would materially increase the cost of such a product. The work will be carried on in testing the present specification oil, but the committee is also planning to supply some manufacturers with oils with viscosity of approximately 150 and 125 sec. Saybolt Universal at 100 deg. fahr. In doing this, naturally the Conradson carbon would be decreased, and it is hoped to be able to have available oils with a carbon content of maximum 4 per cent and possible 3 per cent. This might avoid the carbon deposits which have been mentioned in some of the test data.

It is desired to state that the data herein reported are only preliminary, giving the operating results on the sample fuel sent out, and will serve to indicate generally how the specification fuel will operate when unheated. This and future reports will also indicate to what extent difficulties may be overcome by heating or other possible methods of handling the fuel.

The committee wants to take this opportunity to thank the oil industry and the Diesel-engine manufacturers for their wholehearted cooperation in furthering this work.

Discussion

Edgar J. Kates.[3] The committee is to be congratulated upon the important and very practical start it has made in determining the significance of the various oil characteristics by direct experiments on actual engines. The reports of these tests should be of invaluable assistance in clearing up some of the mystifying questions that have hitherto delayed a solution of this problem.

Presumably the test reports will receive careful interpretation by the committee and full consideration will be given to all factors. For instance, in one or two cases the reports indicated that the engines performed satisfactorily upon the A.S.M.E. special oil when running under normal load, but that there was trouble with irregular operation and misfiring when running at light load. In view of the fact that other engines do not give such trouble when running on the same oil, the committee should determine whether the trouble is with the oil or with those particular makes of engine. There are certain engines on the market in which the fuel-injection and combustion systems are such that irregular operation at light load is characteristic even with fuels of the highest quality. It behooves the manufacturers of those engines to improve their designs to eliminate this trouble rather than to blame the oil.

[3] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

The tests reported were of comparatively short duration, ranging from a couple of hours to 72 hours. For this reason the tests can hardly show the effects of all of the properties of the fuel oil, since the results of sulphur and ash would certainly not become apparent in so short a time. The tests indicate something about the effects of viscosity and Conradson carbon, but of course it will be necessary to have many more reports before any positive conclusions can be drawn.

It is to be hoped that the engine builders will continue to cooperate fully in this exceedingly important investigation.

Results of Further Field Tests on Suggested Diesel Fuel-Oil Specifications[1]

Progress Report No. 3 of the A.S.M.E. Special Research Committee on Diesel Fuel-Oil Specifications[2]

DURING the winter meeting of The American Society of Mechanical Engineers in New York, this committee presented a Progress Report. This report was mostly upon the results of various tests conducted by Diesel-engine manufacturers on the fuel designated as tentative standard specifications. It will be remembered that a great many of these tests showed unsatisfactory operation by a number of the engines when operating on the oil specified for heavy-duty engines with a maximum viscosity of 200 sec. In most cases, in meeting the viscosity specification, the various oil companies had a Conradson carbon content in excess of the suggested maximum of 4 per cent, and the difficulties encountered in operating these engines were due to carbon formation, incomplete combustion, and erratic operation, expecially at low load. Consequently the committee should turn its attention to the question of Conradson carbon and fluidity. If, as was pointed out in the second Progress Report, Conradson carbon in excess of the maximum could be employed and the oils be reduced in viscosity by applying heat to give the necessary fluidity, it is felt that satisfactory operation might be had. If the results are not as expected and the operation is unsatisfactory with the fluid oil, then the logical step would be to lower the Conradson carbon. The oil men on the committee have advised that if such a procedure is necessary, the viscosity will automatically be decreased and the general characteristics of the oil will all be improved, with the natural result of a more expensive oil to the consumer. Naturally it is the desire of this committee to standardize on the cheapest satisfactory oil which is available.

The committee requested the industry, through the medium of its last report, to conduct tests. In answer to this it received some very interesting data from the Florida Power and Light Company in which this company states that it has conducted some tests and has successfully burned fuel oil with a viscosity of 116 sec. at 122 deg. fahr. (Saybolt furol), which is approximately six times the viscosity recommended by this committee on the Universal scale. This oil has a Conradson carbon content of 10.07 per cent and about 15 gravity. It has been found that the oil could be satisfactorily burned in continuous operation with an average load factor of approximately 90 per cent when a temperature of approximately 125 deg. fahr. is maintained at the fuel-injection valve. Of course, this engine is a large and slow-moving two-cycle air-injection engine.

On the other hand, a report has been passed on to this committee in which a 17 by 24 four-cycle solid-injection engine turning at 231 r.p.m. successfully handled 12–14 A.P.I. boiler oil. The oil is heated to approximately 200 deg. fahr. and flows through a jacketed line to the pumps. The report states that the engine can be operated from no load to 30 per cent overload and the exhaust be practically invisible. When an inspection had been made, there was no evidence of carbon formation, and the exhaust valve remained in service the length of time equivalent to operation of light fuels.

One manufacturer has reported to the committee that his engine would not operate satisfactorily on the A.S.M.E. Diesel fuel. Consequently, he has redesigned his fuel system and now reports that this type of engine will successfully operate on fuels of this nature, with the following reservations:

1 Provisions be made to preheat the fuel to approximately 150 deg. fahr.

2 Provisions be made to start and stop the engine on a lighter approved fuel.

3 That the engine is not required to run at light loads, 25 per cent or less, for extended periods.

The oil supplied this manufacturer had a viscosity of 200 sec. and a Conradson carbon content of 5.17 per cent; but in concluding his report he writes as follows:

"From the foregoing it can readily be seen that we need a fuel oil of lower viscosity that will not require special means of heating between supply and nozzle and which can be used for cold starting."

Still another manufacturer of solid-injection engines reports to the committee that after having conducted tests on a fuel of 175 viscosity and Conradson of 3.9 per cent, the exhaust at full load

---

was smoky with high gas temperatures, while at three-quarters and one-half loads the exhaust was clear, with normal temperatures. In quoting the following it more or less substantiates the committee's opinion that the manufacturers of Diesel engines can do much along the lines of design in making this fuel successful.

"All of this is due, no doubt, to the fact that our injection nozzle did not handle the heavier fuel in such a manner as to give the proper atomization and penetration. The test, however, did not result in any carbon deposits on the heads and pistons. Inspection after running on this fuel showed all working parts and filters to be clean.

"Our observation would be that while the engine was capable of handling the fuel, we would not consider this oil as a satisfactory product for normal operation."

The same condition exists as when the committee published its previous results. There is inconsistency in the operation of these various engines, and there seem to be but the two alternative plans. One of them is that the manufacturers of Diesel engines redesign their fuel system and install preheating equipment; but this is practically eliminated, as most of these concerns that have conducted tests have made it plain that they do not wish to operate engines in the field on an oil of these characteristics, and but one manufacturer has shown any desire to reconstruct his motor so that it will satisfactorily burn these fuels. Consequently, but the one alternative is left to the committee, and that is to improve the quality of the oil by lowering the viscosity and simultaneously the Conradson carbon, which will materially increase the price differential between steam-generating oils and Diesel fuel. Comments would be welcomed from the industry upon such a move by this committee.

Light High-Speed Diesel Tests. One of the members of this committee, being a manufacturer of this type of Diesel engine, has conducted a series of very interesting tests on a small four-cycle four-cylinder 7 by $8^1/_2$ solid-injection 80-hp. Diesel engine operating at 650 r.p.m. The first oil was a product of 44 viscosity Saybolt Universal at 100 and a Conradson carbon of 0.48 per cent. The rest of the analysis indicated a distillate fuel. The exhaust was clear, and fuel consumption was normal through full load to half load. The engine started cold. Comment by the test engineer was that the fuel was considered fairly satisfactory.

The next sample was 48 viscosity Saybolt Universal at 100, and Conradson of 1.6 per cent. The exhaust showed a trace of smoke. Fuel consumption was above normal.

The third test was on a fuel of 73 viscosity Saybolt Universal and a Conradson carbon content of 3 per cent. The load dropped off at the specified r.p.m., and the exhaust was slightly cloudy at all loads and the fuel consumption between 124 and 144 per cent normal. When the engine was shut down and left overnight, it failed to start, and when the injection valves were inspected, the tips were covered with a tarry deposit. After cleaning the valves, considerable trouble was encountered in the starting. Even then it took 20 minutes to bring the engine to full-load capacity. In the engineer's opinion the heavy deposit left in the cylinders renders the oil unsatisfactory for this engine.

Another oil was tested, meeting the maximum A.S.M.E. viscosity specification on this grade of 100 sec. Saybolt Universal at 100 deg. fahr. The Conradson carbon of this product was 3.5 per cent. Fuel consumption was high and the power rating low. The exhaust-intake valves were coated with a gummy substance and had to be cleaned before the engine could be started. After considerable difficulty the engine was started and required 30 minutes of idling before any load could be applied. During operation it was necessary for the staff constantly to apply penetrating oil to the valve stem to keep the valves free. After running 15 minutes it was necessary to stop and clean the injection valve. The r.p.m. constantly decreased during operation. Commenting on this oil, the engineer advises that during this test the exhaust was clearer than any of the oils tested, but the power was much lower, and considerable trouble was encountered and heavy deposits of pitch were left in the cylinder.

In analyzing these results it is apparent that Conradson carbon in excess of 1 per cent is unsatisfactory for the operation of motors of this size and speed. The committee has requested that this manufacturer blend sufficient quantities of the first-mentioned oil having a Conradson carbon content of 0.48 per cent with the second grade having a Conradson of 1.6 per cent, in such quantities that the carbon content will be slightly below 1 per cent; then test this oil under similar conditions and advise of the result. It is believed that these data should be of considerable interest even though the viscosity will be considerably below the maximum set by this committee.

One other concern interested in motors of this type advises that, in field operation with motors widely distributed throughout North and South America, the best results are obtained with oils running between 40 and 60 sec. Saybolt Universal at 100, and trouble has been experienced when using oils in excess of 70 sec. Consequently, it feels that 100 sec. Saybolt Universal would not be satisfactory for its engines. With reference to Conradson carbon, this concern states that it has operated engines successfully on quantities as high as $2^1/_2$ per cent, but this is with California Diesel fuel, which, as all know, is of entirely different characteristics from the average fuels east of the Rocky Mountains. Consequently, it is thought safe to say that the 1 per cent is considered satisfactory for them. The other figures specified are felt to be in line with its experience.

In light of these data it does not appear as though this specification would have to be modified to any great extent, although it is self-evident that the viscosity specification will have to be lowered in order that it might conform more closely with actual requirements.

Conclusion. The committee has now arrived at the turning point in the road where it becomes necessary to make a decision on the future policy in this work. One turning will take it into studies to discover the cheapest oil which can be utilized in present Diesel engines. Apparently, if this is the goal, it will have to modify these specifications, perhaps in both classes of engines. The other turning will mean a search for the best compromise between boiler oil and the present cheapest oil which can be used in the present design of engines, but this compromise on oil will necessitate a redesign of Diesel machinery in many instances and the application of pre-heat apparatus. The committee feels that a decision between these policies is a matter which is the concern of the conference in general and the Diesel manufacturer in particular. The committee thinks that this conference should not terminate without some decision being made upon this subject, inasmuch as the work of this committee will come to a standstill very shortly unless the future program is further defined.

Discussion

E. T. LARKIN.[3] We are not builders of Diesel engines, although experiments have been conducted by us during the past twelve years; but we have not marketed or sold oil engines, one of the reasons being the unsatisfactory fuel situation. Suitable fuels were not always obtainable, and available fuels varied greatly in characteristics. We have not considered it advisable to place the burden of obtaining satisfactory fuels on our customers, who in some instances are situated where it is difficult for them to secure proper oils. We have found it necessary, even in our de-

[3] Chief Engineer, Sterling Engine Company, Buffalo, N. Y.

velopment work, to have fuels shipped to us because none were available locally.

Our engines would be of a fairly high-speed type in moderate sizes, and conditions require that they be simple and that auxiliaries such as are used for handling heavy oils be eliminated. The engines must be very easily and quickly started, regardless of air temperatures. Many of our engines are used for standby service where instantaneous starting is frequently required for emergency operation. It is absolutely essential for such work that fuel be of such a character that it will flow easily, be clean, be noncorrosive, and free of material which will clog strainer and lines.

The writer believes that engine builders should be concerned in having available fuels approximating certain standard specifications in order that more uniform performance be obtained from their engines.

E. T. Birdsall.[4] Last winter Mr. Cummins ran a Packard car with a Cummins engine from Columbus, Ind., to the New York Auto Show and from New York to Philadelphia. He also drove from Columbus to Daytona Beach. On all these runs he bought ordinary furnace oil and had no difficulty with the running of the engine. It seems that we are getting too finicky about what oil we are compelled to use in these engines. If Mr. Cummins can do it with that engine, it might be well for some of the faint hearts to look into the matter and see how he does it.

At Mr. Cummins' factory they are running the shop Diesel engine on crankcase drainings.

An engine that requires "specification" oil starts out with a sales handicap and a higher fuel cost than is necessary.

H. C. Dinger.[5] The writer's experience has been that most Diesel engines will run on any clean fuel oil if one can get it warm enough. Take a German engine which ordinarily requires a light oil—such engines have been run successfully with bunker oil heated so as to secure proper fluidity.

If an owner has an engine without a heater and it requires a light oil, he has to get that kind of oil or he may install a heater and use a heavier oil. Engines will run quite differently on different oils, and the most suitable oil for one is not always the most suitable for another. It is a question of whether one wants to arrange the engines to suit the oil that is available or how far he wants to go up in price for fuel. If one gets a light enough oil, he may have a satisfactory oil, but a cheaper oil that will not work entirely satisfactorily on some of the engines will work on most of the engines. A great many of the engines can change the design so that a heavier and cheaper oil can be used. The Diesel engine is competing with the other prime movers, and the price of the fuel oil is an important factor. If the Diesel-engine builders make their engines to use an ideal fuel, which is materially more expensive than bunker fuel oil, they will be unable to compete with steam power in many places. Hence the aim of the builders should be to design their engines or install such accessories (heaters, etc.) as will enable their engines to operate on the least expensive oil that may be available. The standard specification fuel oil for heavy and medium engines should therefore be a fairly heavy oil, and not necessarily a fuel oil that will give satisfaction on any Diesel engine. The economic problem is to make the engine to suit the cheap oil rather than to find an ideal fuel oil that will work satisfactorily on any engine. Such an ideal fuel oil would be too expensive for general use.

[4] Engineering and Research Department, Curtiss-Wright Corporation, New York, N. Y.

[5] Officer in Charge, U. S. Naval Experiment Station, Annapolis, Md. Mem. A.S.M.E.

J. B. Frauenfelder.[6] The principal item of criticism advanced by those who advocate steam as against oil engines is fuel cost. They claim the oil engines will never overcome the differential between $1 per barrel boiler or Bunker "C" oil and $2 per barrel Diesel oil. If the oil engine has to survive, not only its initial cost of manufacture must come down, but also fuel cost. This is important, and it is the Diesel industry's battle and not that of the oil man.

It is suggested that this question of fuel specifications be seriously taken up by the Diesel Engine Manufacturers Association and that it establish a line of procedure for an appropriate committee to work on and cooperate with all the other official agencies now engaged in the solution of the problem of fuel specifications standardization.

L. F. Burger.[7] We do not say that the oil proposition is entirely up to the oil company; the engine builder and the oil company must work together. The oil company should get busy and see the engine builder and find out what the latter wants. If the oil companies do not do this, some of the engine builders will have to make their own fuel oil, which can be very easily made and of a very high grade. For instance, rape seed or castor-oil seeds can be grown very easily and a very high grade of oil made therefrom. In that way the engine operators can easily cut out the oil company. Therefore, the writer believes that Mr. Butler should go to work with the engine builders and find out just what is required so that the engine builders will not be working in the dark at all times.

C. L. Cummins.[8] We have been producing small Diesel engines over a period of years and have met many problems arising from the lack of standardization or knowledge of fuel oils.

It is not believed advisable to establish any closely drawn specifications for fuel oils at this time, as the variety of fuel-injection mechanisms in use demands some differences in fuel oils.

However, the establishing of two or three general specifications covering fuel oils would undoubtedly be of immense value, as it would permit the oil companies and users to work more intelligently with one another.

In the thousands of miles which the writer has driven our Diesel car over the country, he has used a variety of fuel oils with entire satisfaction. The most commonly available fuel has been the light gas oils used in oil burners for home heating. These fuels have been generally satisfactory, except that the lighter oils lack sufficient viscosity to properly lubricate the fuel pump and injection mechanism.

It is therefore felt that viscosity is of considerable importance in any specifications for fuel oil, not only for our own engine, but for practically any Diesel engine.

Wiley H. Butler.[9] The writer has worked with you from a committee point of view. He has supplied you with oils of various characteristics. He also has cooperated with you as closely as he could and as his position as secretary of this committee would permit. The oil industry is ready to cooperate. In changing those limits you change the economic status of that oil. When it comes to the type of the engine, that is an entirely different problem. You have got to have light oils. You can run on them, but you will not run on them for any length of time. You will use the distillate oil until the committee can produce the class of oil that will be satisfactory. We are willing to supply samples and are willing to help in any way we can.

Nitride Hardening of Alloy Steel for Diesel-Engine Use

By C. R. ALDEN,[1] DETROIT, MICH.

In this paper the author discusses metallurgical developments in the nitride hardening of alloy steels and the advantages that may be expected from increased use. With correct analysis of the steel, freedom from distortion in hardening depends upon the operations preceding nitriding. A sequence of operations is given, and nitriding equipment is described. Time necessary to produce and the cost of the nitrided product are given.

IN JUNE, 1913, Adolph Machlet of the American Gas Furnace Company was granted a patent for case-hardening ferrous materials by heating in ammonia at a temperature above 900 deg. fahr. The early process results in an extremely hard non-corrosive case, though it is so thin and brittle, with lack of tenacious bonding between the case and core, that the finished product is not suitable to many mechanical purposes.

At the research facilities of the Krupp Company in Germany under the direction of Doctor Adolph Fry it was determined that aluminum and chromium, alloyed with steel in proper proportion, when treated in an atmosphere nitrogen at the higher temperature of 950 to 1075 deg. fahr., gave to the case a greatly increased depth and sufficient increase in ductility to insure satisfactory bonding between case and core. In the United States much research work has been done by Doctor V. O. Homerberg of the Massachusetts Institute of Technology, consulting engineer for the American licensees.

Definitions

Nitralloy is steel of special analyses for use in the nitriding process. Nitriding is the process by which special steels can be surface hardened at a low temperature by the action of ammonia.

The principal disadvantage of case carburizing and hardening of low-carbon steels is in the difficulties attendant upon heating and quenching the steels after carburizing. The very considerable amount of distortion obtained is an evidence of high internal stresses resulting in a lowering of fatigue resistance, and the checking or cracking of the hardened case, which checks are frequently invisible to the naked eye, would render carburized materials particularly unsuitable for fuel-injection sytem details, even if the process were not ruled out by the low factor of safety incident to the small diameters and thin sections encountered.

For the foregoing reasons both consumers and producers have earnestly sought materials and methods of hardening which would combine the properties of: (1) Extreme surface hardness, (2) resistance to wear, (3) resistance to scoring and abrasion, (4) resistance to corrosion, (5) high physical properties, (6) minimum distortion in hardening, (7) hardness maintained up to high temperatures, (8) machinability, and (9) forgeability.

Presented at the Third National Oil and Gas Power Meeting, State College, Pa., June 12 to 14, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Analysis of Properties

1 The properly nitrided surface is the hardest known form in which steel may be placed. It will readily scratch glass, and the chart Fig. 1 shows the Brinell hardness in comparison with other steels treated for their maximum hardness.

2 and 3 Resistance to wear would seem naturally to follow extreme hardness, but in addition nitrided surfaces possess a certain resistance to abrasion and scoring under high rubbing pressures and in the absence of lubrication. Only two of many possible examples will be cited:

Valve trimmings consisting of plug and sealing rings for large gate valves operated under high steam pressures with high superheat presented an extremely difficult problem which has been solved by nitrided trimmings.

Fuel-pump plungers and bushings which must work under extremely close clearances in the presence of fuel practically devoid of lubricating qualities have also given much trouble due to scoring, but it seems possible to eliminate this completely by proper application of nitrided materials.

4 The surface resulting from the nitriding process is as stainless as any of the stainless steels, and its combined properties of stainlessness and resistance to wear have proved of value in practically eliminating packing-gland wear on water-pump shafts; however, the stainless properties rapidly decrease if too much of the outer surface of the case is removed by grinding. In most applications of this material the nitrided parts can be produced with sufficient accuracy to require no grinding after nitriding.

Fuel-injection details must be ground and lapped after nitriding; however, with proper precautions, no reports of objectionable reduction of stainless properties have been received.

5 Fig. 2 shows the physical properties of Nitralloy G when tempered at various temperatures together with its analysis. The maximum tensile strength of Nitralloy G is in excess of 220,000 lb.; however, as the temperature at which the material is nitrided is usually close to or slightly in excess of 1000 deg. fahr., the tensile strength in excess of 180,000 lb. cannot be depended upon.

Fig. 3 shows the physical properties of Nitralloy H, which is lower in carbon than Nitralloy G; both steels are claimed to possess unusual resistance to fatigue, which claim seems to be well substantiated by test. One motor-car manufacturer operating in the high-priced field has a fatigue test for crankshafts which consists of locating a center bearing 0.040 in. out of line with the end bearings. Shafts are run to destruction at a fixed speed under this condition.

Breakage of standard shafts occurs in about 75 hr.; nitrided shafts in about 1500 hr. The reason given for the marked difference in results is that the long period during which the material is held at approximately 1000 deg. fahr. during the nitriding operation has a normalizing effect upon the core thoroughly relieving any internal stress which would tend to start fatigue stress failures in service.

6 Due to the sequence of machining and heat-treating operations later to be covered and to the fact that temperatures in the hardening process do not approach the critical temperature

of the material there is very little distortion in hardening. The distortion is so small that for most classes of service parts may be finish-ground to size before hardening.

This property of small distortion in hardening is a decided boon, especially to makers of spiral bevel gears, for which there is no thoroughly satisfactory method of correcting hardening distortion. It is claimed that the most accurate hardened gears have been made of nitrided material, and it is known that both

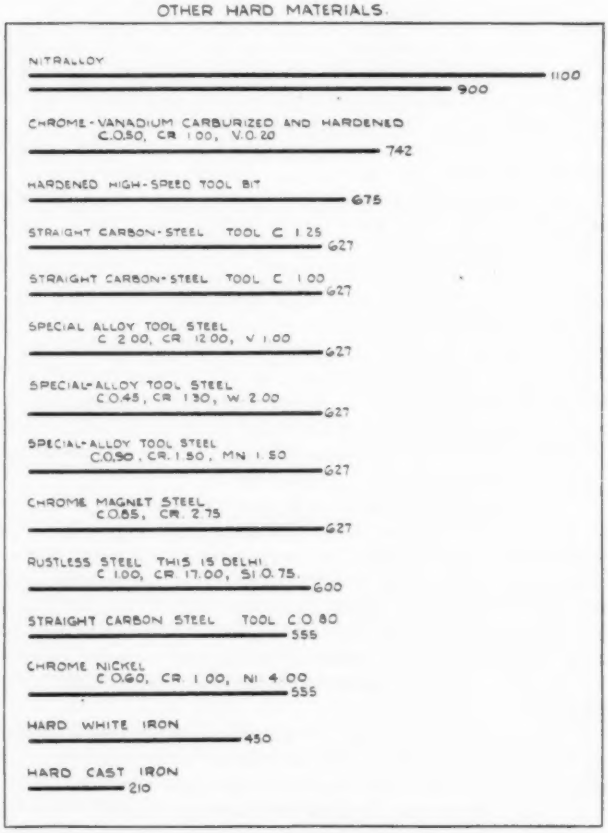

FIG. 1 HARDNESS OF NITRALLOY COMPARED WITH OTHER MATERIALS

accuracy and extreme surface hardness are factors in gear longevity. Nitrided materials, however, have not been recommended for transmission shifting gears as the extremely hard surface is too brittle to withstand the impact incident to improper shifting.

7 The nitrided case suffers no change whatever in hardness at temperatures up to 932 deg. fahr. and does not entirely lose its hardness even when heated to temperatures between 1400 and 1500 deg. fahr., though scaling occurs at the last named temperatures if oxygen is present.

Some applications to valve stems, valve guides, and even valve heads have been made with good success, for in such service lubrication is likely not to be of the best, with a tendency to abrasion under the high temperatures. Nitrided balls have also been used in continuous core ovens and similar applications where high temperatures are encountered.

OPERATIONS PRECEDING NITRIDING

The choice of steel for any given service is made in accordance with the characteristics of the service required. Assuming correct analysis of the steel, freedom from distortion in hardening is altogether dependent upon the operations preceding nitriding, and the preliminary operations can also affect the character of the case.

The sequence of operations in the case of complicated machined sections of articles to be forged is as follows: (1) Forge as S.A.E. steels, (2) heat-treat as per tables for physical properties, (3) rough machine, (4) normalize at drawing temperature four to five hours, (5) finish-machine, grind, and lap, and (6) nitride.

As the material machines more readily before heat treatment for the physicals, it is sometimes desirable to perform a first rough-machining operation between (1) and (2) in the foregoing schedule.

In the case of parts being produced by machining from bar stock, when also no rigid requirements as regards physicals must be met, it is possible to omit some of the foregoing operations; however, in all but the very smallest and simplest sections where great accuracy is not required, the normalizing between rough machining and finish machining is required.

Heat-treated bar stock may be obtained to specifications on mill orders. It is of the utmost importance that all quenched-

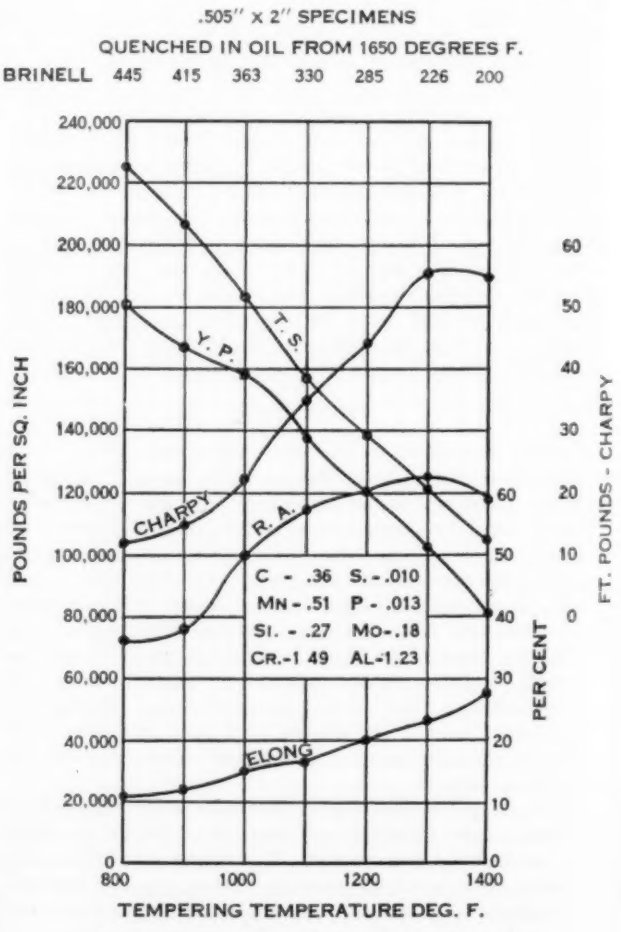

FIG. 2 PHYSICAL PROPERTIES OF NITRALLOY G

and-drawn parts shall be normalized at the drawing temperature; the annealing temperature may be below, but never above the drawing temperature. In the case of parts having to be straightened after rough machining, an additional anneal at 1000 deg. fahr. for four to five hours should always be employed to relieve straightening strains.

Due care should always be exercised in the design and prepa-

ration of parts for nitriding to see that all sharp edges are relieved and suitable fillets are used to avoid chipping of the hardened case at these edges. The removal of all decarburized surface and all scale left from forging or rolling is also imperative as erratic results will certainly be apparent otherwise.

Nitriding and Nitriding Equipment

Parts to be nitrided are placed in a gas-tight box loosely and without any packing material. Sealing may be obtained by a lid clamped on an asbestos gasket or preferably by a positive oil seal. The retort may be heated by electricity, gas, or oil, but the temperature should be under automatic control, as constancy of temperature is important and record of the temperature of the entire run should be kept by a recording pyrometer.

Anhydrous ammonia gas from the conventional steel cylinder is throttled through a suitable pressure-regulating valve, carried through lime to insure removal of moisture, and introduced into the retort through nickel pipes. The outlet gas is passed through apparatus making possible a frequent check on the percentage of dissociation, thence through a wash bottle as a water seal and to the atmosphere as shown in Fig. 4. The per cent dissociation should be maintained between 20 per cent to 40 per cent. Lower dissociation does not harm, but is wasteful of ammonia. Positive circulation of the gas in the retort as by fan is advantageous in securing rapid and uniform results.

In Fig. 5 (*Iron Age*, March 13, 1930, page 787) a large oil-fired box-type furnace is shown having a length capacity of 11 ft. as used by the Camden Forge Company. Fig. 6 (*Iron Age*, March 13, 1930, page 788) shows a large Nitralloy roll for rolling corrugated paper and a Diesel-engine piston rod, both products of this furnace. Numerous other types of furnaces are either on the market or are in process of development. One of particular note is of the continuous-production chain-belt type.

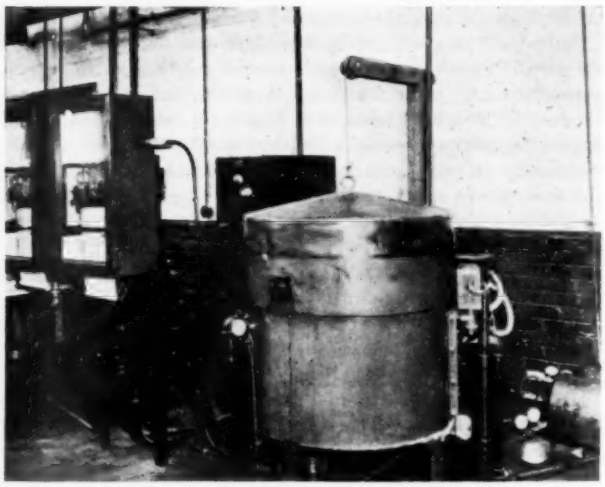

FIG. 8 HOMO FURNACE OF THE LEEDS AND NORTHRUP COMPANY

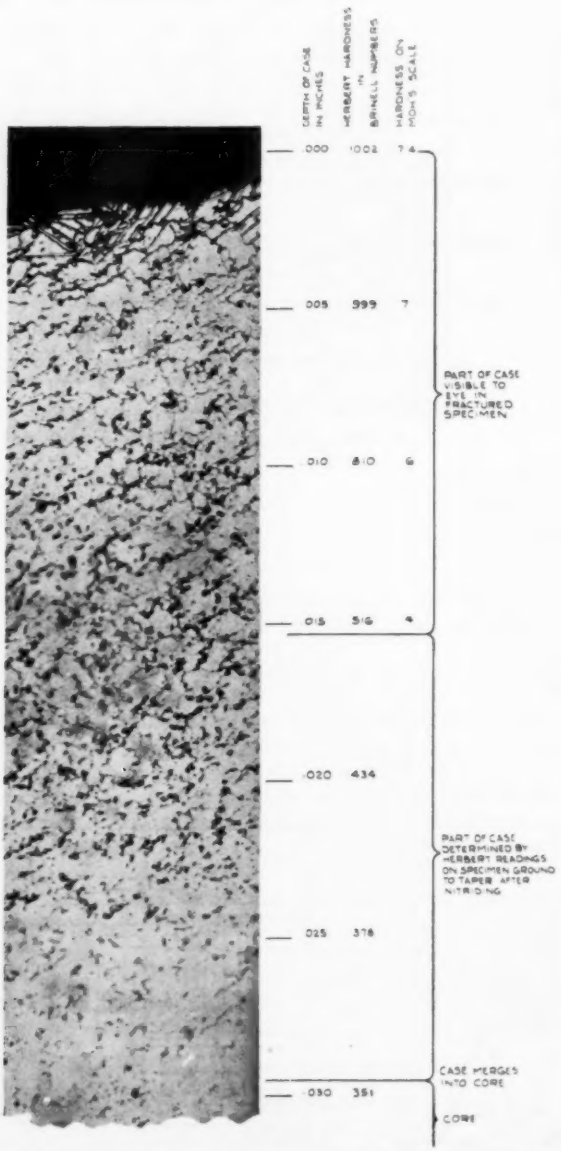

FIG. 7 PHOTOMICROGRAPH SHOWING DEPTH OF HARDNESS OF CASE

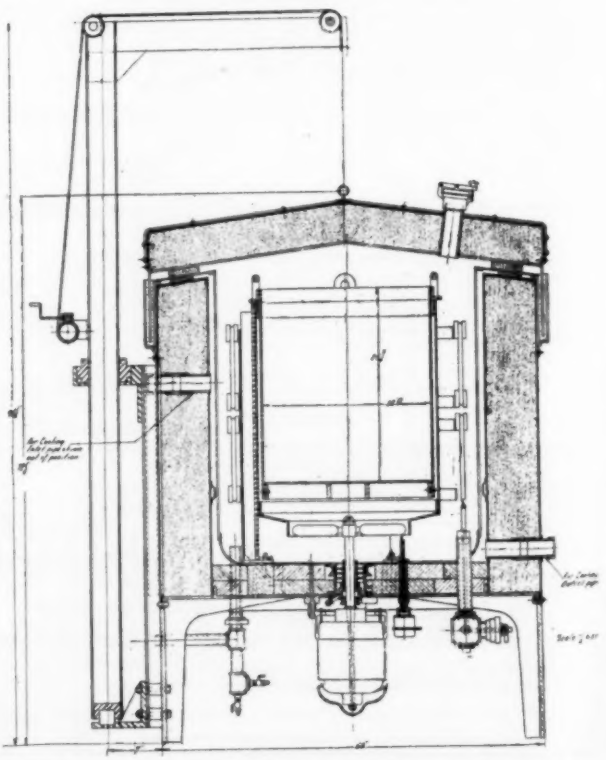

FIG. 9 SECTION OF HOMO FURNACE OF LEEDS AND NORTHRUP COMPANY

Time Required for Nitriding

Both the depth of penetration and the hardness of the nitrided case are affected by the temperature and length of time the material is held at the given temperature in the presence of ammonia. The longer the time and the higher the temperature the greater is the penetration, while higher temperatures do not result in obtaining the maximum hardness of the case.

When first introduced the process was scheduled to be accomplished in 60 to 90 hr. exclusive of heating and cooling time; however, improved materials and equipment are now reducing this time, though a minimum safe figure cannot be quoted as methods are changing rapidly. It is quite conclusively shown, however, that dual-cycle treatment consisting of 950 deg. fahr. for 12 hr. followed by an increase in temperature to 1125 deg. fahr. for 16 hr. is productive of case hardness of 1000 to 1125 Brinell, the high temperature portion of the cycle being for the purpose of increasing the depth more rapidly than could otherwise be accomplished. Combination cycles still further reducing this time are being talked of, but are not proved.

Cost of the Nitrided Product

Comparing the cost of Nitralloy material with carburizing steels disclosed the following figures: Nitralloy, 0.14 cents per pound; S.A.E. 1020, 0.07 per pound; and S.A.E. 3115 and 2315, 0.10 per pound.

On a 60-hour run the electrical energy consumed was 237 kw-hr. at a cost of $3.08, and the ammonia consumed was 1080 cu. ft. at a cost of $8.21.

These figures are for a small Homo furnace of 300 lb. or $1^1/_2$ cu. ft. capacity. Of course the cost of the ammonia and electrical energy per 100 lb. capacity decreases rapidly as the furnace size increases, so that the cost of nitriding in large quantities should compare quite favorably with carburizing when done in equal quantities.

An element of the cost of a nitrided product is the re-machining after heat treatments which required a second set-up. To prevent the nitriding action on a part of any given surface, several methods may be used. European practice covers that portion not to be hardened with a heavy nickel plate. Tinning the portion not to be hardened or covering with ordinary solder is an effective preventative through care must be used to see that all excess tinning material is removed or prevented from dropping onto other parts of the work as the material becomes molten during nitriding. A newer and more easily applicable preventative not subject to the foregoing difficulty is the painting of those portions not to be hardened with a coating of oxide of tin in glycerin.

A questionnaire circulated to the Diesel-engine industry asked the following questions:

1 Have you made use of nitride-hardening steels in any of the parts of your product?
2 What were the anticipated advantages which led you to turn to the nitride-hardening steels?
3 Have the anticipated advantages materialized? As a frank, unbiased discussion confined entirely to users is contemplated, reports of unsuccessful as well as successful applications will be appreciated.
4 Are there additional parts of your product in which the use of nitride-hardening steels seems attractive?
5 What are the reasons which have deterred you from the use of this material for the parts just named?

1 Of the replies received, seven of the Diesel-engine manufacturers indicated the application of nitrided Nitralloy to the following parts, quite a few being in the experimental stage: Fuel-valve tappets and guides, fuel-pump plungers and cylinders, fuel-pump regulator, bypass valves and guides, valve stems, valves and seats, piston wristpins, piston rods, gears, fuel-injection nozzles, crankshafts, cylinder liners, fuel-nozzle spray tips, fuel-nozzle check valves, and cams.

2 and 3 In nearly every instance the anticipated advantages were as follows: (*a*) Closer fits without danger of sticking and seizing, (*b*) elimination of distortion in heat treatment, (*c*) resistance to corrosion, (*d*) increased wear due to extreme hardness of case, and (*e*) ease with which the parts are handled in the shop due to the material being finished to size before nitriding.

4 Of seven replies received four mentioned various parts they had contemplated making of nitrided Nitralloy, among which were the following: Cylinder liners for high-speed Diesel engines, pins, valve guides, push-rod ends, rollers, valves and seats, plungers and bushings, and buttons for exhaust tappets.

5 In most cases manufacturers had been deterred from the use of nitrided materials due to lack of equipment for handling such work, the extra cost of material, nitriding, and machining, and in some cases it was felt that the additional cost was not justified as compared with the service obtained from these parts as now made.

One Diesel-engine manufacturer reported a rather unusual application of nitrided Nitralloy. The piston rod for one engine was the largest ever nitrided, 14 ft. long, $6^1/_4$ in. in diameter, and weighing approximately 1400 lb. After nitriding, it was found that the rod had warped only 0.020 in. in its entire length.

The outstanding use of Nitralloy in the Diesel-engine field will probably be its application to the details of the fuel-injection system, particularly to fuel-pump plungers and bushings, bypass valve stems and guides, distributor disks, and in fact any place where extreme precision is required and danger of scoring is invited by close operating clearances with absence of good lubrication facilities. Neither on test nor in service have examples of sticking or scoring been known to the author, though in test instances, parts have been fitted to less clearance than would be required for the purpose of causing scoring if possible, but without objectionable results.

Discussion

P. R. Letz.[2] It is gratifying that this paper outlines completely the present uses of nitrided Nitralloy and gives some possibilities of applications on the various parts of engines, but it is difficult to agree with several statements made in this paper.

While it is claimed that a nitrided Nitralloy possesses rustless properties to a decided degree its resistance to corrosion cannot be compared with stainless steels. Even the rustless properties are decreased very materially when the outer soft film, which is formed during the process of nitriding, is removed. In a series of tests carried out under the writer's supervision to determine the resistance to corrosion of various metals to hydrogen-sulphide gas, it was found that nitrided Nitralloy resists under the conditions of the test only slightly better than cast iron containing 12 per cent steel and not nearly as well as stainless steel. The losses of weight per square meter of area at the end of the 400-hr. test were: cast iron, 248 grams; nitrided nitralloy, 192.2 grams; and stainless steel, 24.8 grams.

Fatigue resisting properties of nitrided Nitralloy are illustrated in this paper by describing a test carried out by an automobile manufacturer. This test checks up closely with the tests conducted in the laboratories of the Cooper-Bessemer Corporation on the cantilever type fatigue-testing machine. Nitralloy G, $1^3/_8$ in. round, was used for the test. A series of fatigue and tensile test bars were made from this steel and tested before they were

[2] Chief Inspector, The Cooper-Bessemer Corp., Mt. Vernon, Ohio, and Grove City, Pa.

nitrided and after nitriding. Average results of tensile tests were as follows:

HEAT-TREATED TEST BARS BEFORE NITRIDING

Yield point	Tensile strength	Elong. in 2 in.	Red. of area
74,550	102,500	25.3	63.2

TENSILE TESTS FROM THE SAME STEEL AFTER NITRIDING

83,350	107,000	10.2	12.3

Fatigue Test. Under 75,000 lb. per sq. in. stress the heat-treated Nitralloy broke on the fatigue testing machine at 40,800 reversals. When the same stress was put on the nitrided test bar it did not break after 28,000,000 reversals. Only when 85,000 lb. per sq. in. stress was applied, the nitrided specimen broke at 1,000,411 reversals.

The explanation which is given in the paper for the increase in fatigue-resisting properties of nitrided Nitalloy is as follows:

"The reason for marked difference in results is that the long period during which the material is held at approximately 1000 deg. fahr. during the nitriding operation has a normalizing effect upon the core thoroughly relieving any internal stresses which would tend to start fatigue failures in service."

Not denying the importance of relieving the internal stresses by prolonged heat treatment, the writer cannot agree that this is the main reason for increasing fatigue-resisting properties of nitrided Nitralloy. It seems that a tremendous increase of strength in the nitrided case prevents the fatigue check from starting. The effect of stress concentration on the surface in the Nitralloy case is minimized due to the exceedingly dense structure of the case and freedom of defects, such as soft spots, etc.

A good many parts of the engine have been tried out of the nitrided Nitralloy by The Cooper-Bessemer Corp. In a few cases the cost was found to be prohibitive for adopting this material and in other cases several failures prevent the change from being made. These failures could be briefly summarized to two faults of nitrided Nitralloy: (1) Brittleness of the edges, and (2) soft core not capable of supporting a comparatively thin nitrided case under concentrated loads.

The new developments of the process make it possible to increase the toughness and prevent to a certain degree the chipping off of the edges on the nitrided case. However, very few things have been done in increasing the hardness of the core. As soon as this problem is worked out satisfactorily, nitrided parts could be used for such applications as roller and ball bearings, where the loads are concentrated to a great degree.

J. Barraja-Frauenfelder.[3] One of the slides shown was a piston rod of the Cooper-Bessemer Company. The writer is quite sure that the rod shown is one belonging to a two-cycle double-acting engine built experimentally for a company with which the writer is connected. This rod is approximately 4 ft. long and $5^3/_8$ in. in diameter; it is nitrided throughout and has been in operation about 1250 hr. at present.

In a double-acting engine four qualities in a piston rod are desired: resistance against the stuffing-box packing wear, against corrosion in the bore due to the circulating water, against heat in the combustion space, and against fatigue due to the rapidly alternating stresses. All of these four qualities are obtained with nitriding. The suggestion to use Nitralloy nitrided was accepted with some fear. The test results were fully up to expectations. The rod has now undergone over 28 million reversals of stresses without distress and it is planned to reach 40 millions before it is considered an unqualified success. The writer does not wish to imply that the Cooper-Bessemer Co. did not use a nitrided rod, but only to convey that the particular one shown on the slide was the writer's.

N. F. Hench.[4] If the surface of two nitrided parts working together become damaged, such as scoring from excessive friction, lack of lubrication, or from foreign matter working in between the finished parts, requiring re-surfacing by grinding or lapping in parts together, how deep into the surface can grinding or lapping be carried on without losing the value of the nitrided surface?

P. H. Schweitzer.[5] The nitriding process may revolutionize Diesel-engine design. The Diesel engine ten years from now will not only perform better and last longer, but will look different from the present-day engine. The new materials will suggest a change in the arrangement and shape of the constructional parts, and the design will gradually adjust itself to the new materials. The result will be better engines for less money. Think what one material, rubber, did to the automobile. When it was first introduced no one could have dreamed of the far-reaching consequences.

Nitrided steel may have a similarly far-reaching effect on machine design. It is entertaining to speculate on the near-by consequences of the nitriding process on Diesel-engine design, although the chances are that many of the guesses will prove to be wrong.

Practically all wear in machinery is caused by rubbing. Therefore, wherever possible, rubbing friction in machinery is avoided. Frequently one goes a long way to avoid rubbing friction. When it cannot be avoided lubricants are used to reduce the rubbing friction. Many hundred million dollars are spent in the United States yearly to reduce friction between machine parts. This is done partly to save energy, i.e., fuel necessary to overcome frictional resistance, but more so to reduce wear.

If the latter should become a minor consideration, the present economical equilibrium might be upset. The wear due to friction being negligible it might be economical to permit metallic surfaces to be negligible; it might be proper to simplify design and omit efforts to eliminate rubbing contact at the expense of a more complicated and more expensive construction.

For example, for cam followers the roller is standard except in inexpensive automobiles. Tappets or fixed shoes on rockers are simpler, lighter, and less expensive, but they wear quicker. The writer predicts that due to the nitrided steel the roller followers will entirely disappear, even on large Diesel engines, and nitrided shoes or tappets will take their place.

One of the most annoying things in large Diesel engines is cylinder wear, in small Diesels the erosion of the small nozzle orifices, and in both small and large sizes the wear of pump plungers. For nozzle orifices, for nozzle and fuel-pump plungers and sleeves the use of nitrided steel will become universal. With that material closer fits can be used and they will keep.

The use of nitrided-steel liners and eventually piston rings will make frequent dismantling of cylinders for maintenance superfluous. Then the accessibility of the parts will be a less important consideration. There may result a comeback of the integral heads.

Inserted nitrided-steel sleeves for valve guides will eventually be welded in place for better heat transmission. The use of soft bearing metals will decrease with the increased use of nitrided material for shafts. An unlined aluminum connecting rod on a nitrided crackshaft is an interesting possibility.

Nitrided steel may open up an entirely new road for development, that is, the use of higher compression ratios. The use of higher compression ratios like 18 or 20 instead of the conventional 14 or 15 has distinct possibilities, particularly for high-speed engines. The higher pressure and temperature are bound to reduce the ignition lag, which is a serious obstacle in speeding up the Diesel engine. The extra high compression ratios are, however, very hard on piston rings and liners. Progress in making these parts of nitrided steel may pave the way for the extra-high compression ratios.

L. F. Burger.[6] In using Nitralloy steel for cylinder liners some difficulty arises when the upper end of the liner is threaded in the holes for the spray nozzle. The work must be practically all done on these cylinder liners before the liner is nitrided. During this operation the threads must be protected in order to make them strong enough when put into use and at the same time have a good fit. In doing so, the question came up, what would be the best plan to protect these threads? A cast-iron ring was proposed. As the cast iron would stand the heat, this sleeve or ring would be screwed on to the Nitralloy sleeve and then the nitriding operation takes place. It was found that this works out fairly well, but not as good as one would wish, and it may be necessary to go back to the old system of tinning the threads. The writer would like to know what can be done in a condition of this kind.

In regard to the fuel-pump situation, the writer has had some experience with the fuel-pump plunger passing a hole in the barrel. The plunger passed the hole from $^1/_8$ in. to $^5/_{32}$ in. This seems to be fairly satisfactory, but after a while the pump leaks. Most of the leakage is at the point where the plunger passed the hole in the barrel. This wear was due to very poor oil which contained quite a lot of grit and erosive matter. Considerable erosive matter was removed in various places in the pump.

One would not expect that the pump would give long service with such poor oil. It is felt that there is going to be a great future for this material. In a short time all the new engines will be using Nitralloy steel nitride. Even with this high-grade steel, unless the oil companies produce a cleaner oil, the engine builders will still be at a handicap.

On the other hand, an engine operating on gasoline, which has run since early this spring, having an aluminum piston, Nitralloy sleeve, aluminum connecting rod, and a Nitralloy crankshaft, has been running practically all of the time, and up to the present has shown no wear that could be measured.

[6] International Harvester Co., Chicago, Ill.

Regarding engine sleeves made of Nitralloy steel, the writer cannot agree that this steel can be nitrided without changing its shape. For instance, with a $4^1/_2$-in. sleeve which had a true dimension of $4^1/_2$ in. before nitriding, it was necessary to regrind to 0.008 in. oversize, in order to have the sleeve round, and in doing so the hardness was reduced to 90 Shore.

C. H. Taylor.[7] What is the possibility or the practicability of using Nitralloy as two rubbing surfaces, the fully hardened surfaces working against each other? Is there any difference in the hardness required for the two surfaces? Can the highest hardness be used one against the other for relatively moving parts?

E. T. Larkin.[8] Replying to the ability of the nitrided surface to resist impact forces, and the strength as regards spalling or other surface failures, is there any tendency toward flaking?

C. Harold Berry.[9] Speaking not as a metallurgist but as one who has seen nitrided valve parts enter the steam-power field, the writer reports that nitriding seems to be the complete solution of valve difficulties due to scoring and tearing of seating surfaces. Two nitrided pieces that were rubbed together dry in a testing machine under a load of 200 lb. per sq. in. with a movement of 1 in. at the rate of 120 times per minute completed 100,000 back-and-forth movements with no sign whatever of the least effect on the surface. In plant service, large gate valves with nitrided disk and seat rings seem to give promise of standing up indefinitely.

The steam accumulator often proves effective in balancing variable steam supply and demand. The circumstances that are favorable to an accumulator are low pressure level, large pressure variation, and moderate quantity of steam to and from the accumulator. Whether the steam quantity is at a low rate for a long time or at a high rate for a short time is immaterial, for the size of the accumulator is determined by the total quantity of steam produced or absorbed, and the pressures at the beginning and end of the period. For high pressures, for small pressure variations, or for large steam quantities, the accumulator often proves too large and costly to be justified, but for more moderate requirements in one or more respects, its possibilities should not be overlooked. In operation it is wholly automatic and its maintenance should be negligible.

Economics of the Use of Diesel Engines for Electric Power Generation

By T. A. BURDICK,[1] FORT WORTH, TEXAS

A discussion of the application, merits, and economics of Diesel-engine generating plants for the production of electric energy for distribution and sale, together with unit, investment, and operating cost figures, and a complete tabulation of the results obtained in three different practical solutions of a specific problem.

IN CONSIDERING use of Diesel-electric generating units in the production of electric power for distribution and sale, the economic side of the situation is of probably the greatest concern to interested individuals. With this thought in mind, the author has assembled and is presenting tabulated figures of investment and operating costs which are representative of his experience to date. The figures presented therefore should be accepted merely on the basis of one man's experience in the southwestern section of the United States. It is felt, however, that with slight modification for variations in conditions which may be encountered in other localities, these figures may be accepted in the study of the production and distribution of electric energy in any section of the country. Unit figures will be subject to some little variation under different conditions peculiar to the specific location.

In presenting a solution for a typical problem which may be met in the electric-utility industry, the purpose is to present a method of attack in the consideration of such a problem rather than to indicate a correct solution. The great number of variable quantities and values involved makes possible many different solutions, some one of which will likely be the best in the specific case, but others of which may have considerable merit.

In certain fundamental respects the assumptions of the problem are incomplete, such as, for instance, an assumption in regard to the rate of increase of business of the town served. These facts have not been overlooked, but have merely been disregarded in order to relieve the problem of unnecessary complications.

Investment Costs

The cost of Diesel-electric plants of similar capacity will vary between rather wide limits with variation in local conditions affecting the design and other conditions affecting construction. It will also vary to a consiberable extent with the type of structure selected for the plant, and in case provision is made for installation of additional equipment at some later date, the cost may be increased quite materially. In Table 1 will be found estimated costs of 17 different Diesel-electric generating plants of representative design and varying in installed capacity from 117 kw. to 10,110 kw. The cost of the plant has been subdivided into five different accounts which were selected from the N.E.L.A. classification. Certain assumptions have to be made in the selection of equipment for the plants and in the selection of the type of structure. The designs on which these estimates are based and the cost of the installations are consistent with actual experience in the construction of many similar plants.

Plants one to six inclusive are equipped with two-cycle airless-injection engines; other plants have two-cycle and four-cycle air-injection engines. Plants one to five inclusive are

Notes:
1 Fifteen per cent overhead cost has been included in all figures.
2 Plants 1 to 6 inclusive are equipped with two-cycle airless-injection engines; others with two-cycle and four-cycle air-injection engines.
3 Plants 1 to 5 inclusive are equipped with an open-type jacket water-cooling system; others with a closed-type system and heat exchangers.
4 Plant structures 1 to 4 inclusive are wood frame covered with corrugated metal; structures 5 to 8 inclusive are steel frame with corrugated asbestos cover; structures 9 to 17 inclusive are steel frame, brick wall, and fire-resisting roof construction.
5 Power plant equipment has been separated into three accounts, each of which bears its proper proportion of installation, foundation, and overhead costs.

GENERAL NOTES

Poles are creosoted yellow pine and 80 per cent of them are figured as being the standard height indicated in the tabulation; 12 per cent are 5 ft. longer; 6 per cent are 10 ft. longer; and 2 per cent are 15 ft. longer.

Labor, material, construction equipment costs, general construction costs, and 15 per cent overheads are distributed in correct proportion to the various divisions of the cost tabulated.

Cost of survey, right of way easements, cost of securing right of way, crop and property damage have been included in "Land."

Aluminum conductor is provided with armor rods and clamps for each point of contact.

NOTE: No line sectionalizing switches included.

equipped with open-type jacket water-cooling systems, and others with closed-type systems and heat exchangers. Plants one to four inclusive are housed in wood-frame structures covered with corrugated metal; five to eight inclusive are housed in steel-frame structures with corrugated asbestos covering; nine to seventeen inclusive are housed in steel-frame structures with brick walls, fire-resisting roof construction, and modest exterior decorations. In general the structures have been made large enough to accommodate one additional generating unit. All of the engines have sea-level ratings; however, loss of power due to the increase in elevation will not be sufficient to affect the figures to any extent below 3500 ft. elevation.

Fifteen per cent overhead costs have been included in all figures, overhead being understood to cover administrative expense, cost of financing, engineering, superintendence, cost of purchasing and storing material, construction accounting, interest, and insurance during construction. Detailed estimates have been prepared on all of the plants listed, but it has not been found practicable to include the details in this paper. Cost of the various items of equipment is based on recent quotations, and the point of delivery selected is Texas.

In studying the cost of producing and distributing electric current, it becomes necessary to know the cost of transmission lines, transformer substations, and distribution systems. In Tables 2, 3, and 4 will be found outline data and estimated average costs of each of the above items. The cost figures submitted are based on finished designs and actual construction, and are representative of good practice in the southwest. Sufficient ground has been covered in these cost tabulations for selection of all facilities required in the solution of a problem to be discussed later.

OPERATING COSTS

The next item of interest after studying investment costs are costs of operation. In Table 5 there are presented representative operating and maintenance cost figures and unit economy figures for each of the Diesel-electric plants listed in Table 1. The figures presented are based on average good results obtained in the use of such plants in electric utility operation. No attempt has been made in this tabulation to show results other than those that can and have actually been obtained, and which under normal circumstances are representative of the various types of plants

listed. Fuel oil is of 18,500 B.t.u. heat content, and of gravity and viscosity best suited to the type of engine in which it is burned. Figures appearing in this tabulation will be used later in the solution of a problem to be discussed.

Under operating costs the matter of fixed charges on investment must be considered. For use in this paper a figure of 13½ per cent has been selected consisting of 6 per cent interest, 6 per cent depreciation, and 1½ per cent for insurance and taxes. This figure is applied to the total investment both in plant and distribution facilities and may therefore be considered an average figure.

In Tables 6 and 7 will be found representative costs of operation and maintenance of wood-pole transmission lines and electric distribution systems respectively. It is quite conceivable that there may be a wide difference of opinion as to whether these figures are sufficiently accurate to be called representative. There is found to be a very wide variation in cost, depending on many variable factors such as the extent of the system, climatic conditions, and price of labor. The figures presented in this tabulation have been selected, however, as representative of the average costs to be realized in a system of some magnitude and located in the southwestern section of the country.

Load Data

In studying the application of Diesel-electric plants to electric utility systems, it is necessary to have some knowledge of the characteristics of the loads to be served. In this paper consideration is being given to electric service in small and moderate-sized towns. The towns to be considered will run in population from

500 to 5000 and the number of electric connections will vary correspondingly from 100 to 1000. In Table 8 there is presented a typical classification of electric-system customers, together with a statement of the per cent of the total customers in each class in towns of various sizes. In towns of 100 and 150 connections, load is assumed to be single-phase while in larger towns it is three phase.

In Table 9 are shown representative figures of demand and consumption of all customers in each of the various classes and each of the various sizes of towns. These figures are brought to a total which is to indicate the customer demand and consumption in each of the towns. Representative figures of losses or unaccounted-for energy in distribution systems are also indicated in this tabulation; the losses being added to customer consumption to give a figure of total kw-hr. delivered into the local system. Additions to demand due to the system losses have also been computed and added to the customer demand figure after application of an average diversity factor of 1.25, to give an effective annual kilowatt-demand figure.

In distribution systems such as those considered, it has been found by analysis and calculation that the losses will be divided up about as follows: Transformer core loss 35 per cent, transformer copper loss 25 per cent, line loss 40 per cent. The transformer core-loss energy will have a load factor of 100 per cent and therefore the yearly maximum demand of this loss will be the kw-hr. yearly loss divided by 8760. On the assumption that the maximum load current is on the line 14.3 per cent of the time, $1/2$ of the maximum load current is on the line 28.5 per cent of the time, and $1/4$ of the maximum load current is on the line 57.2 per cent of the time, it is found that 57.2 per cent of the transformer copper and the line losses occurs during the period of maximum loads and therefore the yearly maximum de-

NOTES:

A diversity factor of 1.15 has been applied to the sum of the kw. demands of all towns to determine the combined town demand in solution "C."

The same diversity factor has been applied to the sum of the kw. demands of all outlying towns and the quotient added directly to the kw. demand of the central town of the group to determine the combined town demands in solution "B."

The same principles as above have been applied in solution "A." When the central town is large with respect to the outlying towns, the method used in solution "B" has been followed; and where the towns in a group are of about the same size, the method used in solution "C" has been followed.

mand of these losses will be the kw-hr. yearly loss divided by 2190.

Power-factor conditions in the systems vary to a certain extent, depending on the nature of the load. Representative conditions of power factor are shown in the tabulation, together with total kva.-demand figures for use in transmission calculations. It is interesting to note that, under the assumptions made, the yearly load factors of the towns vary from 15.5 per cent in a town of 100 connections to 37.5 per cent in a town of 1000 connections, and

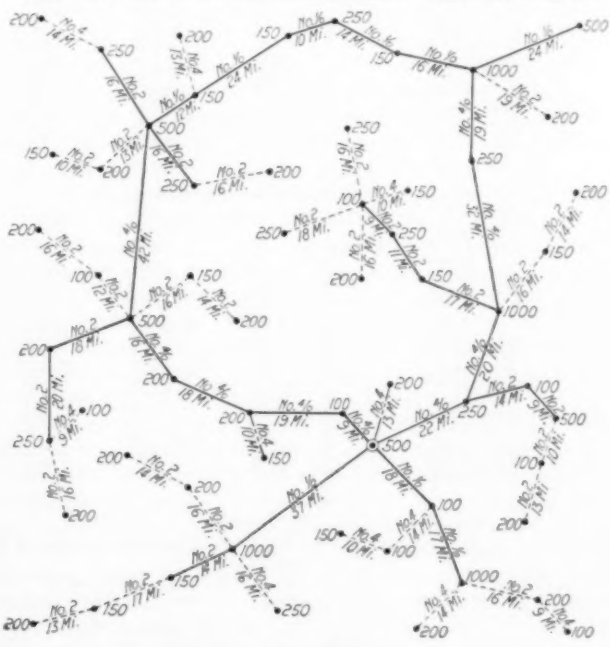

FIG. 3 FOR COMBINED SYSTEM WITH ONE PLANT

similarly the kva.-demand per connection varies from 0.27 kva. to 0.975 kva. These figures on load are presented as fairly representative of conditions to be found in the less thickly populated sections of the country, and will be used as a basis for the load assumptions in the specific problem to be presented.

Illustrative Problem

In order to give a concrete illustration of the probable investment and operating costs of a complete system for the production and distribution of electric energy with energy produced in Diesel plants, a certain problem has been selected and three solutions of the problem are presented herewith for comparison. The problem consists of producing and distributing energy to 15,700 customers in 60 different towns with the number of connections in

TABLE 12 COST OF TRANSMISSION SUBSTATIONS FOR EACH OF THREE SOLUTIONS OF PROBLEM PRESENTED

NOTE: Total energy delivered to consumers in each case is 19,674,290 kw-hr. per year. Cost of lubricating oil for plants numbers one to six inclusive, $0.45 per gallon; for other plants $0.50 per gallon.

the towns varying from 100 to 1000 and the towns located within an area of about 125 by 140 miles.

In solution "A" the towns to be served have been divided up into 21 different groups or individuals and are served with energy from 21 different plants. This may be called the individual plan system wherein a plant is installed in every sizable town and no attempt is made to transmit energy except in small quantities to adjacent towns.

In solution "B" the towns to be served have been divided into 6 separate groups, each one of which is served from a plant similarly located in the largest town within the group. This arrangement may be called the local group-plant system. In this system considerable use is made of transmission lines of intermediate voltage serving towns a considerable distance away from the generating plants.

In solution "C" a single plant has been installed and all towns have been interconnected by means of a transmission network system. Locations of property, plants, and transmission lines in each of the three arrangements are shown in Figs. 1, 2, and 3. All transmission lines and transmission substations have been designed with ample capacity to serve the loads indicated with voltage regulations at point of delivery within satisfactory limits. Present-day requirements in electric service are exacting to such a degree that a high standard of service is required both in regard to voltage regulation and continuity. The systems as laid out will be found to follow good engineering practice in fulfilling these requirements.

In Table 10 the results of calculations required for determination of the demand and amount of energy to be generated are shown in tabular form, and a certain plant, identified by a number which refers to Table 1, has been selected to serve each group. Load assumptions for the various customers are in accordance with data presented in Table 9. Determination of total kw-hr. to be generated and of the kw. demand on the plants involves calculations of line and transformer losses and the addition of energy used by plant auxiliaries. Loads in towns of 100 and 150 connections are single-phase, others are three-phase. The size plant required in each group is determined by the maximum kw. demand, and except in the very smallest plants, sufficient generating capacity has been provided to handle the maximum load with one generating unit out of service for repairs.

It is of interest to note that in solution "A" the total amount of energy lost in transmission and distribution is 13.1 per cent of that delivered from the plant. In solution "B" the percentage is 15.1 per cent and in solution "C" 17.6 per cent. This appears to work out in about the correct proportion found in actual operation. There will be a further loss occasioned by imperfect metering and theft of current which would raise the percentage to some little extent; however, no allowance is made in this paper for such losses.

In Tables 11 to 14 inclusive will be found tabulations of investment costs of transmission lines, transmission substations, transmission line sectionalizing and main control switches, and distribution systems for each of the three solutions. Unit-cost figures have been taken from data previously furnished in Tables 2, 3, and 4. All transmission lines have been indicated as being constructed of aluminum conductor, steel reinforced, on account of its lower cost than copper. Some slight variation in the costs of electric distribution systems for the three solutions will be found on account of changes in voltage for certain of the towns in the different group arrangements. In all instances where a step-down substation with 6600 volts or 6900 volts secondary is serving more than one town, the local distribution as well as that of other towns served has been built for 6600 volts operation, and in fact all towns served by transmission lines at 6600 volts are provided with 6600 volts distribution systems.

In Table 15 the total investment cost for each of the three solutions is summarized, and it is rather disconcerting to note that there is but slight variation of total costs in any of the three solutions. Solution "B" with the local group-plant arrangement is the least expensive with a total cost of $276 per connection, while solution "C" is the most expensive with a total cost of $297 per connection. The percentage of total investment, however, in each of the various parts of the system varies between wide limits. In solution "A" for instance, power plants constitute 56 per cent of the total investment, whereas in solution "C" they constitute only 27 per cent.

Final results of this study are embodied in annual operating-cost figures for each of the three solutions in Table 16. In this table all operating costs considered plus fixed charges on total investment have been brought together to a final figure and divided by the amount of energy delivered to the customers. In spite of the fact that plant production costs vary from 3.39 cents in the smallest plant to 0.44 cents per kw-hr. in the largest, the difference in final costs per kw-hr. delivered to customers in all solutions is rather close together. It can be pointed out that consideration has not been given to all expenses incident to operation of this group of properties inasmuch as no allowance has been made for superintendence and administrative expenses nor for meter reading, accounting, advertising, nor legal expenses. These items of expense have been purposely omitted, however, since they are not affected directly by the type of system installed. Although solution "C" shows a final figure of cost one mill lower than solution "B" there may be quite honest and well-supported differences in opinion as to which of these two solutions is the more desirable, weighing the relative hazards of transmission-line operation as against power-plant operation.

Conclusion

In conclusion it may be stated that nothing definite has been proved in regard to the use of Diesel plants. The purpose of this paper, however, has been to present representative investment and operating cost figures. If in solution "C" of the problem, a steam plant were used instead of a Diesel plant, there would likely be a slight difference in the cost per kw-hr. delivered provided the two plants used the same fuel. No doubt the steam plant could be built at considerably less cost than the Diesel plant with a resulting credit in fixed charges in the comparative operating cost statement. This credit, however, would be somewhat more than offset by the difference in cost of fuel and labor since the steam plant probably would not generate more than 7 kw-hr. per gallon of fuel and the number of plant employees would be greater.

There is a definitely established field for Diesel plants where the capacity of the plant is small, where water and cooling conditions are unfavorable for condensing turbine operation, where the site is relatively inaccessible or where space available is extremely limited. It is of more interest, however, to compare the Diesel plant with other types of plants for situations where none of the above conditions exists, strictly on a basis of operating and investment cost.

On such a basis and in cases where there is no cheaper fuel available than oil, it would appear that the Diesel plant is on par with any other type of plant, provided the engines used are of correct and satisfactory design and can be relied on for uninterrupted service when a proper maintenance schedule is followed. The success or failure of this type of prime mover, then, in the final analysis, depends on the manufacturers of the engines. Adequate engineering, suitable design, proper selection of materials, good workmanship, and a willingness to stand behind their product in operation as as well in sales promotion should establish a high and important position for Diesel engine in the power field.

Discussion

P. H. Schweitzer.[1] The paper is original, for the author does not compare the economics of Diesel oper tion with steam operation, which has been done so many times, but compares three different solutions to the problem of supplying a certain area with electricity, in all three solutions using Diesel engines for power generation. His figures and conclusions should be interesting to those who face problems of economical generation and distribution of power.

One surprising result of the author's analysis is that, in spite of the fact that plant production costs vary from 3.34 cents to 0.44 cents per kw-hr., the differences in final costs per kw-hr. delivered to customers in all solutions are rather close together.

The writer cannot help thinking, however, that the author's figures for small plants are too high and for large plants too low. Let a few items be taken in illustration: For a 120-hp. power plant the first cost is given as $33,114, or $283 per kilowatt of generating capacity. Most engineers will find this at least $100 too high. Mr. Edgar J. Kates estimated $160 per kw-hr. as the first cost of such an installation. On the other hand, the first cost of a 10,000-kw. power plant consisting of six 2400-hp. engines estimated at $122 per kilowatt sounds too optimistic.

The specific fuel consumption of a small engine is not 80 per cent greater than that of a large engine, as indicated in Table 5. The writer would suggest figures as 0.4 lb. per hp-hr. for the largest engines and 0.6 lb. per kw-hr. for the smallest. The difference is only 50 per cent in favor of the large engine and in practice is probably less.

Estimating the lubricating-oil economy as 500 kw-hr. per gal. is pessimistic enough, but the author expects only 215 kw-hr. per gal. of lubricating oil. Labor repair and maintenance costs as given are similarly somewhat discriminating against the small engine.

If one corrects for these items, the calculations of the author will show a decided preference for decentralized power, so far as Diesel engines are concerned. Solution A, employing 21 different plants, will come out economically superior to solution B and C, using 6 plants and 1 plant, respectively.

One solution of the problem was not touched upon, although it perhaps deserves consideration, and that is to use light interconnections for part or all of the base load supplied centrally and to generate part or all of the peak load locally in decentralized stations. The writer would like to know if the author gave thought to such a solution and what he thinks of it.

The adaptability of the Diesel for peak-load power generation is very clearly shown in the writer's article, "Diesel Engines for Peak Load," in *Electrical World*, Dec. 21 and 28, 1929. The figures of the author on transmission lines supplement these figures and strengthen the conclusions.

H. C. Thuerck.[2] The author has given completely and clearly a method to be used in solving the problems of power generation and distribution in territories that are comparatively sparsely populated. His paper indicates that he has gone to considerable length in order to obtain data for it. In using the information given in his treatise it should be kept in mind that these data were obtained in communities located in the South and Southwestern parts of the United States.

Author's Closure

Professor Schweitzer has raised several questions in regard to

[1] Associate Professor of Engineering Research, Pennsylvania State College Engineering Experimental Station, State College, Pa. Mem. A.S.M.E.

[2] Power Sales Manager, Associated Gas and Electric System, New York, N. Y. Assoc-Mem. A.S.M.E.

values and average economies reported. The first question raised is that of the cost of the Diesel plants, and the statement is made that a plant with one 60-hp. and one 120-hp. units installed should cost less than $22,000 instead of $33,114. Possibly this idea arises from the habit of thinking of costs in unit terms rather than by actual detail, and the unit cost figures in mind say that a Diesel plant should cost $160 per kw.

The plant, as estimated, is housed in a wood-frame structure with corrugated sheet-metal cover in which sufficient space has been allowed for installation of auxiliary equipment and a third unit, as well as for proper storage of plant supplies and spare parts. This building is priced at $3758, including 15 per cent overhead, and it has been erected on a lot worth $1000. Possibly the building could be erected for less money than this, but it is submitted that the margin of possible saving on this item cannot be very wide.

An item of $4777 has been included for auxiliary and accessory equipment. This item has been estimated at $3967 for material and $810 for labor and includes one 10,000-gal. fuel-oil storage tank of permanent and substantial construction; fuel-oil transfer pump, strainer and heater; two centrifugal jacket-water pumps; one cooling tower and basin; lubricating oil-storage tanks and filter; air, oil, water, and exhaust piping; one air compressor and storage tanks; foundations for all equipment included under this heading; necessary gages and thermometers; freight and handling charges.

Cost figures on the Diesel engines are based on recent quotations, and under the heading of engines there also are included freight charges, excavations, foundations, exhaust tunnels, air-intake conduits, air filters, labor of erection, and starting up.

The electric plant item consists of one 90-kva. and one 50-kva. generators, each direct-connected to their respective engines; two belt-driven exciters; one standard 2300-volt switchboard consisting of two generator panels and one feeder panel; station wiring; freight and handling charges, and labor of erection and installation.

There has been added 15 per cent overhead to all items in arriving at the total cost figure. This figure is more nearly a minimum cost than it is a maximum cost, since many refinements which might be necessary or desirable have been omitted on account of the small capacity of the plant. Refinements might consist of fireproof building construction, overhead crane, more real estate, grading and improvement of the site, sanitary plumbing, painting of building and equipment, multiple feeder circuits, underground construction for outgoing feeders, exhaust silencers, twin tanks for fuel-oil storage, closed jacket-water cooling system including heat exchangers, and lubricating-oil centrifuge.

It has further been stated that a plant equipped with six 2400-hp. units should cost more than $122 per kw. The plant as actually estimated includes all the refinements mentioned in the foregoing paragraph, and the only reason for exceeding the total cost figure given would be unusual or extraordinary expense met on account of difficulty of access to plant site, high price of real estate, necessity of building in cramped spaces, unfavorable labor conditions, freight and handling costs above average, excavations to be made in rock, and similar reasons. It is not felt therefore that the estimate is low when considering average conditions.

It should be readily appreciated that the cost of land, structures, electric plant, and auxiliaries and accessories per kilowatt or per horsepower of installed capacity will decrease quite rapidly as the size of the installation increases. Consequently, even though the cost of the engines per horsepower does not vary to any great extent, the overall cost of the complete plant per unit of installed capacity will decrease as size of plant increases. This point may be better appreciated by reference to the itemized cost of plants 1 and 17 tabulated as percentages of the total:

	Plant 1	Plant 17
Land	3.0	0.7
Structures	11.4	5.5
Engines	45.0	76.0
Electric plant	26.2	9.0
Auxiliaries and accessories	14.4	8.8

Referring to fuel and lubricating-oil economy as indicated in Table 5, there has been no discrimination against the small engine plant in favor of the large one. The figures presented are based on operating summaries maintained over a period of several years, in which the performance of 75 different units in 29 different plants is being tabulated. The figures presented are not specific economy at any particular load, but are representative of actual results obtained in the particular type and size of plant referred to. Load factors and plant-capacity factors of small plants such as Nos. 1 and 2 will average less than for larger plants due to the character of load which they are carrying. It should also be remembered that plants 1 to 6 inclusive are powered with two-cycle, solid-injection engines of the crankcase-scavenging type, and the specific economy of this type engine, both in regard to fuel and lubricants, is much below that of the type engines used in the larger plants. Fuel economy remains constant in plants 7 to 17 inclusive, and improvement in lubricating-oil economy from 800 kw. capacity to 10,000 kw. is indicated as only 18 per cent. In any case economies shown are those which have actually been experienced and which may reasonably be expected in similar installations.

Data presented in Table 16 will not support the contention that solution "A" of the problem is economically superior to solutions "B" and "C," and it is not thought that any advantage can be demonstrated for decentralized power. A case has been presented, however, for thorough and complete analysis of each individual problem of generation and distribution rather than to follow a predetermined and fixed policy in regard to such developments. In this particular case the difference of a half cent in final cost and charges per kilowatt-hour delivered to the customers between solutions "A" and "C" may represent all or more than the entire amount of the net profit in the operation of the properties.

In preparation of Table 16 fixed charges have been taken arbitrarily as 13½ per cent of the total investment. These charges may be detailed as follows:

Interest	7.50
Insurance	0.33
Taxes	0.67
Replacements	5.00
Total	13.50

Interest charges may be considered as constant for all of the individual parts which make up the fixed capital investment. Even though accounting procedure may treat the other elements of the fixed charges in the same way, there is an actual difference in depreciation, insurance, and taxes between the individual parts of the investment. In other words, in respect to fixed charges certain parts of the total investment are more desirable than others, and those parts are the ones on which insurance, taxes, and depreciation actually realized are a minimum. It can be readily appreciated that a dollar spent in construction of a building of fireproof design which will have a probable life of 50 years is better invested than one spent in construction of a wood-frame structure with a probable life of 20 years.

Fire and windstorm insurance rates are lower on plants of fireproof construction than they are on those of wood-frame or

TABLE 17 ANTICIPATED ACTUAL DEPRECIATION IN EACH OF THE THREE SOLUTIONS OF THE PROBLEM PRESENTED

Depreciation, rate, in per cent	Description	Solution "A" Investment	Solution "A" Annual depreciation	Solution "B" Investment	Solution "B" Annual depreciation	Solution "C" Investment	Solution "C" Annual depreciation
0	Power-plant land	$ 47,000	$	$ 24,000	$	$ 8,000	$ ....
5	Power-plant structures, wood frame	45,642	2,282	.....	....	.....	....
3	Power-plant structures, steel and asbestos	104,514	3,135	.....	....	.....	....
2	Power-plant structures, steel and brick	144,860	2,896	232,224	4,644	68,668	1,373
6	Engines	1,429,330	85,759	1,183,856	71,031	938,023	56,281
5	Electric plant	383,277	19,164	204,816	10,241	113,492	5,675
6	Auxiliaries and accessories	330,306	19,818	204,324	14,419	108,213	6,493
0	Transmission-line land	135,181	....	188,037	....	203,981	....
2	Transmission-line overhead conductors	206,900	4,138	460,086	9,202	1,033,935	20,679
5	Transmission-line poles, towers, and fixtures	317,600	15,880	480,924	24,046	567,362	28,368
5	Transmission substations	67,329	3,366	125,654	6,283	235,933	11,797
5	Transmission sectionalizing and control switches	8,769	438	15,117	756	58,717	2,936
5	Overhead distribution systems	1,188,250	59,413	1,181,800	59,090	1,179,150	58,958
	Total	$4,408,958	$216,289	$4,336,838	$199,712	$4,515,474	$192,560
	Average depreciation		4.9%		4.6%		4.25%

merely fire-resisting construction. As a consequence, insurance costs for solution "C," in which plant investment is only half that of solution "A" and in which fireproof construction has been used, will be lower than those for solution "A" by as much as 1 per cent of the total annual costs and charges. Insurance cost for solution "B" will be about half that for solution "A."

In the matter of taxes, experience has shown that plants will be assessed at a higher percentage of their actual value than lines will be. This fact works to the advantage of the centralized system in which the percentage of the total investment which has been spent on plants is much less than that for the decentralized system, and as a consequence the assessment for taxation will be much less in proportion. This may account for a difference of as much as 1 to 1½ per cent of the total annual costs and charges.

Taking up the matter of depreciation actually realized, Table 17 has been prepared in which the investment, under each of the three solutions, has been broken down into its component parts and representative straight-line depreciation rates have been applied to each part. The results speak for themselves and indicate decided advantages for the combined system over the local plant system by as much as 3 per cent of the total annual operating costs and charges.

Professor Schweitzer has suggested that a desirable solution might be arrived at by use of several interconnected plants, one of which is designed to carry a base load while the others are used only on the peaks. There would be advantages in such an arrangement, but in the case of the particular problem in hand no economic advantage can be shown for it. If, for example, solution "C" were modified to the extent of providing one base-load plant to handle about 4000-kw. load and two peak-load plants each to handle about 1400-kw. load, the base-load plant would be No. 15 and the peak-load plant No. 12. The cost of these three plants would be $219,572 more than that for the one No. 17 plant. Transmission-line investment avoided in this arrangement would amount to changing the conductor on 100 miles of 44-kv. line from No. 1/0 A.C.S.R. to No. 2 A.C.S.R. at a saving of $185 per mile and also a change of conductor on 197 miles of 44-kv. transmission line from No. 4/0 to No. 2 at a saving of $1061 per mile. The total saving in transmission-line costs would amount to $227,517, or about $8000 more than the additional cost of the generating plants. This means that from an investment standpoint practically no saving has been effected. From an operating standpoint, however, the original solution is to be preferred, since the difference in operating labor alone will amount to $10,000 a year.

Report on Oil-Engine Power Cost for 1929[1]

THIS REPORT contains information covering 36 oil-engine plants, which submitted data sufficiently complete to permit calculation of total power-production cost. Questionnaires were sent to 106 plants, and the replies to these questionnaires may be classified as follows:

	Plants
Complete data furnished, tabulated in this report	36
Insufficient data submitted	13
Unable to furnish data	9
Engines not operated	3
No engines installed	1
No replies to questionnaires	41
Reported under other serial numbers	3
Total number to which questionnaires were sent for 1929	106

Questionnaires were sent in 1929 to all plants which had submitted sufficiently complete data for the preceding period, which data were contained in last year's report. The method followed in the preceding report of identifying plants by numbers was retained in the present report, identical serial numbers shown in both reports representing the same plants.

Period Covered. Most of the data submitted refer to the calendar year 1929, though a few reports are based on other periods.

Output Represented. The total *net* output for the thirty-six plants listed in this report amounts to 134,766,761 kw-hr.

Questionnaire. The questionnaire sent to the various plants in 1929 differs in many respects from that which was sent out in the preceding year, principally in that it contained a number of additional questions.

Minimum Data Required. Although some of the plants were unable to supply information covering each and every question listed in the questionnaire, the data submitted by such plants were incorporated in this report provided the minimum required information was contained in their replies.

No attempt was made to differentiate between well-run and poorly run plants. Reference is made, however, in this report to the lowest cost charges for fuel oil, lubricating oil, attendance, and repairs for three groups of plants having rated capacities of 2000 b.hp. and over, 1000 to 2000 b.hp., and less than 1000 b.hp., respectively. Results obtained from all plants which were considered explicit, correct, and sufficiently complete to permit calculation of power cost are included in this report. That at least the following question of the questionnaire had to be answered was considered the criterion for listing plant data in this report. The numbers are the question numbers as appearing in the questionnaire, followed by the data required.

1 Name and address of plant
4 Period covered by data
6 Type: Two or four cycle, air or mechanical injection, vertical or horizontal
7 Rated power: B.hp. or kw.
8 Number of cylinders
9 Diameter of cylinders, in.
10 Stroke, in.
11 Rated revolutions per minute
13 Type of drive (i.e., direct-connected, belt, rope, etc.)
14 Driven unit (i.e., generator, pump, lineshaft, etc.)
17 Output of each engine during period, kw-hr.
18 Net output of entire plant during period, kw-hr.
22 Peak load on entire plant during period, kw.
26 Fuel oil: Total cost for period covered, number of gallons used by entire plant
27 Lubricating oil: Total cost for period covered, number of gallons used by entire plant
28 Attendance: Total cost for period covered
29 Supplies: Total cost of all supplies used in period covered
30 Repairs: Total repairs for entire plant in period covered.

Basis for Costs and Performances. Cost figures per power unit referred to in this report are based on net kw-hr.

The term "net kw-hr. output" as used in this report is defined as the difference between the total gross output in kw-hr. of the individual units of the plant and the power in kw-hr. required for plant auxiliaries and for station lights.

Figures of power output per gallon of fuel oil and of lubricating oil are based on the gross output of the individual units or plants.

Load and capacity factors are based on gross kw-hr. output.

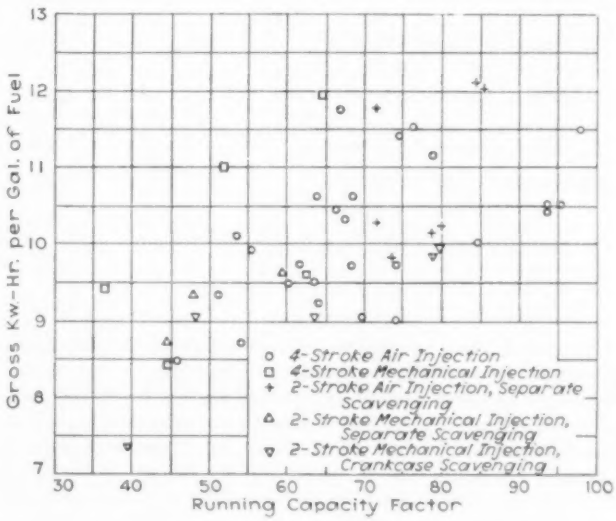

FIG. 1 FUEL ECONOMY OF DIESEL ENGINES
(This covers 37 individual units and 9 plant averages of 24 units.)

Formulas defining running engine capacity factor, running plant capacity factor, annual plant load factor, and plant service factor are as follows:

$$\text{Running engine capacity factor, per cent} = \frac{\text{Engine output in gross kw-hr.} \times 100}{\text{Kw. rating} \times \text{hours operated}}$$

$$\text{Running plant capacity factor, per cent} = \frac{\text{Plant output in gross kw-hr.} \times 100}{\text{Total rated kw-hr. of individual units}}$$

$$\text{Annual plant load factor, per cent} = \frac{\text{Plant output in gross kw-hr.} \times 100}{\text{Plant peak load in kw.} \times \text{hours in period}}$$

$$\text{Plant service factor, per cent} = \frac{\text{Total rated kw-hr. of individual units} \times 100}{\text{Total installed kw.} \times \text{hours in period}}$$

Kilowatt ratings given in the tabulation are those shown on the nameplates of the generators as reported by the operators, except in the case of plant No. 46, the generator nameplate ratings for which are evidently too low.

Answers to questions 1 to 14, inclusive, can be supplied readily by every oil-engine operator. Replies received to questions 1, 2, 3, and 5 were filed by the committee, but not published.

[1] Submitted by the Sub-Committee on Oil Engine Power Cost, Oil and Gas Power Division, A.S.M.E., Franz Eder, Chairman; Engineer, Robert W. Hunt Company, New York, N. Y.

Presented at the Third National Oil and Gas Power Meeting, State College, Pa., June 12 to 14, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Replies to questions 13 and 14 are not shown in the tabulation, all the data applying to direct-connected electric-generator units. All engines referred to in the tabulation of this report are of vertical construction.

The report incorporates information obtained in reply to questions 23, 24, and 25 pertaining to liner wear, piston cooling, and use of air filters. An attempt at drawing conclusions from this information has not yet been made at this time. These questions have been asked in the belief that the information obtained over a period of years may permit of conclusive interpretation.

Fuel-Oil Data. Questions contained in the 1929 questionnaire under heading "Fuel Oil" include those relating to the physical properties of the oil and are in line with the work of the A.S.M.E. Special Research Committee on Diesel Fuel-Oil Specifications. Although complete information on physical properties of the fuel oil has not been available in many cases, it is felt that the listing of these questions in the questionnaire serves to draw the operators' attention to the importance of these properties, and in view of its educational value a continuance of this policy is strongly recommended.

An analysis of the data submitted on fuel oil is as follows:

Prices paid for fuel oil:	Cents per gal.
Price range	2.15 to 6
Arithmetical average of prices	4.19
Weighted average of prices	4.18
Fuel-oil costs per net kw-hr.:	**Mills**
Arithmetical average of all plants	4.729
Weighted average of all plants	4.139
Lowest fuel-oil costs per kw-hr.:	**Mills**
a Plants of 2000 total b.hp. and over: Plant No. 92	2.199
b Plants of 1000 to 2000 total b.hp.: Plant No. 11	2.116
c Plants containing less than 1000 total b.hp.: Plant No. 99	2.683

The chart (Fig. 1) shows the fuel consumption for various types of engines expressed as the number of gross kilowatt-hours produced per gallon of fuel oil and plotted against the running capacity factor. The points plotted cover the individual engines in plants Nos. 2, 3, 10, 11, 13, 26, 43, 45, 46, 52, 67, and 68, and plant averages for plants Nos. 7, 24, 91, 92, 93, 94, 95, 97, and 102. Not included in this chart are corresponding data for plants for which only the plant average is available and which have engines of different types.

Lubricating Oil. An analysis of the data submitted on lubricating oil is as follows:

Prices paid for lubricating oil:	Cents per gal.
Price range	37.9 to 85.5
Arithmetical average of prices	52.1
Weighted average of prices	51.5
Lubricating-oil costs per net kw-hr.:	**Mills**
Arithmetical average of all plants	0.858
Weighted average of all plants	0.516
Lowest lubricating-oil costs per net kw-hr.:	**Mills**
a Plants of 2000 total b.hp. and over: Plant No. 45	0.092
b Plants of 1000 to 2000 total b.hp.: Plant No. 95	0.319
c Plants containing less than 1000 total b.hp.: Plant No. 99	0.413

It is interesting to note that plant No. 99 has not only the lowest fuel cost, but also the lowest lubricating-oil cost in its division.

Engine hours operated were reported by 29 of the 36 plants.

A summary of the data submitted by these 29 plants is given in the following list:

Total installed b.hp. (rated)	57,995
Total installed kw. (rated)	40,176
Total rated hp-hr. operated	276,151,590
Total gross kw-hr. produced	130,490,331
Total gallons of lubricating oil used	123,214
Rated hp-hr. per gal. of lubricating oil:	
Arithmetical average	2,400
Weighted average	2,242
Gross kw-hr. per gal. of lubricating oil:	
Arithmetical average	1,093
Weighted average	1,058

The average operating time for the engines of these 29 plants was 4760 hr., which corresponds to a weighted average running capacity factor of 68.3 per cent.

The data given in Table 1 are rearranged below according to engine types:

Plant and engine	Rated b.hp.	Rated b.hp-hr. per gal. of lubricating oil	Running capacity factor	Kw-hr. per gal. of lubricating oil	Lubricating oil purification[a]
Four-Stroke Cycle, Air Injection, Crosshead					
43-e	1000	1238	60.2	522	BC,S&C
43-f	1000	1178	63.7	525	BC,S&C

[a] For key see notes at foot of Table 1.

Plants containing some semi-Diesel power are not included in this tabulation, although they furnished information which permits the calculation of plant rated horsepower-hours per gallon.

Nor are any plants included the results for which are averaged for several different types of Diesel engines. Engine No. 68-e was not included because of the high ratio of the amount of initial filling of the crankcase to the oil used.

The questionnaire did not cover the filtering of lubricating oil, and it may be assumed that oil was filtered where the tabulations do not indicate any purification of lubricating oil.

Table 1 - Information Covering Lubricating Oil

NOTES:

* A - Air
M - Mechanical

** S - Separate
C.C. - Crank Case
(For 2 - Stroke Cycle Only

*** C.C. - Continuous Centrifuging
B.C. - Batch
S - Settling
C - Chemical

1 - Semi-Diesel.
2 - K.W. Rating Assumed; Name plate Ratings are 700 and 1,300.
3 - Includes 500 gallons Initial Filling.
4 - May 10, 1929.
5 - January, 1929.
6 - July, 1929.

The remarkable lubricating-oil economy obtained in the case of plant No. 45 deserves particular mention. When the committee questioned the figures, this operator was able to furnish written proof from his oil company as to the total amount of oil used and gave in addition a plausible explanation for the differences in economy as shown by the various units. Engines 45a and 45b are of trunk-piston construction, whereas engines 45c, 45d, and 45e are crosshead type. Engine 45c has two oil leads per cylinder, set 180 deg. apart, and is equipped with plain piston rings. Engines 45d and 45e have each four oil leads per cylinder, spaced 90 deg. apart, and are equipped with special patented piston rings.

Attendance. The questionnaire used this year called for the total cost of the attendance per period, the number of men per shift, and the number of shifts per day. The individual plants were asked for additional information relative to the cost of superintendence chargeable to the production cost, and this cost for superintendence is included in the attendance cost for every plant.

In next year's questionnaire this point will be brought out more clearly.

The greatest horsepower in charge of one man per shift is 3450, which obtains in the case of plant No. 91. The summary of attendance and superintendence cost is as follows:

Cost per net kw-hr.:	Mills
Arithmetical average of all plants	4.228
Weighted average of all plants	2.031

Notes:
1 - Includes Management
2 - Building Repairs not Included
3 - Supplies Included in Repairs
4 - Includes Cost of Water Treatment, Supplies and Repairs

Lowest cost per net kw-hr.:	Mills
Plants containing 2000 b.hp. and over:	
Plant No. 43	0.601
Plants containing 1000 to 2000 total b.hp.:	
Plant No. 94	1.925
Plants of less than 1000 total b.hp.:	
Plant No. 67	1.602

Supplies and Repairs. A total of 34 plants presented data which allowed segregation of the total supplies from the total repairs. For these 34 plants the supplies totaled 23 per cent of the supplies plus repairs, and the repairs totaled 77 per cent. There were 28 plants that fully segregated their costs under supplies, and it is found from these totals that the cost of water accounted for 27.5 per cent of the total supplies, the cost of water treatment for 0.7 per cent, and the cost of miscellaneous supplies for 71.8 per cent. There were 20 plants that furnished figures in which the repairs were completely segregated. For these 20 plants the cost of repairs on account of regular upkeep amounted to 47.4 per cent, the cost of repairs on account of accidents to 36.5 per cent, the cost of betterments to 2.7 per cent, and the cost of repairs to auxiliaries, electrical equipment, and buildings to 13.4 per cent of the total repairs.

If it is assumed that the various ratios outlined in the foregoing apply to the entire list of 36 plants, the weighted average costs of supplies and repairs, or 1.449 mills per net kw-hr., can be considered as made up from the following items:

	Mills
Cost of water	0.092
Cost of water treatment	0.002
Cost of miscellaneous supplies	0.239
Cost of regular upkeep repairs	0.529
Cost of accident repairs	0.407
Cost of betterments	0.031
Cost of repairs to auxiliaries, electrical equipment, and buildings	0.149

Inasmuch as these segregations have been arrived at by totaling actual costs, they are applicable only to weighted averages.

A summary of supply and repair costs follows. These costs represent the total of the cost of water and the cost of other supplies and repairs.

Cost per net kw-hr.:	Mills
Arithmetical average all plants	2.444
Weighted average all plants	1.449

Lowest repair and supply cost:	Mills
Plants of 2000 total b.hp. and over:	
Plant No. 2	0.472
Plants of 1000 to 2000 total b.hp.:	
Plant No. 10	0.456
Plants of less than 1000 total b.hp.:	
Plant No. 67	0.246

This year's questionnaire provided no space for listing repairs to plant auxiliaries, electrical equipment, and building. All of the plants listed, however, were requested to supply this information, and the total repairs in Table 4 include repairs to plant auxiliaries, electrical equipment, and buildings. Questionnaires to be sent out in the future will specifically require this information.

The various water-cooling systems are indicated by the following symbols:

System A, raw water going to waste after one pass
System B, raw water recirculated after passing over cooling tower or spray pond
System C, soft water continuously recirculated, cooled by raw water going to waste after one pass through heat exchanger
System D, soft water continuously recirculated, cooled by raw water also recirculated after cooling by cooling tower or spray pond
System E, any of the foregoing systems with engine circulating water treated.

Total Production Costs. The figures on total production costs can be summarized as follows:

Cost per net kw-hr.:	Mills
Arithmetical average of all plants	12.259
Weighted average of all plants	8.135

Lowest production cost per net kw-hr.:	Mills
Plants of 2000 total b.hp. and over:	
Plant No. 2	4.828
Plants of 1000 to 2000 total b.hp.:	
Plant No. 94	6.109
Plants of less than 1000 total b.hp.:	
Plant No. 99	7.359

Fixed charges. The following list contains the information received covering fixed charges:

Annual plant load factor, per cent (to nearest 5 per cent)	Percentages allowed for: Depreciation	Interest	Insurance-Tax	Misc.	Cost per net kw-hr., mills
Plants of 2000 total b.hp. and over					
85	4.0	4.5	1.0	0	2.078
35	3.41	5.02	0.32	1.56	7.800
30	5.0	4.15	0	0	6.435
Plants of 1000 to 2000 total b.hp.					
35	5.0	5.5	0	0	2.324

15	6.67	0	0	0	6.353

[a] Equipment. [b] Building.

The committee wishes to take this opportunity to thank the various oil-engine owners and operators who cooperated with it in this study. The data furnished were generally of a high degree of accuracy, and full credit is due to those who devoted time and effort to collect and supply this information.

Discussion

H. C. Thuerk.[2] The report submitted this year represents a very fine piece of work and includes a great deal of detailed information. The percentage of complete questionnaires received is relatively high and indicates that the committee is receiving cooperation from many Diesel-plant operators.

The data are well summarized, although the writer questions very seriously the advisability of stating weighted averages, as such values do not convey a correct picture of actual results. This is evident when it is realized that the output of three of the plants represents 47.3 per cent of the total output of the 36 plants included in the summary in Table 4. These three plants also operate at comparatively high load factors. Just what does this weighted average mean and of what value is it in connection with this cost investigation?

In this connection it should be pointed out that, under "Summary on Lubricating Oil Consumption," there is given a weighted average of 2,242 rated hp-hr. per gal. of lubricating oil. There are 21 of the 29 plants that have lubricating-oil consumption in excess of this quantity. The median value of lubricating-oil

[2] The J. G. White Management Corp., New York City. Assoc. Mem. A.S.M.E.

consumption for the 29 plants is 1669 rated hp-hr. per gal., or 814 gross kw-hr. per gal.

Under "Attendance Labor" a weighted average is given of 2.031 mills per kw-hr.; yet 28 plants out of the 36 have values higher than this. The median value for the 36 plants is 3.44 mills per kw-hr. In this connection it is interesting to note that this value checks very closely with the median value of 3.84 mills per kw-hr. for 22 plants listed in the 1929 report of the General Power Committee of the N.E.L.A.

Under "Total Production Cost" a weighted average is given of 8.135 mills per kw-hr. There are 26 of the 36 plants that have total production costs in excess of this value. The median value for these plants is 10.534 mills per kw-hr.

In several instances reference is made to the lowest or best results obtained for the various items. Since it is the objective of the Cost Committee to present a broad summary of these results, would it not be advisable to state the high and low limit of each of these items?

Since maintenance costs are based on the net output of the plants, would it not be more consistent to express fuel-oil and lubricating-oil consumptions on the same basis? In this connection it might be of interest to know that the statistics reported by the National Electric Light Association on power-plant generation are all based on the net output.

It is difficult to make use of the data given on "Fixed Charges" because the plants listed there are not identified with the plants listed in Table 4. It would also be of considerable value to know the total investment in each of these plants. Would it not be advisable to include this investment item on the questionnaire used to record the data for 1930?

It is also of help in using data such as are contained in this report, if it is known just what use is being made of the plant. In other words, it would be desirable to classify the plants so as to show whether they are municipal plants, private utility plants, or industrial plants. The General Power Committee of N.E.L.A. has reached this same conclusion and will use such a classification in its next year's report.

From the information given under "Fixed Charges" it is apparent that practically all of these plants are municipally owned. It would be of interest to know why two of the plants report no interest charges on their investment.

In comparing this year's report with the report submitted by the committee in 1929, it is noted that 14 of the 27 plants in the 1929 report are not included in the 1930 report. It is unfortunate that it was not possible to obtain another year's record on these 14 plants.

If the data on these 14 plants of the 1929 report are included with the data on the 36 plants recorded in this year's report, the following median values are obtained:

	Mills per kw-hr.
Fuel oil	4.85
Lubricating oil	0.625
Attendance labor	3.829
Maintenance	1.137
Supplies	0.430
Total operating cost	10.871
Median of totals	12.125

The 1930 report includes another year's data on 13 plants listed in the 1929 report. It would add materially to the value of the present report if a table had been included giving the operating results of these 13 plants over the two-year period. The writer would like to suggest that, in subsequent reports, two tables be published, one giving the current year's operating data and the other giving the accumulative data for as many years as possible. The latter table would give a much better picture of average costs to be obtained in a Diesel power plant, as it is well known that many of the items of cost, particularly the maintenance cost, do not reach stable values until several years after the plant has been placed in operation.

In the 1930 report the arithmetical average of the total operating costs for the 13 plants reported in both reports shows an increase of 6.2 per cent over the same value in the 1929 report.

E. W. Hammond.[3] This excellent report, prepared only with the greatest of effort, is of special value in the study of operating costs for Diesel plants. The report does deal slightly on fixed charges which need consideration when calculating the total cost of producing power. Since there is no common bases established for figuring these charges, nor does the cost of equipment remain fixed over a period of years, the committee has wisely refrained from dealing at length on this item. When fixed charges are to be considered, it is necessary to show the detail of the individual charges made, preferably expressed in percentage figures, as well as totals, and the cost of the plant, segregating equipment and plant buildings so that comparison of one plant can easily be made with another plant on a common base. In the plant installed in 1915 the Diesel cost was approximately $120 per hp. as against a cost of $60 per hp. for the Diesel installed in 1929. It is obviously unfair, therefore, when considering fixed charges, to compare the exact size of plant installed in 1915 with that of a plant installed in 1929 without making proper correction for the difference in costs of plants. It would seem inadvisable, therefore, to attempt to include any data on fixed charges in the next report, as a questionnaire to obtain this data completely would necessarily be lengthy, and the real value of the report is to show actual operating performance. Fixed charges for any new plant are easily computed where required.

We hope this report will continue to be an annual paper covering the operating cost of Diesel plants, for the data are invaluable to both the user and the manufacturer of Diesels.

Edgar J. Kates.[4] This is an exceedingly creditable report and compares favorably with previous reports on oil-engine power costs compiled by the A.S.M.E. and other organizations. The report discloses, for each plant, many more items of information than usual, and this greatly facilitates making cost comparisons between some specific plant in the report and some other plant in which the reader is interested, whether it be already in operation or merely in prospect.

It seems that for the present, and for some time to come, this sort of comparison will be the most useful application of such reports. In other words, when one desires to judge the performance of an existing oil-engine power plant or to estimate the operating cost of a projected plant, he will locate in the report several plants of approximately the same size, the same load factor, and the same operating conditions as the one in which he is interested, and from these similar plants he will select for his standard of performance the one which shows the best results.

In the case of fuel and lubricating oil such specific comparisons can readily be made, inasmuch as the report includes the cost per gallon of these commodities, thus enabling adjustment to be made for different prices. When one knows the kilowatt-hours per gallon of fuel and the rated horsepower-hours per gallon of lubricating oil, it is easy to compute the fuel and lubricating costs for whatever unit prices may apply.

Likewise the usefulness of the report would have been increased if, also, some attempt had been made to report attendance cost on a unit basis. Wage scales vary widely, and some such figures as

[3] Sales Division, Buffalo Works, Worthington Pump and Machinery Corporation, Buffalo, N. Y.

[4] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

"average wage per hour" or "rated horsepower-hours per man-hour" would have facilitated comparisons.

As for maintenance costs, it is well understood that for any one engine the maintenance cost varies considerably from year to year, and consequently it is necessary to obtain the maintenance cost over a period of at least five years to obtain a fair average. It is presumably the intention of the committee, when compiling future reports, to include maintenance costs for previous years so that trustworthy averages will finally result.

Attempts have been made to draw conclusions from this and similar reports as to the *average* cost of operating different types of oil engines. Such attempts are, however, quite unsound because of the small number of plants included in the report and the vital influence of variations in load factor and in the price of fuel, lubricating oil, and attendance. Averages computed on the basis of the amount of data now available may be worse than meaningless—they may be quite misleading. When a great deal more data shall have come to hand, some worth-while conclusions based on averages will be possible through careful selection, but at the present time averages mean less than nothing.

A. E. Flowers.[5] The committee is to be congratulated upon the large amount of data obtained and the very complete tabulation already made and presented in such manner that it may be subjected to further analysis whenever desirable.

It is noted that considerable information is given in regard to the characteristics of the fuel oil used, which will be very useful to the Research and Standardization Committees on Diesel Fuel Oil.

There is given complete information in regard to the engine and lubricating oil consumption and its cost, but no information at all in regard to the characteristics of the lubricating oil. If it is possible to do so, the present information should be supplemented by data upon the viscosity, carbon residue, and sulphur in the lubricating oil and the symbols used for describing, in the tabulation, the method for lubricating-oil treatment clarified further, as there is some chance of confusion between the use of similar symbols for centrifuging and chemical treatment.

R. C. Paul.[6] The thought of the writer is that although some of the methods of calculation could be questioned and perhaps the individual items could be figured in different ways than that shown in the paper, the results clearly show that the cost of producing power was slightly over 14 mills per kw-hr., which is an item which should be interesting to all Diesel-engine men and interesting to producers of power.

Committee's Closure

To Mr. Thuerk: Mr. Thuerk will recall that last year's cost report presented only weighted averages. Due to some extent to his helpful criticism at that time, the committee decided to present, not only weighted averages, but arithmetical averages. The committee feels that the comparison of the two averages has a meaning for those who can see it. For instance, the weighted average fuel oil price of 4.18 cents per gallon compared with the arithmetical average of 4.19 cents tells at once that, so long as fuel oil is bought in tank cars, the small plant can buy as cheaply as the large one. On the other hand, the comparison of the weighted average attendance cost of 2.031 mills with the arithmetical average of 4.228 mills illustrates one advantage of the large plant quite forcibly.

The committee realizes that men not informed along engineering lines may be more misled than helped by averages. However, since this report is made to engineers, this consideration was waved aside. The committee is not decided upon the utility of this "median" value cited by Mr. Thuerk. Possibly it is much valued by statisticians. Certainly its use by engineers is not so extensive. It is probable that the committee should stop reporting averages altogether rather than attempt to add yet another brand (and perhaps more, if some one discovers them) with the alternative of an argument from the party whose thesis is damaged when one kind of average is discontinued.

In regard to publishing the high limits of costs as well as the low in the summary, the committee cannot agree that these high limits are of interest. The technical press has never considered inefficiency as news although efficiency always has been news. Any one can establish a new "high cost" record; not every one is able to break a "low cost" record.

In respect to a net kilowatt-hour basis for fuel and lubricating-oil consumption figures, the committee agrees with Mr. Thuerk that it might be more consistent to adopt this. However, this basis would restrict the tabulated results to plant averages (weighted), a situation which Mr. Thuerk should not prefer to actual data for individual units, for which only the gross output is known.

The information on fixed charges is fragmentary and should either be improved next year or discontinued. The committee feels that the proper course would be to list total investments as Mr. Thuerk suggests, where obtainable, and leave the selection of percentages to others. Since the primary aim was to arrive at the facts on production cost, the fixed charge information was not followed up as closely as it could have been, time permitting. Possibly some better plan can be worked out for next year's program. The committee also agrees that a classification of plants according to use would be of interest and shall devote some future attention to this matter.

The absence of information for some of the plants reporting last year is accounted for in the text of the report—either these plants made no report or submitted inconclusive data. The committee did not rule any one out on any other grounds. Possibly some of these plants were embarrassed by the more formidable questionnaire form.

The basis of the figures having been slightly changed this year from last, the committee felt that no useful purpose would be served by a direct comparison of last year's figures with this year's. Cost figures have been reduced to the net output basis instead of the gross, for instance, and maintenance figures include costs for the entire plant instead of for engines only. This change of basis may account for the increase in average cost noted by Mr. Thuerk.

To Mr. Hammond: As stated, probably the only fixed charge information we should attempt to collect is the total investment. Since the age of the plant is already an item called for, due allowance could be made for the date of installation.

To Mr. Kates: Some of the figures suggested by Mr. Kates are available from the report. Rated horsepower-hours per man-hour can be arrived at from Table 3, which lists the number of shifts and the attendants per shift. It is true that the hours per shift are not listed. However, all three-shift plants are 24-hr. plants, and there are only several that are not three-shift plants.

To Dr. Flowers: The committee realized when the questionnaire was framed that the lubricating-oil information requested was not complete. However, the danger of complicating the form with questions the average operator cannot answer was considered quite great enough as it was. Most operators know nothing about their lubricating oil except the name of the brand. If Dr. Flowers can recommend simple and concise questions

[5] Engineer in Charge of Development, De Laval Separator Co. Poughkeepsie, N. Y. Mem. A.S.M.E.

[6] McIntosh & Seymour Corporation, Auburn, N. Y. Assoc. Mem. A.S.M.E.

when the questionnaire is revised, we shall be glad to include them, however. We do not believe the information received will repay the effort, at least for the first year, but the innovation should have a definite educational value in that the operator's attention would be directed to the properties called for.

The symbols used in the text to describe lubricating oil treatment are explained at the bottom of Table 1. Those replying to the questionnaire were not in danger of becoming confused, for the reason that these symbols were not used on the form and were adopted in the report as a space-saving move only.

OGP-52-12

Purification of Diesel-Engine Lubricating Oil

By A. E. FLOWERS[1] and M. A. DIETRICH,[2] POUGHKEEPSIE, N. Y.

The paper is a continuation of earlier research on a 10 by 12 Diesel engine. Its most important novelty appears to be a reference to avoiding dilution of the lubricating oil from mechanical leakage, an explicit statement upon this subject being contained in the paper. Deterioration of the lubricating oil and its increasing contamination with various substances not originally present are again shown as a function of operating power, and emphasis is placed on the large percentage of products resulting from cracking. It is not stated, however, whether the cracking products are traceable to the fuel or to the lubricating oil.

IN a previous paper[3] the authors presented the effects of 1300 hours' operation on the lubricating oil of a Diesel-electric locomotive. This paper presents further results obtained during a 2300-hr. test run (16 weeks) on the same Diesel-electric locomotive equipped with a disk-type purifier operating continuously on a by-passed portion of the oil in circulation through the bearings and crankcase.

Samples of the oil were taken weekly from the purifier outlet and from the crankcase of the engine. These, together with the total quantity of sludge removed from the bowl of the purifier, were sent to the DeLaval Process Laboratory for examination.

Lubricating-Oil Data

Dilution. In all previous test runs dilution of the lubricating oil with fuel oil necessitated early removal of the oil. In this run, following some mechanical adjustments on the engine, no fuel dilution occurred during the 2300 hours of test, indicating that, in general, fuel dilution of the lubricating oil in Diesel engines is not a factor inherent in the engine and occurs only because of some accident or some improper mechanical adjustment.

Oil Condition. The condition of the lubricating oil after stated intervals of service was found to be as indicated in the following table:

	New oil	Hours of service 1000 hr.	2000 hr.	2300 hr.
Sediment (by volume), per cent	Trace	0.70	1.00	....
Ash (by weight), per cent	None	0.015	0.019	0.020
Specific gravity at 60 deg. fahr.	0.896	0.899	0.897	0.897
Flash point, deg. fahr.	445	410	380	385
Fire point, deg. fahr.	500	495	455	450
Pour point, deg. fahr.	30	35	30	35
Viscosity at 100 deg. fahr., Saybolt universal seconds	554	622	548	519
Neutralization number	0.01	0.86	0.47	0.83
Conradson carbon residue	0.65	1.19	1.05	0.97

Sediment. The per cent sediment in the oil rose fairly rapidly to 0.70 per cent by volume at the end of 600 hr. It remained constant at this value until 1300 hr. of service had been reached. The value then rose very gradually to 1.2 per cent by volume at the end of the test. For *this oil* it appears that an equilibrium value between the rate of sediment formation and the rate of its removal either does not exist or is not reached until after a much more prolonged service period. In other tests of this kind equilibrium values have been reached, and there seems no reason to doubt that further tests will reveal an equilibrium condition.

Ash. The per cent of ash in the oil remained between approximately 0.01 and 0.02 per cent by weight throughout the test.

Neutralization Number. The neutralization value of the oil during service showed very marked fluctuations. No good reasons can be given at present for this fluctuation.

Carbon Residue. The Conradson carbon residue of the oil rose to a value of approximately 1.00 per cent at the end of 1140 hr. and stabilized at this value (within reasonable variations) for the remainder of the test.

Cracking and Oxidation. The major changes which the lubricating oil showed in service are similar to those caused by "cracking" and by oxidation of the oil. Analyses of the oil and sludge indicate that "cracking" plays a greater part in the oil deterioration than oxidation. The changes which occur in the oil are not greater than would normally be expected under the operating conditions to which the oil is subjected. The per cent of oxidized, asphaltic, resinous material dissolved in the oil, as measured by precipitation with normal benzine, was very low and showed no appreciable increase between 1000 and 2300 hr. of service.

Engine and Purifier Operating Data

The lubricating-oil requirements of the engine during this 2300-hr. period were:

Make-up oil required per 100-hr. operation, gal.	2.00
Total oil consumption per 100-hr. operation, gal.	4.35

A summary of the data on the operation of the disk-type purifier is as follows:

Average time of run between bowl cleanings, hr.	77
Average quantity of oily sludge removed per bowl cleaning, grams	344
Mean rate of sludge removal per 100-hr. engine operation, grams	455 (400 cc.)
Mean rate of *dry weight* sludge removal per 100-hr. engine operation, grams	200

Engine Condition. This run was brought to a close because of mechanical failure of connecting-rod bearing No. 3. Some of the oil-feed passages were found partially clogged by deposits along the walls, which may have occurred during this or earlier runs made without oil purification. The bright parts of the

---

[1] Engineer in Charge of Development, DeLaval Separator Company. Mem. A.S.M.E. Dr. Flowers received his M.E. from Cornell University in 1902, his M.M.E. in 1914 and his Ph.D. in 1915. From 1904 to 1912 he served as instructor and assistant professor of electrical engineering at the University of Missouri, and later held the chair of electrical engineering at Ohio State University. During the War he held the commission of captain in the Signal Corps of the Army and afterward was connected with the engineering department of the National Aniline & Chemical Co. and the Chemical Machinery Construction Co. He has been associated with his present concern since 1923.

[2] Process Chemist in Charge of Process Laboratory, DeLaval Separator Company. Mr. Dietrich received the degree of A.B. in 1921 from Oberlin College and in 1924 his A.M., the following year receiving an A.M. from Princeton University. Since his graduation he has been associated with his present firm.

[3] "Service Characteristics of Diesel Engine Lubricating Oil," presented at the Annual Meeting of The American Society of Mechanical Engineers, December 2 to 6, 1929, New York, N. Y.

Presented at the National Oil and Gas Power Meeting, State College, Pa., June 12 to 14, 1930.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

crankcase sides were covered with a thin black coat. This suggests that there may be a tendency for some of the cracked or oxidized residues to deposit on walls or upon oil passages, and special tests upon this point are to be carried out immediately. Deposits of this nature are not *necessarily* to be expected, as some Diesel engines have been found after a year's operation with crankcase walls and finished surfaces of running parts as bright and clean as new, when equipped with disk-type purifiers on the lubricating-oil system.

Wear. Measurements of clearances of the bearings at the end of the test (2300 hr.) showed no measurable changes in the main bearings. Measurements of clearances on the connecting-rod bearings at the beginning and end of the test are as follows:

Bearing No.	Clearance, in inches, at Start of test	2000 hr.	2300 hr.
1	0.005	0.006	0.008
2	0.005	0.006	0.007
3	0.005	0.006	Gone
4	0.005	0.006	0.006
5	0.005	0.005	0.006
6	0.005	0.006	0.007

These values compare very favorably with the average wear of 0.001 in. per month (or about 700-hr. operation) before using the disk purifier.

Purification Rate. The purified-oil throughput was about 15 per cent of the oil circulated to the bearings, and this rate was sufficient to purify an amount equal to the content of the crankcase about every 5 hours.

Data on Sludge Analysis

Sludge Particles. The curves for rate of removal of sludge and carbonaceous material per 100-hr. operation pass through several maxima and minima. This indicates that the "carbon" particles gradually grow in size or agglomerate until they reach a size where they can be removed by the purifier, following which the process is repeated. After each such cycle of agglomeration it appears so far that the particles left in the oil are finer than those present during the preceding cycle.

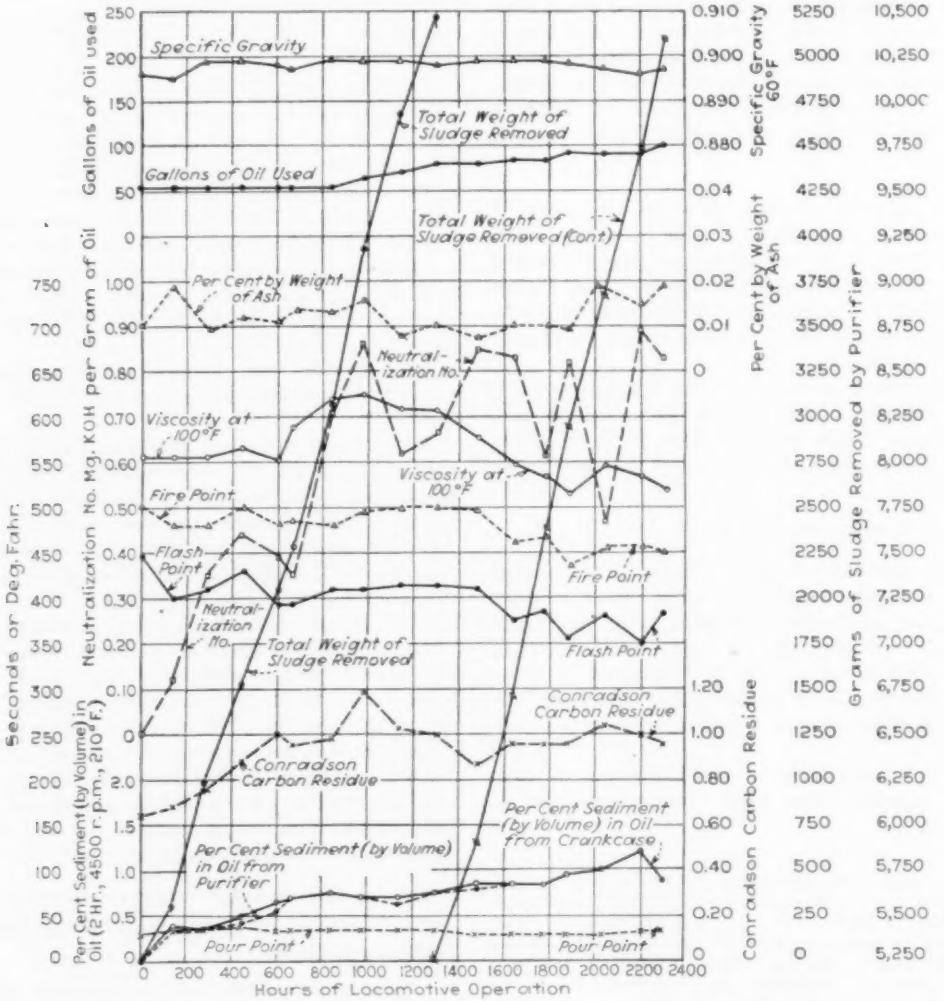

FIG. 1 EFFECT OF SERVICE ON CHARACTERISTICS OF LUBRICATING OIL USED ON DIESEL-ELECTRIC LOCOMOTIVE, EQUIPPED WITH PURIFIER

Metallic Oxides. After the pistons had been run in (during the first 30 hr. of test), the average rate of removal of metallic oxides was 12 g. per 100-hr. engine operation. This value checks fairly closely the value of 10 g. obtained during a previous test run of 1369 hr. on this locomotive and indicates only slight wear on the engine parts.

Silica. The rate of silica removal remained at the usual amount of 1.5 to 2.0 g. per 100-hr. engine operation.

Fuel Dilution

One explanation for the fuel dilution observed in previous

runs was found when reconditioning the engine prior to this test. On dismantling the Diesel engine it was discovered that the ground joints between the cylinders, combustion chambers, and cylinder heads were not tight. This allowed fuel oil to leak out around the cylinder studs and into the crankcase through the pushrod crosshead guides. Also the air-starting valves in the cylinder heads were leaking, allowing fuel oil to get past and run into the crankcase. Correction of these mechanical troubles eliminated fuel dilution during this test.

Description of Diesel Engine

A description of the Diesel engine used in the test is as follows:

Brake horsepower, 300
Speed maximum, 600 r.p.m.
Cycle, four-stroke
Number of cylinders, 6

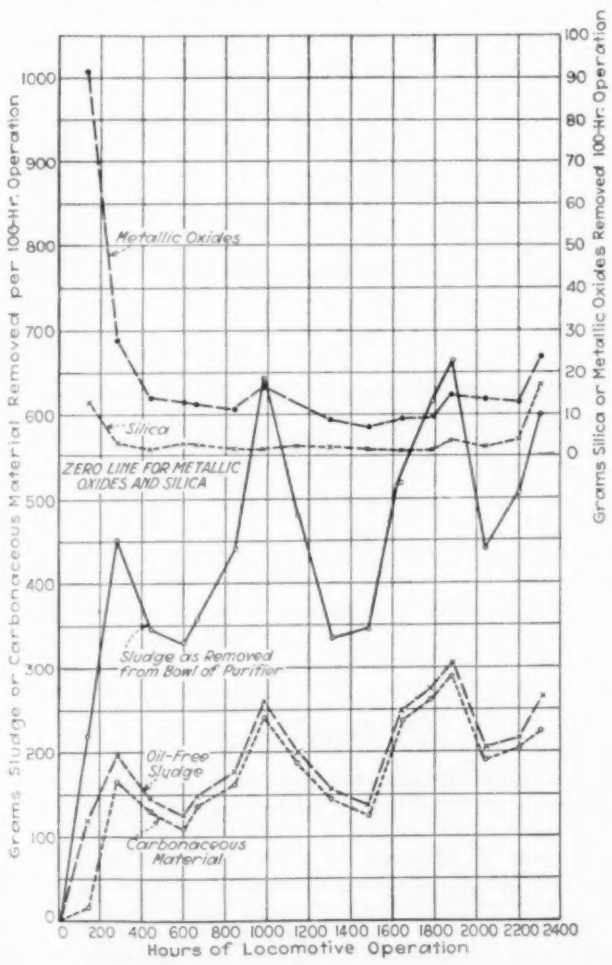

Fig. 2 Analyses of Sludge Removed From Bowl of Purifier on Diesel-Electric Locomotive, Equipped With Purifier

Arrangement, vertical
Bore, 10 in.
Stroke, 12 in.
Piston speed, 1200 ft. per min.
B.m.e.p., 70 lb. per sq. in.
Weight, 20,125 lb.
Length overall, 10 ft.
Height from base, 7 ft.
Width overall, 4 ft.
Method of starting engine, motor generator
Fuel injection, direct
Injection pressure, 3000 lb. per sq. in.
Fuel distribution, rotating distributing valve and feed pump
Lubrication, forced feed
Lubricating-oil purification, disk-type purifier
Quantity of oil in engine, 54 gal.
Rate of oil circulation through oil pump, 12 gal. per min. (720 gal. per hr.)
Rate of oil circulation through purifier, 11 gal. per hr.
Cooling of engine, water cooled
Cooling-water inlet temperature, 150 deg. fahr.
Cooling-water outlet temperature, 160 deg. fahr. (Regulation of normal outlet temperature depends on air blast delivered by cooling-system blowers.)

The locomotive was used during the 16 weeks' test for railroad switching service.

Description of Disk-Type Purifier

A description of the disk-type purifier is as follows:

Rates speed of bowl, 7000 r.p.m.
Number of disks, 21
Calk thickness, 0.050 in.
Diameter of disk, 120 mm.
Type of disk, solid

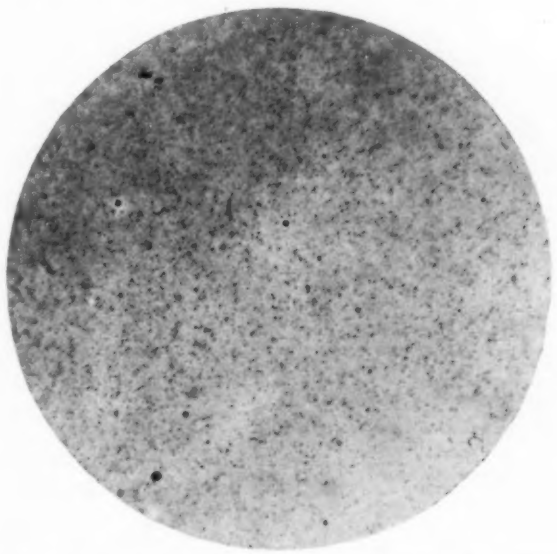

Fig. 3 Photomicrograph of Lubricating Oil From Crankcase of Diesel-Electric Locomotive × 470

Motor data, compound wound, d.c., 1750 r.p.m., 220 volt, approximately 1/3 hp. rating
Motor pulley (to purifier) dimensions, 155 mm. outer diameter
Purifier pulley dimensions, 37.5 mm.
Purifier oil pump, positive delivery, 1/8-in. pipe connections
Oil throughput through purifier, 11 gal. per hr.

Methods

Tests on the used oils were conducted according to the latest A.S.T.M. methods, as follows:

Specific gravity	D287–28T
Viscosity at 100 deg. fahr.	D88–26
Flash point	D92–24
Fire point	D92–24
Conradson carbon residue	D189–28
Pour point	D97–28
Neutralization number	D188–27T

Sediment. The per cent sediment was determined by centrifuging 100 cc. of oil at the very high speed of 4500 r.p.m. on a 16-in. circle and 210 deg. fahr. for 2 hours.

Ash. Per cent ash was determined by igniting and burning 30 to 50 grams oil to constant weight.

TABLE 1 ANALYSES OF SLUDGE SAMPLES BY EXTRACTION ON AN OIL-FREE BASIS

	Hours of service 979 hr.	2199 hr.
Benzole soluble, by weight, per cent	22.8	27.0
Chloroform soluble, by weight, per cent	3.3	2.3
Carbonaceous material insoluble in above solvents, by weight, per cent	66.6	62.8
Ash, by weight, per cent	7.3	7.9

TABLE 2

Length of service, hr	979	2040	2300
Precipitated material, per cent by weight	0.0112	0.0104	0.0116

decomposition products in the oil are the result of "cracking," which is due to the high temperatures that are met with in the engine.

TABLE 3 EFFECT OF SERVICE ON CHARACTERISTICS OF LUBRICATING OIL USED ON DIESEL-ELECTRIC LOCOMOTIVE EQUIPPED WITH PURIFIER

Sample No.	Quantity of oil added to system, gal. Single addition	Quantity of oil added to system, gal. Data

Data on the changes in characteristics of the oil and analyses of sludge are given in the accompanying charts (Tables 3 and 4 and Figs. 1, 2, and 3).

The data given in Table 1 indicate from the low percentage of material insoluble in both benzole and chloroform that the sludge consists largely of heavy cracked material rather than oxidized materials such as resins or asphalts.

Oil Analysis by Precipitation Number. In order to determine whether the used oil contained an appreciable quantity of dissolved oxidized material, 25 grams of the used centrifuged oil were diluted with 250 cc. Holde's normal benzine (equivalent to A.S.T.M. precipitation naphtha) and allowed to settle 4 hr. at room temperature (25 deg. cent.), filtered through a Gooch crucible and weighed.

The data given in Table 2 show that the quantity of dissolved oxidized product in the oil is small and that it has not increased with length of service, at least between 1000 hr. and 2300 hr. The quantities of soluble oxidized materials reported in Table 2 do not seem to be sufficient to have saturated the oil with respect to them and may be taken as further indication that the main

Discussion

WINSLOW H. HERSCHEL.[4] What is the explanation for the increase in silica and metallic oxides toward end of text?

CHARLES W. STAPLES.[5] If dilution did not occur, why did viscosity fall off? Are metals removed from engine as oxides?

ROBERT C. HARDY.[6] (1) Initial increase in viscosity may have been due to oxidation together with suspended matter present. (2) If no fuel dilution occurred, decrease in viscosity, flash point, and fire point in latter part of run was evidently due to dilution with products of the cracking indicated by the character of the sludge (Table 1). (3) Wear in connecting rod bearings was much more rapid in last 300 hr. than in first 2000 hr. The increase in metallic oxide in sludge in last part of test is probably the result of which the increase in silica content may have been the cause. (4) What was oxidation number of the new oil? If it was low, the apparently minor

part played by oxidation in this test does not indicate that oxidation test is not important. (5) Apparent lack of relationship between various test results might be removed if proper compensation could be made for the effect of various factors such as addition of new oil and periods of idleness.

Authors' Closure

Regarding the comments on the percentage of metallic oxides in the sludge at the beginning of the test, it is well to bear in mind that in every test of this kind which we have run so far, we find a larger percentage of metal, metallic oxides, and silica during the first few days of operation of the engine on any test run.

The question regarding the causes of fuel dilution in previous test runs and their elimination in the present test run is answered in the paper under the paragraph entitled "Fuel Dilution."

Relative to the deposition of carbon or sludge in the oil-feed passages, we have tests under way which we hope will disclose some of the factors governing deposition of sludge.

This test run was made with the cooperation of the representatives of the owners of the locomotive who controlled the addition of make-up oil. The amount of oil in the crankcase was kept fairly constant by means of the oil-level gage.

There appears to be no explanation for the increase in metallic oxides toward the end of the test, other than the fact that extra rapid wear of some of the engine parts may have then been taking place. Metallic material is present in the engine oil, both in the metallic form and also as oxides. In the methods of analysis used herein they are determined as oxides.

Decrease in viscosity of the oil during the latter part of the test may be due to the fact that *no* new oil was added during the first 979 hours of test, after which (in the last 1321 hours) 146 gallons of make-up oil were added. From the examination of the data, it will be seen that the viscosity of the oil started to decrease after the first addition of make-up oil. The slight increase in viscosity also occurred during the months of October and November, during which time the weather was warmer than in the latter part of the test. The possibility exists that in the warmer weather the more volatile products resulting from "cracking" were evaporated off, while in the colder months they were partially condensed and kept in the crankcase.

We believe that the constant quantity of silica found in the sludge is due to contamination from the air. Any increase in the silica content at the close of the test may be due to an abnormal contamination of the air. Mr. Hardy's suggestion that the increase in silica content may have been the cause of the wear may have some basis, but it must be kept in mind that other and more powerful causes are also present to explain wear, just before the wear-out of a bearing liner.

The Sligh oxidation number of the new oil was 10 mg. per 10 g. oil. This is generally regarded as a very low oxidation number for an oil of this viscosity.

The results given in this paper were based upon actual service conditions of a Diesel-electric locomotive in switching service.

Power Plant and Diesel Generating Installation of R. H. Macy & Co., Inc.

By GEORGE D. POGUE,[1] NEW YORK, N. Y.

To meet the demand for electricity for lighting, elevators, escalators, ventilating fans, etc., in Macy's store, New York City, two Diesel-driven units each of 1000 b.hp. are used. The rates for purchased power were such that it could not be considered in comparison with a company-owned plant. The author in this paper describes the load demands and shows the advantages of Diesel-driven units in addition to steam-driven units.

THE DEPARTMENT store of R. H. Macy & Co. in New York City has enjoyed a very rapid growth. The business was started in 1858 and moved to its present site at Broadway and Thirty-fourth Street in 1902. The original unit on this site provided 1,012,500 sq. ft. of floor area, or 16,600,000 cu. ft. Additions have been made from time to time, and the latest addition at the close of 1929 increased the total floor space to approximately 1,600,000 sq. ft., and the volume to about 26,000,000 cu. ft. These buildings occupy more than three-quarters of a city block. Recently almost the entire remainder of the block has been taken over, which will increase the floor space to nearly 2,000,000 sq. ft. and the building volume to about 31,500,000 cu. ft.

From the very beginning, all electrical energy and steam have been generated on the premises, no occasion having arisen for even temporary use of breakdown service from the outside. The increase in load has more than paralleled the increase in building space owing to the enhanced demand for electrical energy for lighting, elevators, escalators, ventilating fans, etc. The original boiler installation of 2720 boiler hp. has been increased from a total capacity of 2000 kw. in 1902 to 3350 kw. in 192€, the present equipment consisting of four 400-kw., two 750-kw., and one 250-kw. compound steam engines. At the same time the boiler output was greatly increased by substituting fuel oil for coal.

This permitted the output of the boilers to be pushed up to a maximum of 150 per cent, although 125 per cent is the rate now maintained in the interest of keeping down maintenance expense on the furnaces. It was only after the power demands of recent years began to exceed all expectations that the addition of a 565-hp. boiler became unavoidable. With fuel oil obtained under contract at less than 4 cents per gallon and coal costing about $6.70 per ton, the greater efficiency of the oil-burning system and reduction of the fireroom payroll resulted in a saving of about $20,000 per year, not counting the elimination of $4000 worth of ash-removal service. Notwithstanding these good results, the addition of further boiler and steam-generating capacity would meet with extraordinary difficulties due to lack of space, while the excess of unused exhaust steam would be further added to. The relatively high cost of city water for condensing, $1 per 1000 cu. ft., is a further consideration opposed to the enlargement of the present steam-generating capacity. At present one of the factors favoring the use of condensers at all is the necessity for maintaining a high vacuum on the turbo-refrigerating units, which are fed with exhaust steam at about 0.5 lb. per sq. in. pressure and which exhaust into a vacuum of about 24 to 26 in.

Only a partial idea of the rapid load increase faced by those in charge of the Macy power plant is given by the phenomenal increase in building space already outlined. Parallel with this the rate at which the store space already in use is increasing its demand for power has been startling, the increase from 1928 to 1929 alone being from 9,433,845 to 11,459,691 kw-hr. Many a sizable city requires less current than this per year. About half of the electrical output is used for lighting, while the remainder is consumed in motors driving more than 40 escalators, an equal number of elevators, and other services. The installed capacity of the motors in the heating and ventilating system is approximately 1000 hp., 275 hp. in the air-conditioning system, 250 hp. in the refrigerating plant, 350 hp. in the pneumatic-tube system, and 90 hp. for the package conveyors. Exhaust steam from the engines is partially used for building and service-water heating and for two 410-hp. turbo-refrigerating machines of 350 tons capacity each. Although between 20 and 40 per cent of the exhaust steam is therefore utilized in summer and winter, more than half of it at present is discharged into the atmosphere. From the brief outline of equipment given here it is apparent that the interrelations among the component parts is complex and varies from day to day. A really thorough study would require that each day's record in a given year be analyzed by itself and, although the remarkable power-plant bookkeeping system in force at the Macy store has provided the basis for doing this, the presentation of the data, if handled in this manner, would require not one paper but a long series of them.

One of the factors which contributed to the rapid increase in load is the air-conditioning system placed in service in June, 1929. Electric motor-driven pumps aggregating 115 hp. circulate the water while seven fans driven by motors of some 160 hp. total capacity circulate the air. A substantial part of the heavy demand for water which the store draws from the city supply system on hot summer days, approaching 100,000 cu. ft. per day, and costing close to $100, is attributable to the air-conditioning system. Steam-heating elements placed in the air ducts are provided for warming the air in cold weather.

Another modern feature of this unique store is the incinerator installation consisting of two units. They are rated to consume 1600 lb. of rubbish per day, but it has been found possible to operate them at a considerably higher rating than this. One of them is fitted with economizer tubes, which deliver water to the boilers at approximately 265 deg. fahr. A large feed-water heater handles the returns from the various heating systems, including the service-water heaters, as well as the condensate from the condensers on the turbo-refrigerating units. It is important to observe that the problem of keeping books on functioning of the entire thermal system of the Macy power and heating plant is an exceedingly complex one.

During the early part of 1929 the management realized that additional generating capacity would have to be installed, but

[1] Eastern Representative, Fulton Iron Works Co.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

as the sub-basement was already crowded to the limit with power equipment the problem of selecting the additional apparatus necessitated an elaborate study. The decision was finally reached to utilize a space approximately 19 ft. wide by 90 ft. long with 15 ft. head-room. Until then this had been occupied by surge tanks needed for the hydraulic elevators which had been installed in the original building and which had just been replaced with electric elevators. Practically no other space was available at that time, and the question of supplying additional power-generating equipment became focused on making the

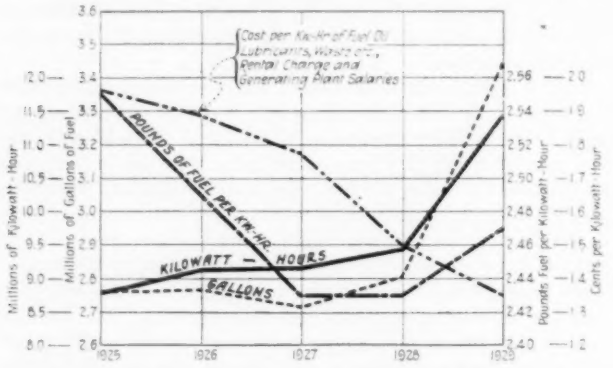

FIG. 1 PLANT CONDITIONS FOR FIVE YEARS' OPERATION

15 ft. by 19 ft. by 90 ft. space yield the greatest possible capacity. Two Diesel engines of 1000 b.hp. each gave the answer to the question. Another solution would have been to purchase power from a public-utility company, but this did not receive serious consideration on account of the prevailing rates for the class of service involved. The Diesel engines also gave promise of meeting other urgent conditions in the power-supply system of the Macy store more satisfactorily than any steam prime mover. The figures relating to water consumption, power distribution, and heat balance given here are intended rather as an aid to visualizing the broader aspects of the situation than to represent an accurate balance sheet of the conditions.

The almost spectacular way in which conditions change is illustrated in Fig. 1, which covers five representative years, beginning with 1925, of operation with oil fuel under the boilers. The effects of building and equipment additions, and above all the increase in business done by the store, are represented. Most striking is the increase in electrical output, which rose from about $8^3/_4$ to $11^1/_2$ million kw-hr. per year. Paralleling this is the rise in total fuel consumed, but the improvements in equipments show up as a decided drop in the specific rate of fuel consumption. Only as the total output begins to overtax the facilities does the specific fuel consumption rise, but not nearly in proportion to the extra energy produced. Most remarkable is the consistent fall in overall cost per kw-hr. generated, which includes the expense for fuel, lubricants, waste, rental charge, and salaries paid to employees of the generating plant. This figure includes no repair costs, which were rather difficult to arrive at for the years prior to 1928. For the latter year and for 1929, respectively, the total cost, including repairs and maintenance, was 1.603 and 1.504 cents per kw-hr. However, no credit was given for exhaust steam utilized for heating and for the operation of the air-conditioning system. The cost of generating this steam separately is roughly estimated at $37,000 per year and would, if credited, reduce the cost per kw-hr. by something like 2 mills. Whatever the significance of this figure may be, it must be conceded that $1^1/_2$ cents per kw-hr. is a phenomenally low figure in consideration of the fact that about $2^1/_2$ lb. of steam fuel are consumed per kw-hr. put on the switchboard. This amounts to only about 3.3 kw-hr. per gallon, and reflects in a highly complimentary manner on the heat economics of the plant as a whole. No allowance is made for capital charges, in view of the fact that the greater part of the equipment is more than 27 years old and therefore written off the books for all practical purposes.

Another feature which throws the remarkable operating economy of the plant into sharp relief is the fact that a considerable amount of exhaust steam is thrown into the atmosphere, even on the coldest winter days when the heating system makes its maximum demand. Were it not for the good management already referred to, this lack of balance between the heat and the power load would interfere with good economy, particularly in view of the fact that the weight of the steam exhausted is more than half the total weight of water fed to the boilers. An approximate representation of the water balance as it now stands is given in Fig. 2A. According to this estimate, only $^1/_3$ of the water entering the boilers is condensate, the remaining

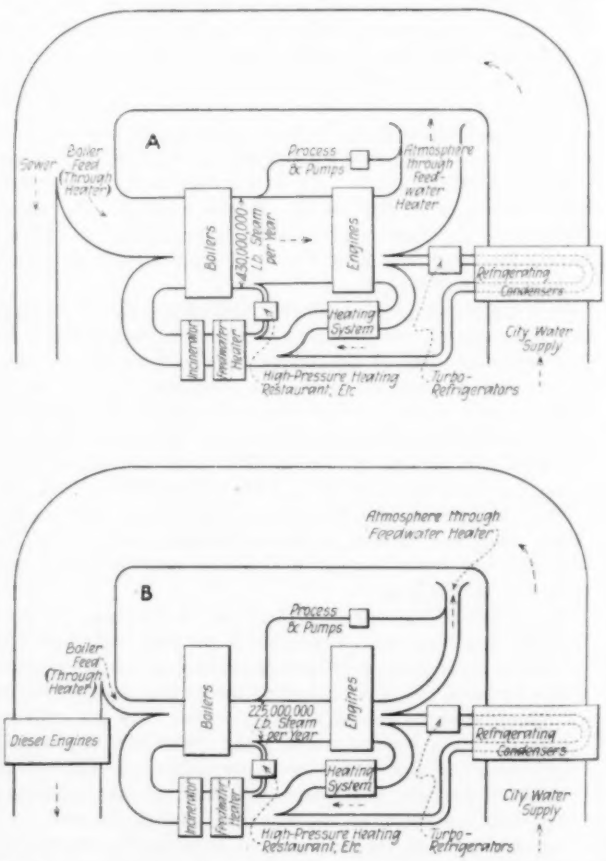

FIG. 2 APPROXIMATE WATER AND STEAM CIRCULATION; A, PRESENT CONDITIONS; B, WITH DIESEL ENGINES

$^2/_3$ being obtained from the city supply system through the feedwater heater, economizer, and condensers. To balance this an almost equal quantity of steam is exhausted into the atmosphere.

Of the total amount of steam generated about 94 per cent is supplied to the steam-driven generators. Some, but not all of the high-pressure heating steam, such as that supplied to the restaurant, comes back in the returns. Of the steam passing through the engines approximately 66 per cent is exhausted to the atmosphere, while the remaining 34 per cent of this quantity (not of the total) is utilized partly for heating or air conditioning

and returns to the feedwater heater. In view of the condition shown here it is apparent why the addition of further steam-generating equipment to take the added electrical load was not looked upon with favor, quite independently of space considerations.

Large quantities of cooling water are required for the steam condensers on the turbo-refrigerating apparatus as well as for the refrigerant condensers. However, as these units are operated with exhaust steam that would otherwise go to waste, the cost of cooling water, therefore, represents virtually the principal operating charge against them. The net cost of the very considerable amount of power required is probably considerably lower than it would be if obtained in any other way.

Operation With Diesel Engines

As a general basis for estimating the manner in which the Diesel engines may be expected to fit into the rather complex scheme of power supply, heating, and ventilating system of the Macy store the daily load curves shown in Fig. 3 have been plotted on the basis of actual meter readings. Extreme summer and winter days were selected, with the remarkable result that the electrical demands for the two are found to lie quite close together. "Daylight saving" seems to have little effect on the lighting requirements of a large department store, while the slight reduction in the summer population of the store is virtually without effect on the operation of elevators and escalators. The demand for boiler make-up water, however, is materially

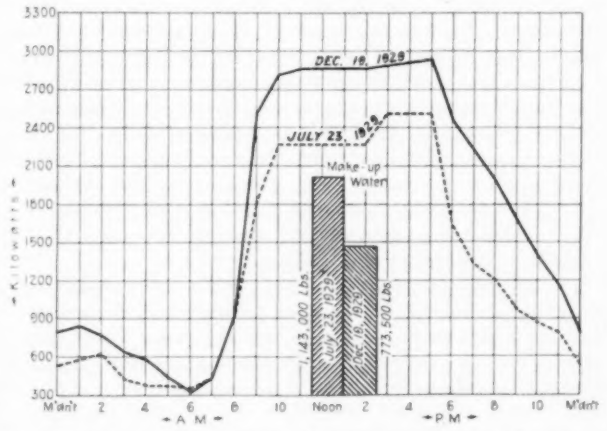

Fig. 3 Daily Load Curves for Summer and Winter Compared

reduced, mainly on account of a fall in the demand for heating steam.

One of the most important results expected from the installation of the Diesel engines will be the provision of stand-by power, which is not now as ample as desired. The installed capacity of the steam units is only 3350 kw., and now requires that all the available units be operated during the periods of higher load. A further consequence of operating the Diesel engines will be a reduction in the weight of water handled through the boilers and consequently of the amount of steam exhausted to atmosphere. An inspection of Fig. 4 shows how the combined outputs of the Diesel engines and some of the steam units may be expected to take the total load. Even with the Diesel engines running at maximum capacity during the peak period and with the steam output correspondingly reduced it is estimated that there will still be a noticeable surplus of exhaust steam. An indication of how this might work out is given in Fig. 3B. The total steam generated in the boilers is expected to be reduced by something like 50 per cent, but as there appears to be use for only about 35 per cent, a certain margin will still remain. The curves in Fig. 4 are based on a winter day, so that in summer the effect of the Diesel engines in reducing the amount of steam generated should be even more pronounced at times when less use can be made of the exhaust steam.

Owing to the high load factor of the Diesel engines it is probable that they will produce something like 11.5 to 12.5 kw-hr. per gallon of fuel, as against only about 3.3 kw-hr. per gallon of fuel used in the steam-generating equipment. The total elec-

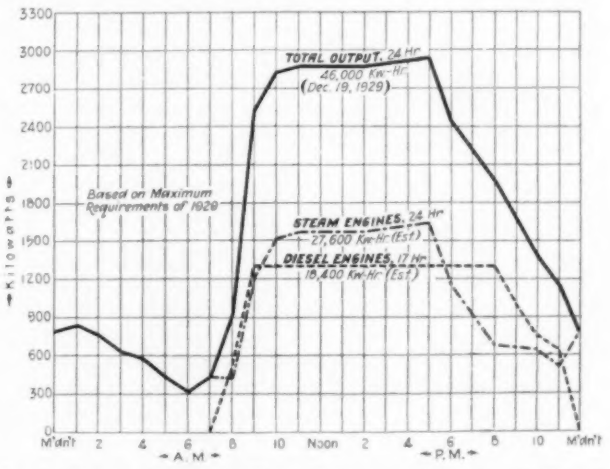

Fig. 4 Graphs Showing How Combined Outputs of Diesel Engines and Steam Units Are Divided

trical output for 1929 was close to 11.5 million kw-hr. and the corresponding consumption of fuel oil 3.5 million gallons. If the Diesel engines had then been available it would have been economical on the basis of the load curves shown in Fig. 4 to produce with them something like 5.5 million kw-hr. per annum. For the steam plant's share of the load approximately 1.8 million gallons of fuel oil would be consumed, while the Diesel engines would generate their share on about 0.4 million gallons and the combined total would be 2.2 million gallons. This reduction is not directly proportional to the cost saving, which is difficult to compute in the absence of official data on the cost of boiler and Diesel fuel. However, no great mistake will be made by assuming $3^3/_4$ cents per gallon as the cost of the boiler fuel and $5^1/_4$ cents as that of the Diesel oil. On this basis about $20,000 would have to be spent on Diesel fuel and $67,000 on boiler oil, or $87,000 altogether, contrasting with about $125,000 that would be spent if steam only were used. The net saving of $38,000 on fuel will naturally be offset to a certain extent by charges other than fuel to be booked against the Diesel engines. Among these are floor space rental, lubricating oil, labor, cooling water, maintenance, and amortization, but their total, in terms of cents per kw-hr. generated by Diesel power, will of course come well within the overall kw-hr. cost recorded for the steam-generating units.

After the Diesel engines are in commission, additional use is to be made of the water now partly fed to the boilers and partly running to waste at a cost per refrigerating season of about $7500, for the Diesel-engine jacket-cooling system has been piped up to the discharges from the turbo-refrigerating condensers, which yield about 670,000 gal. of water per day when operating at full capacity. If the daily output of the Diesel plant is as estimated in Fig. 4, that is, 18,400 kw-hr. or 29,200 b.hp-hr., cooling water will be supplied at the rate of some 23 gal. per b.hp-hr., a supply which should be adequate even after making due allowance for the fact that the condenser water reaches the engines at a temperature close to 115 deg. at times of peak demand on the refrigerating system. A branch line is provided to

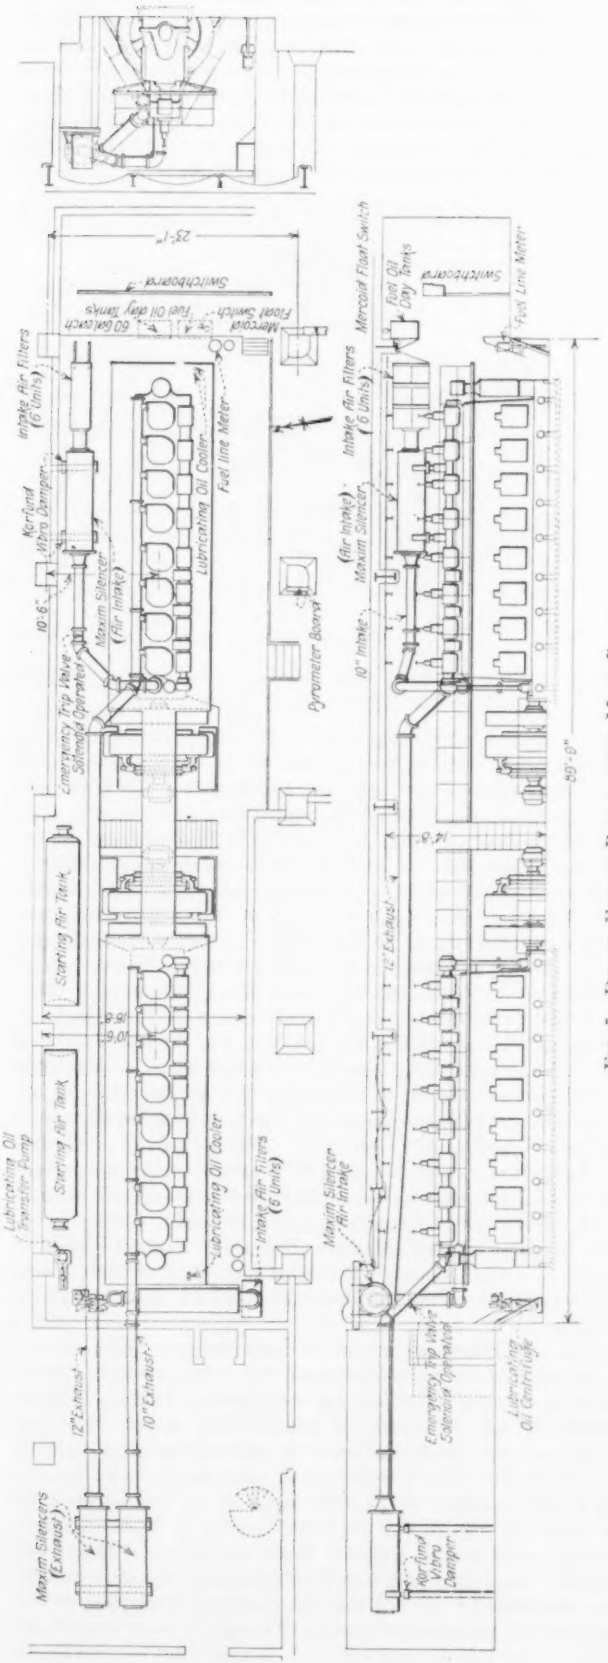

FIG. 5 DIESEL-ENGINE ROOM AT THE MACY PLANT

feed cold water into the Diesel-engine jackets direct from the city supply system when required and is fitted with a Powers automatic regulator and check valve to act without attention whenever the temperature of the water discharged from the Diesel engines exceeds a set limit. A small cold-water line also goes to the injection air compressors and oil coolers, in view of the fact that this equipment would not ordinarily work efficiently with the water temperature expected. Individual distant-reading dial thermometers are provided for each of the cylinder-water discharges on the engines, so that their temperatures may be individually regulated with the valves fitted for that purpose. Brown pyrometers are provided to indicate exhaust temperatures.

Although the operation of the Diesel engines will undoubtedly affect the heat balance of the Macy power plant profoundly, it at the same time provides a valuable security element, in so far as the Diesel engines can keep power on the switchboard without any assistance from the steam installation. Cooling water is the only service requiring energy, and that comes from the city mains, which, as has already been indicated, can be supplied to the Diesel engines without dependence on any other apparatus.

In plotting the estimated Diesel load curve on Fig. 4 it was borne in mind that at times of low load or no load on the air-conditioning refrigerating system considerable water might have to be drawn from the city mains to cool the Diesel engines, and that this might at times be a limiting factor for the percentage of output to be generated by them. At the same time it might happen that at periods of diminished activity by the air-conditioning plant the temperature of the water discharged from the condensers into the Diesel engines might be considerably lower, so that the smaller quantity might be offset by the removal of a greater number of heat units per pound of water within the permissible temperature rise set for the Diesel engines. However, if all the cooling water circulated through the jackets were to be charged for it would scarcely exceed $5500 per year, a sum which would amount to about 1 mill for each of the $5\frac{1}{2}$ million kw-hr. assumed to be generated.

A very general indication of what the cost of Diesel power in the Macy plant may be is given herewith on the assumption that $5\frac{1}{2}$ million kw-hr. will be generated at a yearly load factor of 48.3 per cent and that the annual labor charges assessed against the plant will be $7500.

THE DIESEL POWER PLANT

The Diesel engines selected for the plant consist of two Fulton Iron Works Co., 1000-b.hp., 8-cylinder, trunk-piston, 4-cycle, air-injection units direct-connected to two Crocker-Wheeler, 800-kw., 40 deg. cent., 250-volt, d-c. generators. Bore and stroke dimensions of the Diesel engines are $17\frac{1}{2}$ in. by $24\frac{1}{2}$ in. and their normal speed is 225 r.p.m. Under these conditions the brake mean effective pressure is 74.2 lb. per sq. in. and the piston speed 919 ft. per min. Force-feed lubrication is supplied to all the major bearings by means of a rotary pump integral with the engine, while an oil cooler and a Sharples centrifuge are provided for conditioning the oil. Lubrication of such parts as the cams and camshaft bearings as well as the timing gears has also been made automatic, so that practically no manual oiling service will be required anywhere on the engine. Lubrication of the engine and compressor cylinders is supplied by a Manzel lubricator with 19 feeds. Two Double Seal rings are fitted to each piston.

Compressed air for starting and injection of fuel is provided by three-stage compressors built integral with the engines. Each stage is provided with tubular intercooler separately supplied with cold water from the city mains.

The design of the engine had a direct bearing on its selection for installation in the limited space (Fig. 5) available and in the power plant of a store where customer comfort is elaborately catered to. The eight-cylinder arrangement permitted the attainment of maximum capacity in the relatively long and narrow Diesel engine room, while the inherently good-running balance of the units is a factor in reducing vibrations to a desirable point. Further assurance against undesirable vibration is seen in the frame construction of the units, which comprises a deep box-girder running from the surface of the bedplate to the underside of the cylinder heads. The frame is divided into cells by transverse webs between adjacent cylinders. Into each one is inserted a separate cylinder liner, the space between the liner and the cell wall serving as a water jacket. With the relatively large weight of the engine about 188,000 lb. the secondary dynamic forces due to inertia of the reciprocating parts becomes a negligible percentage of the total mass in which vibrations might be set up.

Installation of the engines in the small available head-room required the removal of considerable quantities of rock in order to provide for the foundation and for space in which to withdraw the pistons and connecting rods under the I-beams of the floor above. According to usual practice the foundation was not allowed to contact with the building structure at any point, a layer of Korfund natural-cork blocks having been laid down before the concrete for the foundation was poured. Cork was also used at the sides of the foundation, while the latter was loaded with heavy steel sections embedded near the bottom.

Air is to be drawn into the engines through Maxim silencers and Midwest viscous-baffle air filters directly from the engine room, which otherwise might become overheated due to the proximity of the steam engines. Each air-intake pipe is also provided with an electrically controlled emergency-stop valve which permits of shutting down the engines quickly under abnormal conditions.

Exhaust lines of ample size are connected to the engines and lead to Maxim silencers at the west end of the Diesel engine compartment. In order to avoid the transmission of possible vibrations to the building, interlocking flexible metallic tubing has been inserted between the engines and the exhaust lines, the longer one of which, leading from the east engine, consists of 12-in. pipe and the shorter one of 10-in. pipe. From the silencers, 16-in. piping leads to the main stack of the plant, the diameter of which is 11 ft. and which rises to a height of more than 300 ft. Under present conditions of operation the stack shows a considerable draft, amounting to some 3 or 4 in. of water.

Daily supply tanks for fuel are located high in the engine room to permit the fuel to flow under a slight head to the fuel pump on each engine. Each of the tanks is kept filled by a small rotary pump discharging at a constant rate through Bowser meters and an air-eliminating tank. The capacity of both the fuel transfer pumps and the meters have been proportioned so that whenever the meter is in action it will be working at near its normal capacity. This feature, and the provision for eliminating air, should assure accurate measurement of the fuel oil used.

A separate switchboard is being installed for the Diesel generating sets at the east end of the compartment. It is connected through heavy copper busses directly to the main switchboard of the plant and is equipped with massive circuit breakers of 6000 amp. capacity.

The d-c. direct-connected generators are provided with interpoles and are of massive construction. Their capacity, 800 kw. each, is larger than would ordinarily be provided for engines of 1000 b.hp., but provisions have been made for later supercharging the Diesel engines up to 1250 b.hp. each and for utilizing the full capacity of the generators in this manner. In the present analysis no consideration has been given to this proposal, because it will probably be possible to do this more satisfactorily after the Diesel engines have been in operation without supercharging and after suitable operating data have been recorded.

Acknowledgments for much of the information contained in this paper are made to Messrs. Cogan, Brennan, Harrigan, and Coghlan of the executive and operating staff at Macy's, and to the consulting engineering firms of Kaiser, Muller & Davies and Werner Nygren, Inc.

Discussion

EDGAR J. KATES.[2] According to the records only 20 per cent to 40 per cent of the steam-engine exhaust in this plant has been utilized throughout the year, prior to the installation of the Diesel engines. This is worthy of note because the *predicted* utilization of exhaust steam in plants of this kind is often assumed at a much larger ratio. The error in such predictions is that they fail to take account of the lack of coincidence between the demands for electric current and steam heat. Studies of power and heat requirements with a view to utilizing the maximum quantity of exhaust steam are too often based upon the *average* power and heat loads for daily, weekly, or monthly periods. Such studies lead to false conclusions because the utilization of the exhaust depends upon the transient relations between the power and heat loads, not upon averages. To be accurate, heat-balance studies must be made in great detail, using power and heat-load curves for all hours of the day and for all times of the year.

The small utilization of exhaust steam in the Macy plant is particularly significant when it is noted that unusual measures have been taken in this plant to utilize it. Low-pressure turbines have been installed to take the Corliss-engine exhaust, and the turbines discharge to condensers cooled by metered city water at considerable expense. These turbines operate an air-conditioning plant in the summer, and thus serve to increase the summer demand for low-pressure steam. Few power plants in city buildings have been elaborated to this extent, and generally their utilization of exhaust steam is still less than in the Macy plant. In such plants the addition of Diesel engines would accomplish even more than at Macy's.

In considering the broad problem of power and heat balancing by means of Diesel engines, it is well to remember that in the case of the Macy installation the Diesel engines were added to a full-size steam power plant that was already in operation. If the project had been that of an entirely new power plant where the designer had full choice as regards both the steam and Diesel equipment, an entirely different set-up would no doubt have ensued. In all probability the steam plant would have been made as simple as possible, the low-pressure steam turbines would have been omitted, and a larger proportion of Diesel power would have been installed.

Pressure Fluctuations in a Common-Rail Fuel-Injection System

By A. M. ROTHROCK,[1] LANGLEY FIELD, VA.

The instantaneous pressures at the discharge orifice of a common-rail fuel-injection system were determined by analyzing the stem-lift records of an automatic injection valve. The fuel injection was obtained by releasing fuel under high pressure from a reservoir by means of a cam-operated timing valve. The period of injection was controlled by the opening of a second cam-operated valve which reduced the fuel pressure between the timing valve and the injection valve to atmospheric pressure. The results show that pressure-wave phenomena occur between the high-pressure reservoir and the injection valve, but that these pressure waves can be controlled in a manner advantageous to the injection of the fuel. The results also give data as to the design of such an injection system for a high-speed fuel-injection engine. An injection system of this type insures the same rate of fuel discharge regardless of engine speed.

THE quantity of fuel delivered by a common-rail fuel-injection system is controlled either by the lift of a mechanically operated fuel-injection valve or by the time during which the oil in a high-pressure reservoir is released to an injection valve. The first type has not proved particularly successful with high-speed engines because of the difficulty of controlling the rate of fuel flow by controlling the lift of a mechanically operated valve. With the second system it is necessary to have one or two mechanically operated valves in conjunction with either an automatic injection valve or an open nozzle.

When one mechanically operated valve is employed, the fuel under pressure is released to the injection valve for a time interval equal to the time during which the mechanically operated valve remains opened. When this valve closes, the fuel continues to discharge until the oil between the mechanically operated valve and the injection valve drops to a pressure less than the injection-valve-opening pressure or to the pressure in the combustion chamber if an open nozzle is used. This results in a comparatively slow cut-off of the fuel spray. If, however, an automatic injection valve is used and a second mechanically operated valve is employed, which causes the stopping of fuel discharge by releasing the pressure between the high-pressure reservoir and the injection valve to some value less than the valve-opening pressure, a sharp cut-off of the fuel spray is assured. Such a fuel-injection system has the following characteristics:

1 Constant time for a given fuel quantity to be discharged regardless of engine speed
2 Sharp start of fuel spray
3 Sharp cut-off of fuel spray
4 Constant fuel dispersion and penetration regardless of engine speed, unless a cylinder head giving a high degree of turbulence varying with engine speed is employed.

In order to control the injection of the fuel into the combustion chamber of the engine, it is necessary to know the pressure variations at the discharge orifice as well as the time of injection and the static pressure in the high-pressure reservoir. These pressure variations are controlled by the design of the fuel-injection system and the physical properties of the fuel.

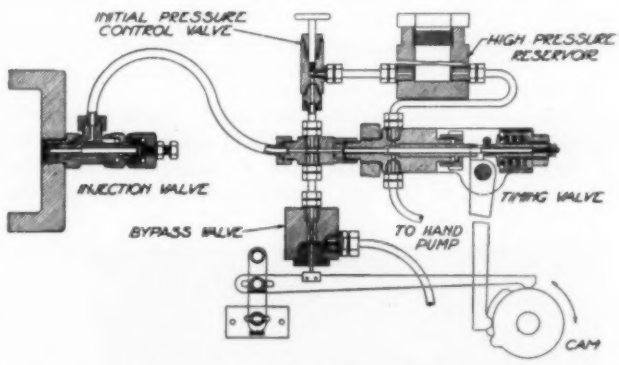

FIG. 1 FUEL-SPRAY-INJECTION SYSTEM

The system should be designed to meet these physical properties in such a manner that the instantaneous pressures at the discharge orifice cause the injection of the fuel according to the requirements of efficient combustion. Since fuel oils are compressible, they are subject to pressure-wave phenomena. To design a common-rail fuel-injection system with a definite rate of fuel discharge, the effect of the different parts of the injection system on the instantaneous pressures must first be determined. If these are known, the pressure fluctuations throughout the injection system and the rate at which the fuel is discharged can be varied almost at will.

The tests reported herein were conducted to determine experimentally the instantaneous pressures at the discharge orifice of a common-rail fuel-injection system in which the timing valve and cut-off valve were at some distance from the automatic fuel-injection valve, and also to determine the methods by which the pressure fluctuations could be controlled.

METHODS AND APPARATUS

The fuel-injection system of the N.A.C.A. spray photography equipment (Reference 1) was used for the investigation. It is illustrated diagrammatically in Fig. 1. The timing-valve cam was operated by a clutch which, when engaged, caused the cam to make one revolution. The cam speed for these tests was 1140 r.p.m., except where otherwise stated. As the timing-

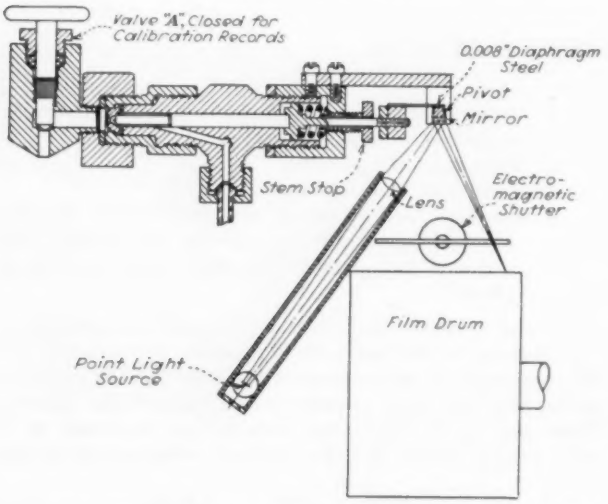
valve needle was lifted from the seat, the oil under pressure in the high-pressure reservoir was released through the injection-valve tube to the injection valve. The oil pressure acting on the annular area of the valve stem forced the steam from the seat, and the oil was sprayed into the chamber. The bypass



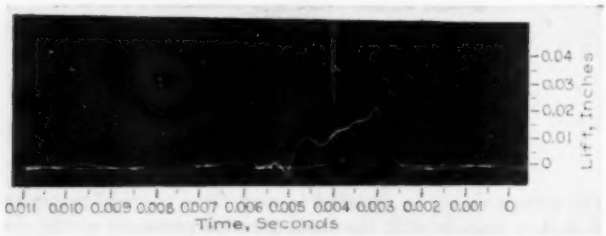


FIG. 2 AUTOMATIC INJECTION VALVE AND APPARATUS FOR RECORDING VALVE-STEM MOTION

or spray cut-off valve then opened; the hydraulic pressure in the injection-valve tube dropped due to the rapid flow of the oil through the bypass valve; and the injection-valve spring forced the stem to the seat, cutting off the fuel spray. The

time interval between the start of opening of the timing valve and bypass valve could be varied as shown in Fig. 1. For these tests the injection period was maintained at approximately 0.0045 sec. except where otherwise stated. The bypass valve was so adjusted that it opened before the timing valve started to close. The initial pressure in the injection-valve tube could be adjusted to any desired value by means of the initial-pressure-control valve. An initial pressure of 300 lb. per sq. in. was used in all these tests unless stated otherwise. The hydraulic pressures were obtained by a hand pump. The static pressures were indicated by a Bourdon spring gage mounted in the line between the hand pump and the high-pressure reservoir. Particular care was taken to remove all air from the injection system before each test was made.

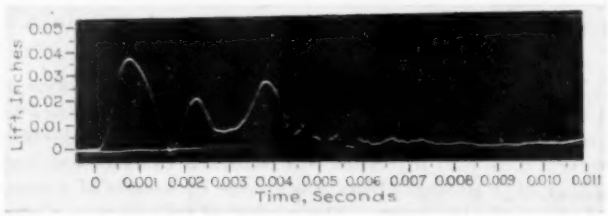

FIG. 4 RECORD OF INJECTION-VALVE-STEM MOTION, WITH NO STOP

FIG. 5 PRESSURE CALIBRATION RECORD

The injection valve shown in Fig. 1 was altered as shown in Fig. 2, so that the stem motion could be recorded. The record was obtained by directing a beam of light from a point source

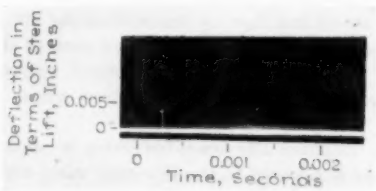

FIG. 6 RECORD OF VIBRATIONS CAUSED BY DIAPHRAGM STEEL LINKAGE

on the mirror operated by the valve stem and focusing the reflected beam on a film mounted on a revolving drum. The drum was driven by a synchronous motor at a peripheral speed of 1038 in. per sec. An electromagnetic shutter operated by the camshaft was placed in front of the film drum so that the beam of light fell on it for not more than three revolutions. This was done so that the line of zero lift would not appear as a heavy band. During the preliminary part of the investigation the injection valve was mounted in the spray chamber as shown in Fig. 1, and records were taken simultaneously of the injection-valve-stem motion and the development of the fuel spray. In order to synchronize the two records a small spark gap was placed in front of the stem-motion film. This gap was connected

in series with the main spark gap for taking the high-speed motion pictures of the fuel spray. Hence, for each spray photograph there appeared a small line on the stem-motion record. Fig. 3 shows records of the injection-valve stem and of the fuel spray taken in this manner. For this particular test the stem stop of the injection valve was set to limit the maximum lift to 0.021 in.

An examination of the chart shows that both the start of the spray and the start of the injection-valve-stem motion occurred between the seventh and eighth photographs and that spray cut-off came between the fifteenth and sixteenth photographs. The stem did not stay against the stop because of the pressure fluctuations. Since the two records taken simultaneously showed that the start and the stop of the spray followed the start and the stop of the injection-valve-stem motion within a few hundred-thousandths of a second, that is, within the accuracy of the experimental data, spray records were not taken for the majority of the tests, and the injection valve was mounted in the special holder shown in Fig. 2 so that calibration records could be taken after each stem-lift diagram.

All of the injection-valve records for the pressure analysis were taken with the stem stop backed off so that the stem did not strike it, in order that the stem motion could be used as the instantaneous-pressure indicator. A typical record is shown in Fig. 4. It is seen that the stem came in contact with the seat after the first oscillation, but did not touch it again until spray cut-off. It then struck the seat and made a series of short bounces. These bounces are the cause of the secondary discharges discussed by Beardsley in his tests on the causes of secondary discharges (Reference 2). They occur when the pressure in the injection-valve tube is still great enough during the bouncing of the stem to cause discharge.

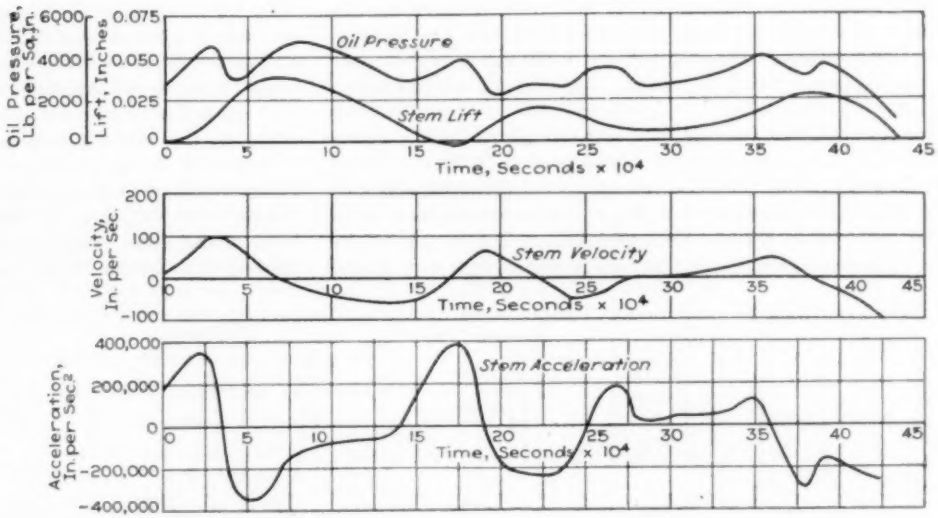

FIG. 7 STEM-LIFT RECORD SHOWN IN FIG. 4 PLOTTED TOGETHER WITH STEM-VELOCITY AND ACCELERATION CURVES AND PRESSURES AT DISCHARGE ORIFICE

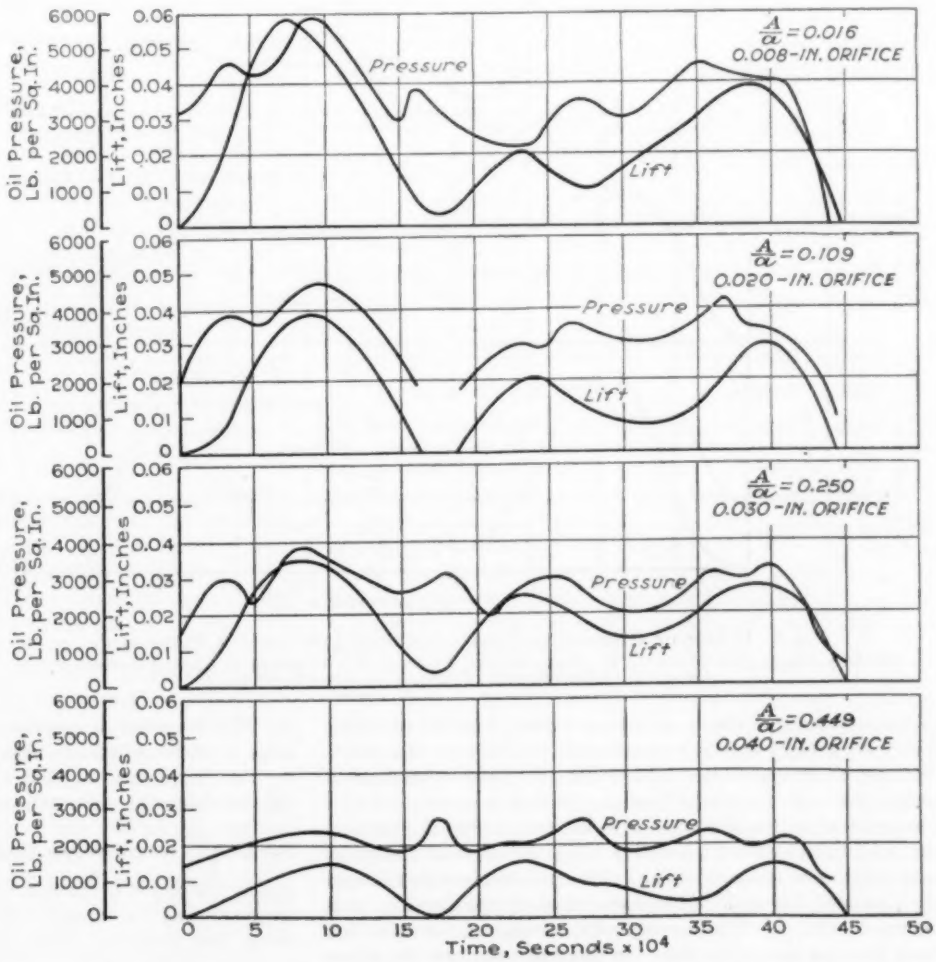

FIG. 8 EFFECT OF ORIFICE DIAMETER ON STEM LIFT AND OIL PRESSURE
(Injection pressure, 3500 lb. per sq. in.; valve-opening pressure, 2500 lb. per sq. in.; initial pressure, 300 lb. per sq. in.; tube length, 13 in.)

The calibration of the spring in the injection valve was obtained by closing the valve A shown in Fig. 2. The stem-recording mechanism was removed, and a dial indicator graduated in thousandths of an inch was placed against the spring follower of the injection valve. The hydraulic pressure was built up in stages of 500 lb. per sq. in., and the lift readings were recorded. From these data the spring scale of 3600 lb. per sq. in. was computed. The calibration of the lift as recorded on the film was obtained by replacing the lift-recording mechanism and building up the pressures in stages of 500 lb. per sq. in. At each pressure increment the point source light was flashed on for an instant so that a record was obtained on the revolving film with straight lines representing the lift for each increment. This record was converted into actual lift of the valve stem in inches from the spring calibration. It was necessary to take film calibration records after each lift record for, in changing the conditions between successive tests, the angle of the point source light was changed and any difference in this angle changed the recorded lift scale. The calibration record for Fig. 4 is shown in Fig. 5. The corresponding pressures for each line have been marked on the film. In this particular case the valve-opening pressure was 2500 lb. per sq. in.; consequently, there was no lift recorded until the pressure reached 2500 lb. per sq. in.

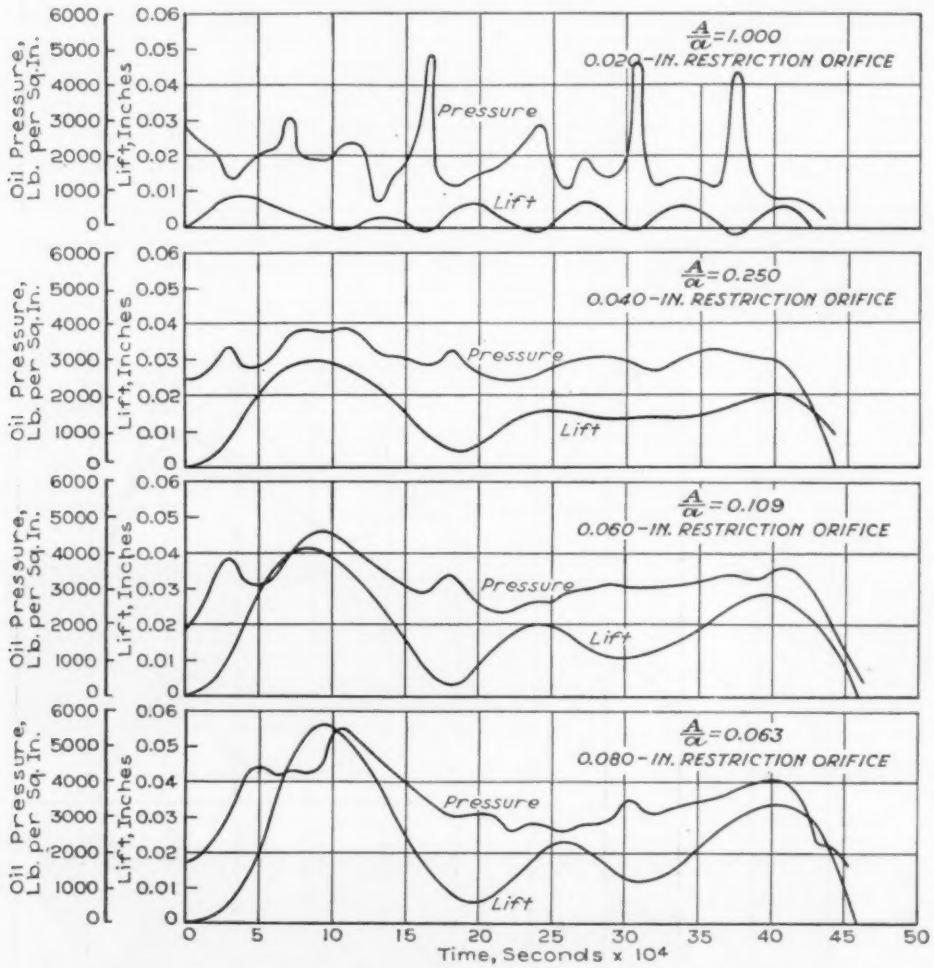

FIG. 9 EFFECT OF RESTRICTION ORIFICES ON STEM LIFT AND OIL PRESSURES
(Injection pressure, 3500 lb. per sq. in.; valve-opening pressure, 2500 lb. per sq. in.; initial pressure, 300 lb. per sq. in.; orifice diameter, 0.020 in.; tube length, 13 in.)

In order to obtain the frequency of the diaphragm steel linkage the diaphragm was deflected slightly and then released, and at the same time a photographic record was taken of the vibration of the reflected-light beam. The record, Fig. 6, shows that the period of vibration was too small to have any material effect on the stem-lift records.

Derivation of the Instantaneous Pressures at the Discharge Orifice From the Stem-Lift Records. At every instant the hydraulic force on the valve stem was opposed by the resisting force of the valve spring plus the product of the mass of the moving parts by the acceleration at that instant plus or minus the friction of the stem in its guide. For the valve with which these tests were made the friction force was negligible in comparison with the other forces and was consequently neglected. The force-equilibrium equation is therefore:

$$f = \lambda s + ma \ldots . [1]$$

in which f is the hydraulic force at any time t, λ the spring scale, s the compression of the valve spring at the time t, m the mass of the moving parts 0.069 lb. for the valve tested, and a the acceleration of the stem at the time t. The spring compression at any instant was the sum of the initial compression of the spring, obtained from the calibration record, plus the stem lift at the instant under consideration, obtained from the stem-lift record. The acceleration at any instant was obtained by first drawing the time-velocity curve from the tangents to the time-lift curve taken at 0.0001-sec. intervals and then drawing the time-acceleration curve from the tangents of the velocity curve taken at 0.0001-sec. intervals. The mean pressure on the stem was the total force divided by the area of the stem, 0.0398 sq. in. Fig. 7 shows the velocity, acceleration, and pressure curves, together with the lift curve for the experimental record shown in Fig. 4. The bouncing of the stem after cut-off is omitted. The stem oscillations indicate that the stem motion was controlled by two harmonics imposed upon each other. The first was the fundamental harmonic of the valve spring. Its period was $2\pi\sqrt{\frac{m}{\lambda}}$ which for the spring used was 0.0014 sec., approximately the period of the first oscillation, 0.0018 sec. The second harmonic was the fundamental harmonic of the oil column between the discharge orifice and the high-pressure reservoir. Its period was $2\pi l\sqrt{\frac{\rho}{2Eg}}$ in which l is the length of the oil column

between the discharge orifice and the high-pressure reservoir, 26.7 in. for the 13-in. tube, ρ the density of the Diesel oil, 53 lb. per cu. ft., E the modulus of elasticity of the oil, 284,000 lb. per sq. in. (Reference 3), and g the gravitational constant. Substituting these values in the expression gives a value of 0.0020 sec. The actual period as obtained from the chart is 0.0026 sec. The difference between the actual period and the theoretical period can be accounted for in part by the fact that the value of E has not been accurately determined, but chosen from the values of other oils of similar properties. The curves show in nearly all cases a sharp drop in pressure after about the first 0.0004 sec. caused by the start of the discharge from the orifice. There is a sharp build-up of pressure due to the restriction to oil flow whenever the stem reaches or nearly reaches the seat during its oscillations.

The flow of oil through the discharge orifice was computed from the pressure curves and the conventional flow formula $Q = AVt$ in which $V = C\sqrt{2gh}$. The pressure for computing the total discharge was taken as the square of the mean of the square roots of the instantaneous pressures. Coefficient of discharge tests made on the 0.008- and 0.020-inch orifice with the apparatus employed by Joachim (Reference 3) showed that the coefficients of discharge of these orifices over the range of pressures investigated did not vary materially from 0.94. The actual discharges were obtained by screwing a small container on the injection valve and weighing ten injections. In every

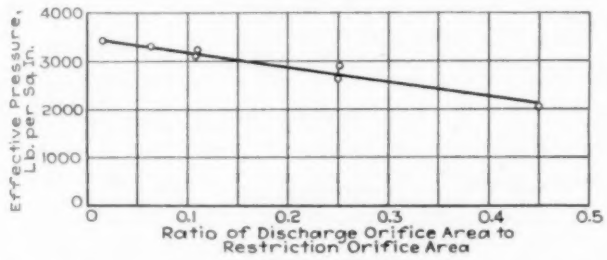

FIG. 10 EFFECT OF RATIO OF DISCHARGE-ORIFICE AREA TO RESTRICTION-ORIFICE AREA ON EFFECTIVE PRESSURE

case two or three sets of ten discharges were weighed and the mean was taken. In no case did the individual weights vary by more than 3 per cent from the mean.

TEST RESULTS

Effect of the Ratio of Discharge-Orifice Area to Area of Smallest Restriction Between the High-Pressure Reservoir and Discharge Orifice. The tube connecting the high-pressure reservoir with the timing valve had an internal diameter of 0.063 in. The diameter of the passage connecting the timing valve to the injection valve tube was 0.094 in. The injection tube was made of seamless steel tubing with an outside diameter of 0.250 in. and an inside diameter of 0.125 in. The oil passage in the injection valve between the injection-valve-tube connection and the passage around the valve stem had a diameter of 0.094 in. Consequently, the smallest restriction was the 0.063-in. tube between the high-pressure reservoir and the timing valve. Two series of tests were conducted to determine the effect of the ratio of the discharge-orifice area to the area of the smallest restriction in the line. In the first series the stem lift was determined for different diameter discharge orifices. In the second series the stem lift was determined with a constant discharge orifice diameter, but with various restriction orifices inserted in the injection line at the entrance to the automatic injection valve.

The effect of varying the discharge-orifice diameter is shown in Fig. 8. The ratio of the discharge-orifice area to the restriction area is symbolized by A/a. As the ratio was increased more of the energy of the initial-pressure wave was expanded in discharging the fuel oil and less of it was utilized in a wave reflected back to the high-pressure reservoir. Consequently, the intensity of the pressure waves and the stem lift decreased as the orifice diameter increased. Between the ratio of 0.25 and 0.45 there comes a point where the wave energy was almost entirely transformed into the kinetic energy of the discharging oil and the pressures at the discharge orifice remained virtually

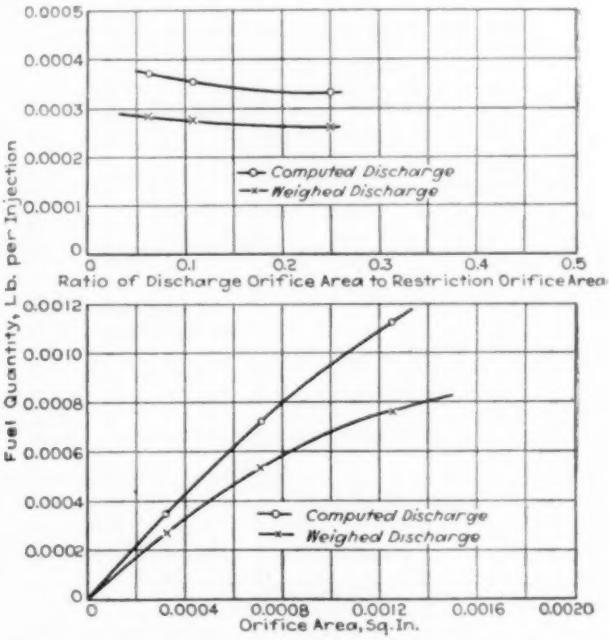

FIG. 11 EFFECT OF RESTRICTION-ORIFICE AREA AND DISCHARGE-ORIFICE AREA ON FUEL QUANTITY DISCHARGED

constant, although the stem oscillated, opening and closing the valve.

Fig. 9 shows the effect of the ratio when the discharge orifice remained constant and the diameter of the restriction orifice was varied. The same phenomenon occurred as is shown in Fig. 8. The important fact to notice in these two figures is the similarity of the curves for the same ratios. For the 0.020-in. restriction orifice with a ratio of 1.0 the valve stem oscillated to a greater extent than with the ratio of 0.45. Although the values given for the instantaneous pressures in this particular case are open to question, because of the difficulty of analyzing the curve at the line of zero lift, the curve does show that there were violent fluctuations of pressure because of the rapid opening and closing of the valve.

The effect of the ratio of the discharge-orifice area to the restriction-orifice area on the effective pressures is shown in Fig. 10. As the ratio decreased, the effective pressure approached the static pressure in the high-pressure reservoir. The difference between the static pressure and the effective pressure was directly proportional to the ratio. Since the effective pressure decreased as the orifice area was increased, the quantity of fuel discharge (Fig. 11) did not vary directly with the orifice area. Both the computed and actual discharge curves follow the same general trend. The discrepancy between the two is due to the losses in weighing the fuel, to the restriction to flow when the valve stem approached the seat, and probably because the mean pressure across the stem was somewhat greater than

the mean pressure across the discharge orifice. In Fig. 11 it also is seen that as the ratio A/a increased, the fuel quantity discharged decreased.

It can be concluded from the charts that, for an injection system of this type, the ratio of the discharge-orifice area to the area of the smallest restriction in the fuel line should not be greater than 0.25.

Effects of Injection-Valve-Tube Length. The effects of the injection-valve-tube length on the stem life and pressure variations are shown in Fig. 12. As the length of the injection-valve tube is increased, the period of vibration of the oil column is increased. The computed periods for the tube lengths are 0.0020 sec. for the 13-in. tube, 0.0028 sec. for the 24-in. tube, 0.0038 sec. for the 37-in. tube, and 0.0063 sec. for the 70-in. tube. Consequently, the 13-in. tube is the only one which permits two maximum pressures to be reached in the injection period. With the 24-in. tube the pressure reaches a minimum and has started to increase when cut-off occurs. With the 37-in. tube cut-off occurs when the pressure has reached a minimum. The 70-in. tube gives virtually a constant pressure during the whole injection period, since the initial wave has just started to decrease at cut-off. As the tube length was increased, the pressure and the lift at the point of cut-off decreased, the bouncing of the stem after cut-off decreased, and with it the tendency for secondary discharges. From these curves and the work of Beardsley (Reference 2), it can be concluded that secondary discharges will occur when spray cut-off occurs during the peak of a pressure wave. These curves also substantiate Beardsley's results (Reference 2), which showed that the spray penetration was slightly increased with an increase in tube length. The penetration of the spray is caused chiefly by the maximum pressure of the initial wave, but is aided to some extent by the pressures which follow this maximum. An examination of the chart shows that the maximum pressures for the 13-, 24-, and 37-in. tubes were very nearly the same. However, as the tube length was increased, the rate of pressure drop after the maximum was reached became less, and the resultant penetration was therefore greater. With the 70-in. tube the maximum pressure was less than with the other tubes, but the pressure remained at this maximum value for a considerable time. The curves show that to obtain a high constant pressure with an injection system of this type the period of injection should be one-half the period of the pressure waves in the injection-valve tube. Stated in another way, the length of the injection tube in inches should be twice the injection period in ten-thousandths of a second.

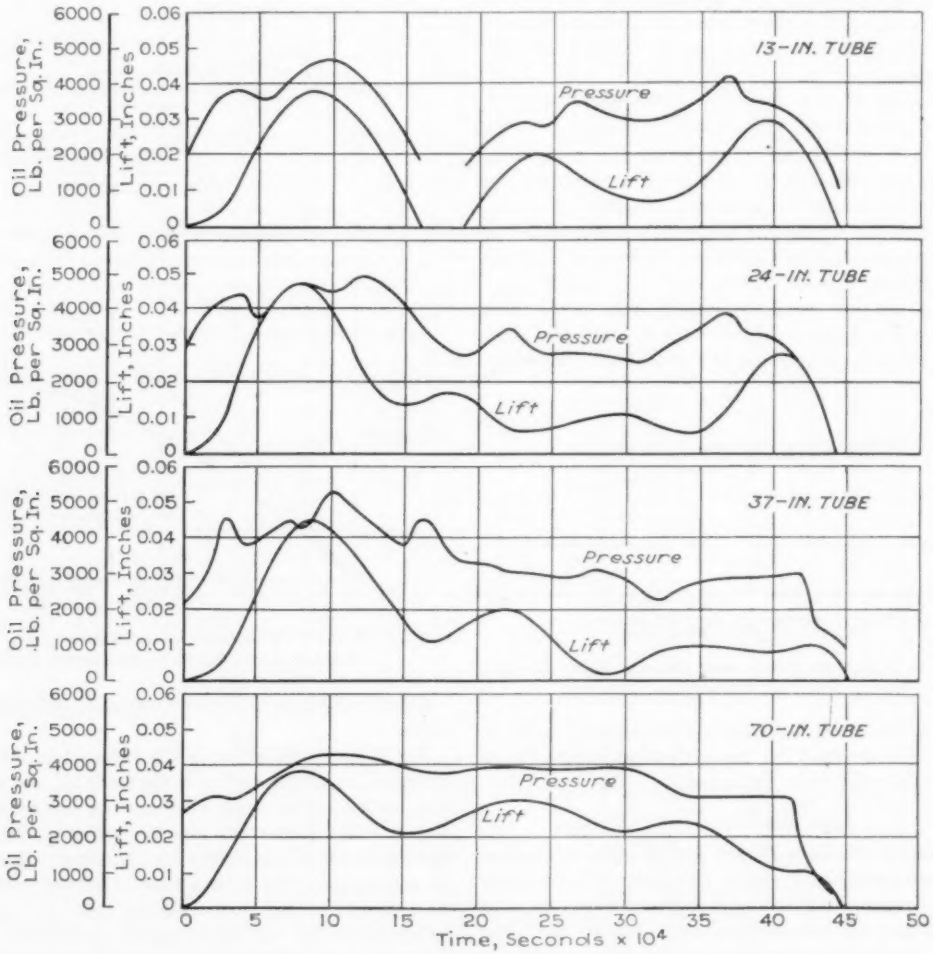

FIG. 12 EFFECT OF TUBE LENGTH ON STEM LIFT AND OIL PRESSURE
(Orifice diameter, 0.020 in.; injection pressure, 3500 lb. per sq. in.; initial pressure, 300 lb. per sq. in.; valve-opening pressure, 2500 lb. per sq. in.)

The effects of the tube length on the effective pressure and fuel quantities discharged are shown in Fig. 13. As Fig. 10 indicates, the effective pressure increases with tube length until

with the 70-in. tube the effective pressure is virtually the static injection pressure. The curves for the weight of oil discharged show that the weight of fuel discharged increases as the tube length is increased. It is interesting to note that with the 70-in. tube in which the pressure remained virtually constant there is considerably less deviation between the computed discharge and the actual discharge. This indicates that the oil flow did not follow the rapid fluctuations in pressure which occurred with the shorter tubes.

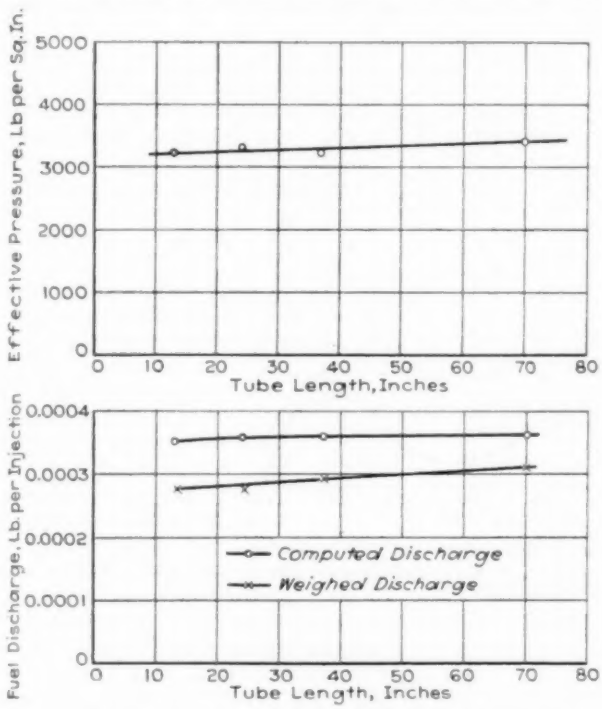

Fig. 13 Effect of Tube Length on Effective Pressure and Fuel Discharged

Effect of Timing-Valve Camshaft Speed and Injection Period. The effect of the timing-valve camshaft speed and the injection period on the pressure fluctuations is shown in Fig. 14. As the timing-valve camshaft speed was decreased, the maximum pressure reached on the first and second waves decreased slightly. The pressure wave was damped out before the third oscillation, so that for the lowest r.p.m. the pressure after the first 0.0045 sec. remained virtually constant at the static injection pressure. Fig. 15 shows the effect of the camshaft speed and injection period on the effective pressure and the fuel quantity discharged. It is seen that the effective pressure dropped from 3300 lb. per sq. in. at 1140 r.p.m. to 3150 lb. per sq. in. at 480 r.p.m. Since the rate of fuel discharge varies as the square root of the pressure, the mean rate of discharge at 480 r.p.m. is only 2 per cent less than at 1140 r.p.m. It can be concluded from these curves that for an injection system of this type the fuel-spray penetration and distribution, except for the effect of air turbulence, and the time for delivering a given fuel quantity are independent of engine speed.

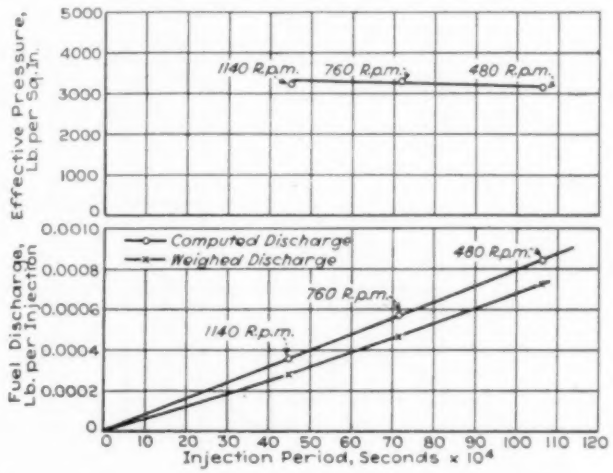

Fig. 15 Effect of Timing-Valve-Cam Speed and Injection Period on Effective Pressure and on Fuel Discharged

Effect of High-Pressure Reservoir Volume. An important factor in the design of a common-rail fuel-injection system is the volume of the high-pressure reservoir. The volume should be of sufficient size so that the pressure drop during injection is small, and at the same time the reservoir should be small enough to be in proportion to the rest of the engine. For the tests already presented the volume was 20 cu. in. A test was made with a 10-cu. in. reservoir. The results of this test in comparison to one with the 20-cu. in. reservoir are shown in Fig. 16. The stem-lift and pressure curves are virtually the same for the two reservoirs. Further research is necessary, however, to determine the minimum high-pressure reservoir

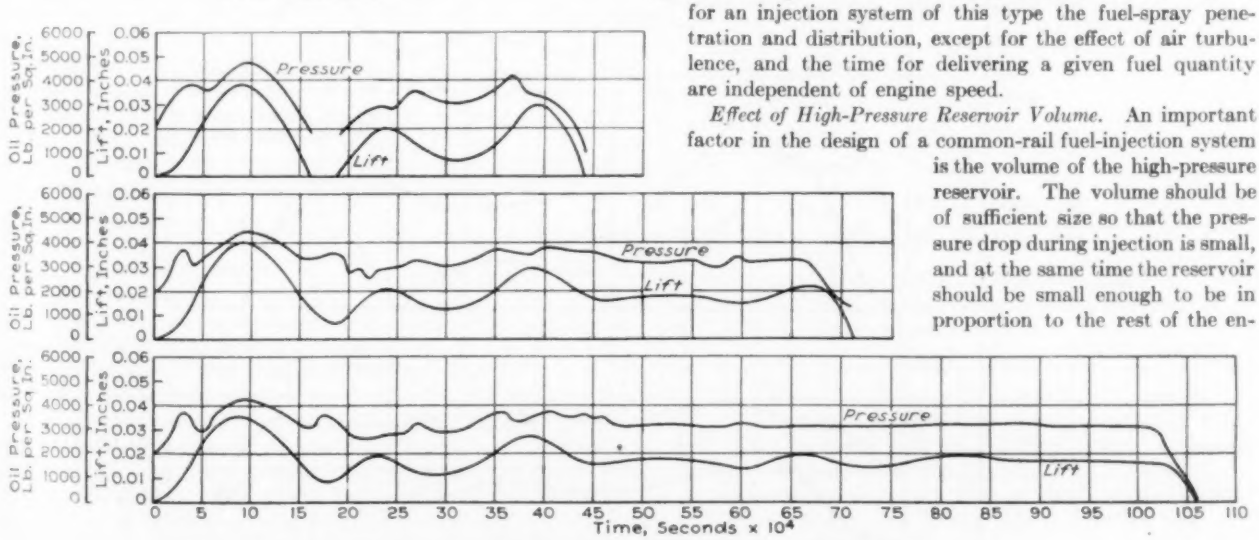

Fig. 14 Effect of Timing-Valve-Cam Speed on Stem Lift and Oil Pressure

(Injection pressure, 3500 lb. per sq. in.; initial pressure, 300 lb. per sq. in.; valve-opening pressure, 2500 lb. per sq. in.; tube length, 13 in.; orifice diameter, 0.020 in.)

volume that can be employed without affecting the pressures at the discharge orifice.

Effect of Initial Tube Pressure. The effect on the stem lift and the pressure variations of the initial pressure in the injection-valve tube before the opening of the timing valve is shown in Fig. 17. As the initial pressure was increased, the maximum pressure decreased, and the pressure curve changed from a wave form to a curve of almost constant pressure. There was, however, little change in the effective pressures, 3100 lb. per sq. in. for the 300 lb. per sq. in. initial pressure, 3300 lb. per sq. in. for the 1000 and 2500 lb. per sq. in. initial pressures. The total injection periods increased with the initial pressure. Therefore, since the setting of the bypass valve remained the same for all the tests, the time lag of injection decreased as the initial pressure increased. In the report on the time lags of injection (Reference 5) it was stated that the time lag was independent of the initial pressure providing the injection pressure was considerably in excess of the valve-opening pressure. The results presented here show that the time lag is dependent on the initial pressure when the valve-opening pressure is comparable to the injection pressure.

When there is an initial pressure in the injection-valve tube

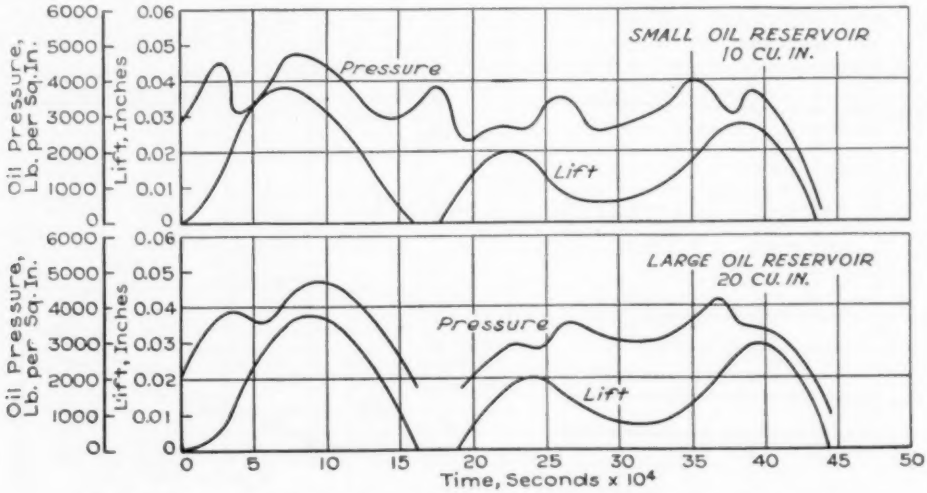

FIG. 16 EFFECT OF OIL-RESERVOIR VOLUME ON STEM LIFT AND OIL PRESSURE
(Injection pressure, 3500 lb. per sq. in.; initial pressure, 300 lb. per sq. in.; valve-opening pressure, 2500 lb. per sq. in.; orifice diameter, 0.020 in tube length, 13 in.)

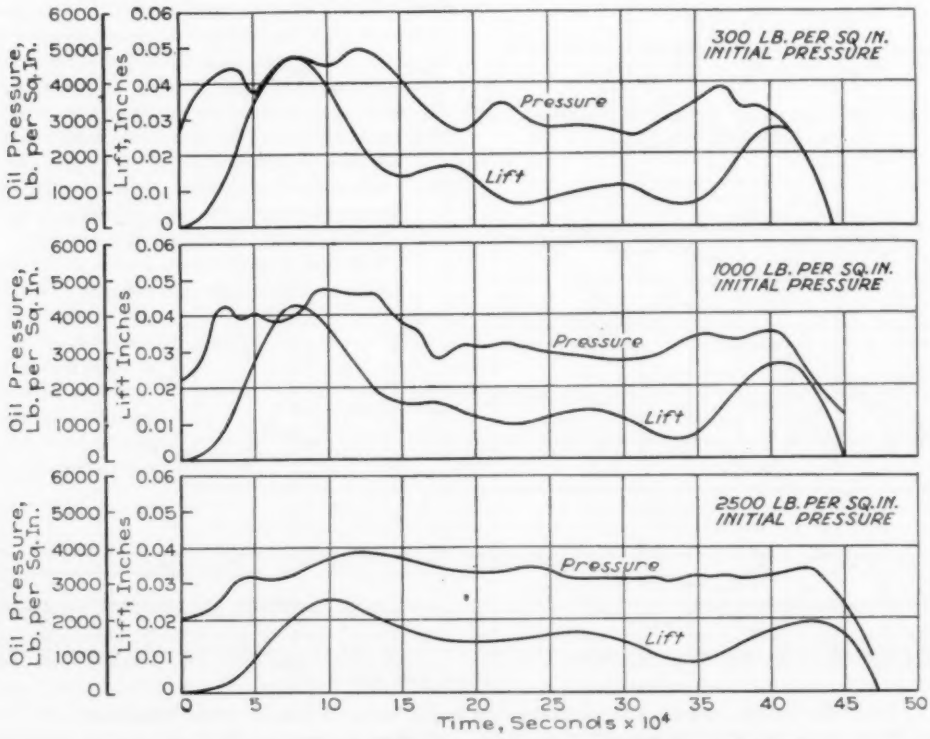

FIG. 17 EFFECT OF INITIAL PRESSURE ON STEM LIFT AND OIL PRESSURE
(Injection pressure, 3500 lb. per sq. in.; valve-opening pressure, 2500 lb. per sq. in.; tube length, 24 in.; orifice diameter, 0.020 in.)

preceding the opening of the timing valve, the same pressure must be left in the tube from the preceding injection. Consequently, the cut-off of the spray would not be as sharp as shown in the chart where the fuel pressure dropped to atmospheric. Beardsley (Reference 3) has shown that the spray penetration increases slightly with the initial pressure. The curves show that this is due to the slower rate of pressure drop after the first wave as the initial pressure increases. It can be concluded from the chart that a high initial pressure in the fuel-injection line does not present any advantages which cannot be obtained by lengthening the injection tube, but does cause a slow cut-off of the fuel spray.

Effect of Injection Pressure. Fig. 18 shows the effects of the injection pressure on the stem-lift and pressure variations. In the first example the injection pressure was less than the valve-opening pressure. However, the first wave from the reservoir built up to a pressure of 2400 lb. per sq. in. and consequently lifted the stem slightly. The valve then remained closed until the second wave reached it. The second wave was of slightly less intensity than the first, but was sufficient to again lift the stem. The period of this wave obtained from the chart was 0.0034 sec. The computed value is 0.0028 sec. With an injection pressure of 2500 lb. per sq. in., the valve opened four times during the injection period. With an injection pressure of 3500 lb. per sq. in., as has been shown before, the valve remained open during the whole injection period. When the injection pressure was further increased to 4000 lb. per sq. in., the pressure and stem-lift curves were of the same form as for the injection pressure of 3500 lb. per sq. in., but of greater intensity.

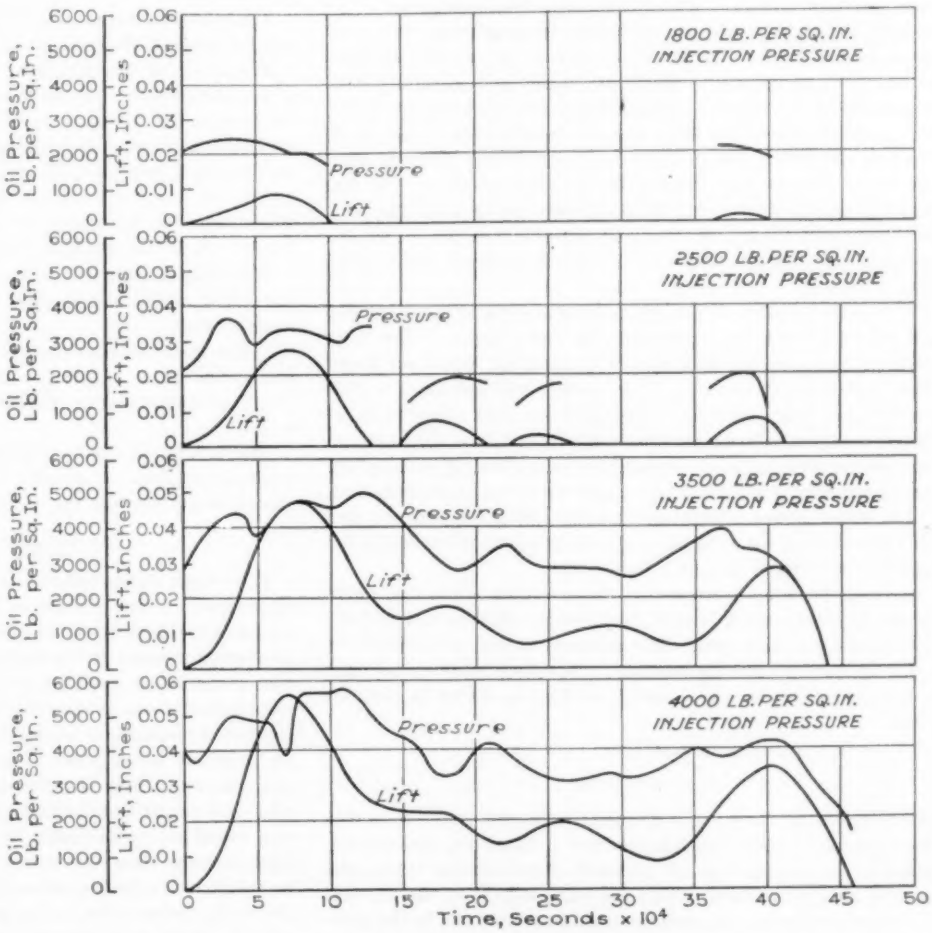

FIG. 18 EFFECT OF INJECTION PRESSURE ON STEM LIFT AND OIL PRESSURE
(Initial pressure, 300 lb. per sq. in.; valve-opening pressure, 2500 lb. per sq. in.; tube length, 24 in.; orifice diameter, 0.020 in.)

The injection pressure to be used in the design of an injection system of this type is based on the time required to get a given fuel quantity into the engine and the spray penetration and atomization desired. The curves show that unless the total hydraulic force on the stem after it is lifted is sufficiently greater than the spring force on the stem when the valve is closed the stem will not remain from the seat during the whole injection period.

CONCLUSIONS

There are two main conclusions to be drawn from these tests: First, with a common-rail fuel-injection system in which the source of high pressure is at some distance from the injection valve, pressure waves will occur at the injection valve. Second, these pressure waves can be controlled in a manner advantageous to the injection system.

Several conclusions can be drawn also as to the design of such an injection system. They are:

1 The injection tube connecting the high-pressure reservoir to the injection valve should have an area at least four times the sum of the area of the discharge orifice.

2 The injection tube connecting the high-pressure reservoir to the injection valve should have a length in inches equal to twice the injection period in ten-thousandths of a second.

3 The instantaneous injection pressures are virtually independent of engine speed, and the injection period in seconds for a given fuel quantity is independent of engine speed.

4 A high residual or initial pressure in the injection tube has no material advantages on the injection of the fuel.

Discussion

P. H. Schweitzer.[2] The writer gladly admits that he learned much from this paper.

In any experimental investigation of this nature the work of the investigator consists of two distinctly different functions: first, to find his data; second, to interpret what he found. The second is more important. One man obtains more useful information from a set of incomplete and inaccurate data than another man from the most complete series of accurate measurements. The making of the tests requires accuracy, thoroughness, and a respect for the facts. The interpretation of the results requires broad view, imagination, deductive logic, and generalization, frequently at the expense of apparently contradicting evidence. One does not often find these characteristics in the same man. Yet it is difficult to assign these functions to two different men, one to lay out the tests and another to interpret them. No one is as competent to interpret the test results as the man who lives and sleeps with them. No one is as competent to lay out experiments as the man who knows how he will interpret them when they are made.

The author displayed considerable skill both in carrying out and in interpreting the experiments on fuel injection. The tests made on pressure fluctuations are interesting, and their interpretations are still more so. The author realized that, at this early stage, when existing information on fuel injection is so scarce, it is better to squeeze the experimental data for practical information than to be too scrupulous by concluding nothing but the obvious from faultless and complete series of experiments.

The writer agrees completely with the author's procedure, and the requests that his comments on certain points discussed in the paper be considered in such a light.

It seems to be established that the bouncing of the fuel valve caused by inertia vibrations is chiefly responsible for the undesirable secondary discharges. The inference would be to make the valve needles as light as possible. But they have to be rigid at the same time, as was pointed out by the writer in his own paper.

In the force-equilibrium equation

$$f = \lambda s + ma \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

f is the hydraulic force and is divided by the area of the stem plus the hydraulic pressure which causes flow. However, the f so computed is the resultant of all hydraulic forces acting (1) on the annular area of the stem, (2) on the seat, and (3) on the tip, and it is equal neither to the pressure before the seat nor to the pressure behind the seat. To compute the discharges from these pressures as done in Fig. 11 is not fully justified. The discharge so calculated will be too small. The pressure drop past the seat is greater with large orifices than with small orifices; therefore the difference in the discharged fuel quantity should increase with the orifice area. That explains the "discrepancy" in Fig. 11 in the opinion of the writer.

The elastic compression of the valve stem was apparently not considered in the calculations. How much did that amount to in maximum?

That the same ratios of orifice area and restriction area produce similar pressure fluctuations is not evident from Figs. 8 and 9.

The effect of the injection tube length on the valve motion is most interesting. If the injection tube length is less in inches than twice the injection period in seconds, one is liable to get undesirable pressure fluctuations. But this cannot hold all the way through, because with very short tubes everything is correct again. It would be interesting to know when the very short tubes begin to misbehave and what small reservoir capacities close to the orifice might help in the injection.

While the investigation reported is very interesting and useful, the writer would like to have it supplemented with these two measurements:

1 The instantaneous pressures in the line taken with a pressure indicator.

2 The instantaneous discharges taken with a spray stroboscope.

The data so obtained would permit the checking of the author's conclusions, and, in combination with the valve-motion diagrams, would result in the drawing of more of them.

Author's Closure

The elastic compression of the injection-valve stem was not considered. Using a value of 30,000,000 lb. per sq. in. for the modulus of elasticity of the stem, and considering the maximum pressure increment on the stem, 4000 lb. per sq. in., the compression of the 2.5-in. stem is computed to be 0.0003 in. Since this compression does not take place instantaneously, its effect on the computed pressures is negligible. As Professor Schweitzer says, an infinitely short tube—that is, one of zero length—would again do away with the pressure waves, since the frequency of vibration would then be infinite. In this case the injection system would have a mechanically operated injection valve, and the high-pressure reservoir would be the controlling factor of the instantaneous injection pressures. In comparing Figs. 8 and 9, the author refers only to the general shape of the curves. The author agrees with Professor Schweitzer that a pressure indicator in the injection line would give interesting results and that measuring the rates of discharge with a spray stroboscope would also extend the scope of the work.

Factors in Diesel Spray-Nozzle Design in the Light of Recent Oil-Spray Research

By P. H. SCHWEITZER,[1] STATE COLLEGE, PA.

NOT every result of oil-spray research can readily be interpreted in terms of nozzle design, but many of them can. In the presence of a bewildering diversity in Diesel spray-nozzle constructions, theory and experimental research furnish some guides that it would be unwise to ignore in laying out spray nozzles.

A fuel-injection system is required to deliver definite amounts of liquid in sufficiently divided sprays of suitable geometrical shape into a number of cylinders accurately timed in relation to the engine cycle. Consequently, the spray nozzle has to perform or help to perform the following duties: (1) Metering, (2) timing, (3) injecting, and (4) spraying.

Metering

Theoretically the nozzle has little to do with metering except in constant-pressure or common-rail systems; practically, however, even with pump regulation the nozzle is a chief factor in metering.

For short orifices with a length up to, say, four times the diameter, the familiar formula[2] $v = c\sqrt{2gp/\rho}$ may be used, taking $c = 0.80$ when the edges, both ingoing and outgoing, are slightly chamfered. The discharge increases with the square root of the pressure and is independent of the viscosity. This means that, for heavy oil and light oil, the same orifice may be used and the discharge will be equal.

For very long orifices the Poiseuille formula should be used, $v = pgd^2/32\,l\eta$, according to which the discharge proportionally decreases when the viscosity of the liquid increases. Now the same nozzle orifice cannot be used for various oils. The heavy oil requires a wider orifice.

For medium long orifices, say 4 to 10 diameters, the square-root formula may be used with a viscosity correction $v = c'\sqrt{2gp/\rho}$, where $c' = \dfrac{1}{\sqrt{\dfrac{32\,l/d}{R} + 2m}}$. R is the Reynolds number; m is a constant with a value 0.5 — 1.12; 0.5 in the vicinity of the critical region.

A practical conclusion is to eliminate the use of nozzle orifices longer than four times the diameter. Then with a change of oil or a change of temperature it is unnecessary to change the orifice in order to get a similar discharge. The discharge of chamfered short orifices can be calculated with the formula $W = 0.80\,a\,2\sqrt{gp/\rho}$.

Another suggestion is not to use square-edged orifices, but always to give a slight chamfer to the edges. The author tried to use geometrical square-edged orifices in order to get reproducible results, but found that the discharge through square-edged orifices varied more than the discharge through chamfered orifices. Small differences in the angle and depth of the chamfer do not make as much difference as unavoidable burrs and irregularities in the square orifices. The author stopped using square-edged orifices even for scientific experiments. In production, a chamber of 0.004 to 0.005 in., at least, should be applied.

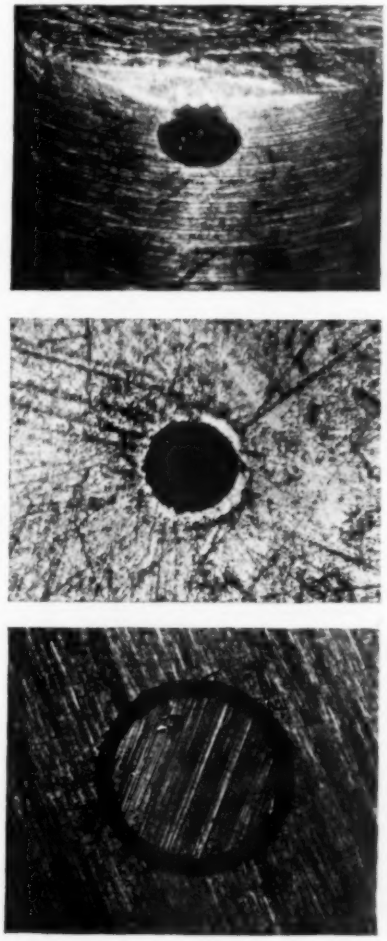

FIG. 1 THREE EXAMPLES OF COMMERCIAL SPRAY-NOZZLE ORIFICES × 24
(Top, poor; middle, fair; bottom, good.)

For determining the diameter of the orifice hole the most practical method is to use a low-power microscope. Every shop which has anything to do with Diesel nozzles should have a microscope of 20 to 30 magnification. With that, one cannot only quickly determine the diameter of the hole, but also can see how perfect the hole is. It is no exaggeration to state that a good part of the Diesel orifices in use should not be in use; they should have been rejected before the assembly, because the holes are crooked, out of round, or partly clogged with metal chips, etc. Fig. 1 shows three commercial orifices in 24 times magnification. An orifice such as the one at the top cannot produce a good spray. Poor workmanship and inadequate inspection of the nozzles are perhaps responsible for more unsatisfactory engine performance than poor nozzle design. The microscope is a good tool for the shop.

[1] Associate Professor of Engineering Research, Pennsylvania State College. Mem. A.S.M.E. Dr. Schweitzer received the degree of Mechanical Engineer in 1917 from the Polytechnic Institute, Budapest, Hungary, and the degree of Doctor of Engineering from Polytechnic Institute, Dresden, Germany. In 1920 he came to this country and became engaged in commercial Diesel-engine development. Since 1923 he has been associated with the Pennsylvania State College, where he is in charge of the Diesel-engine laboratory and is at present conducting an investigation on oil sprays.

[2] NOTATIONS: v, jet velocity; c, coefficient of velocity; g, acceleration of gravity; p, pressure drop; ρ, specific gravity; d, orifice diameter; l, orifice length; η, kinematic viscosity; c', coefficient of velocity with viscosity correction; $R = dv/\eta$, Reynolds number; m, F. Hagenbach constant; W, volumetric discharge.

Presented at the Third National Oil and Gas Power Meeting, at State College, Pa., June 12–14, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Another good shop tool is a simple device shown by the sketch in Fig. 2. A target made of blotting paper with a 1-in. diameter hole in the middle is placed concentrically with and about 20 in. distant from the spray nozzle. One shot against such a target shows whether the nozzle shoots reasonably straight or is off.

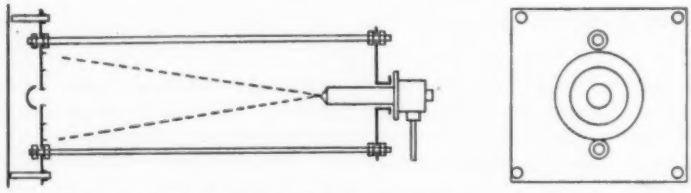

FIG. 2 SIMPLE DEVICE TO TEST CONCENTRICITY OF SPRAYS

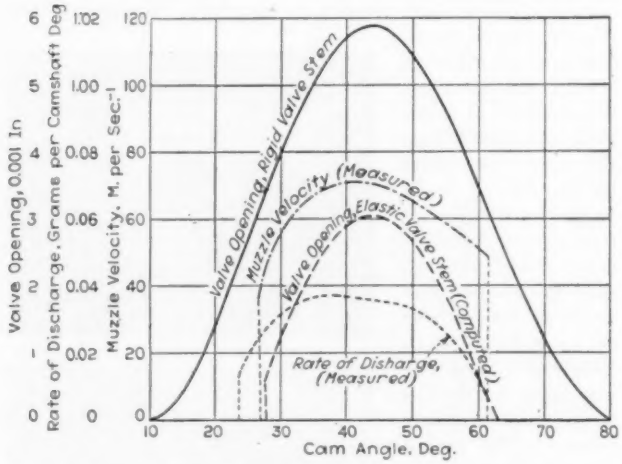

FIG. 3 VALVE LIFT, MUZZLE VELOCITY, AND RATE OF DISCHARGE
(The actual valve opening occurs later, the closing earlier, and the lift is smaller than that corresponding to the cam profile. The elasticity of the valve stem is responsible for the difference. Nozzle, 0.025 by 0.075 in.; speed, 131 r.p.m.; injection pressure, 3000 lb. per sq. in.; chamber pressure, at atmosphere; oil, Gulf heavy black.)

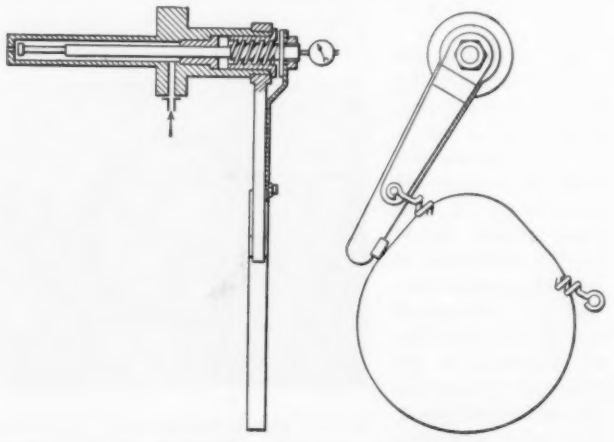

FIG. 4 SPRAY-VALVE MECHANISM

Every nozzle should be tested for concentricity before putting it into an engine, because defectives are very common.

The other factor in metering in a common-rail system is the time element, the opening period of the valve. This is closely related to the timing, and therefore it will be touched upon under that heading.

TIMING

Timing in a common-rail system is ordinarily effected by means of a mechanically operated admission valve actuated by a cam. If the follower follows the cam profile, it is usually assumed that the spray-needle tip follows it also. Therefore the valve opening, closing, and rate of injection are all determined by the cam profile. If anything is wrong with the timing, the first thing blamed

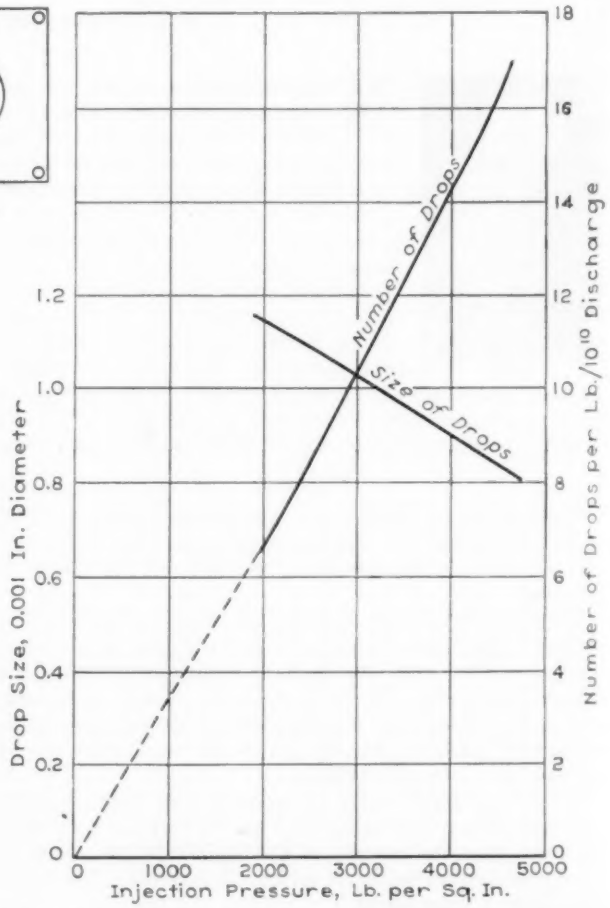

FIG. 5 RELATION BETWEEN DROP SIZE AND INJECTION PRESSURE
(Chamber, pressure, 145 lb. per sq. in.; orifice diameter, 0.024 in.)

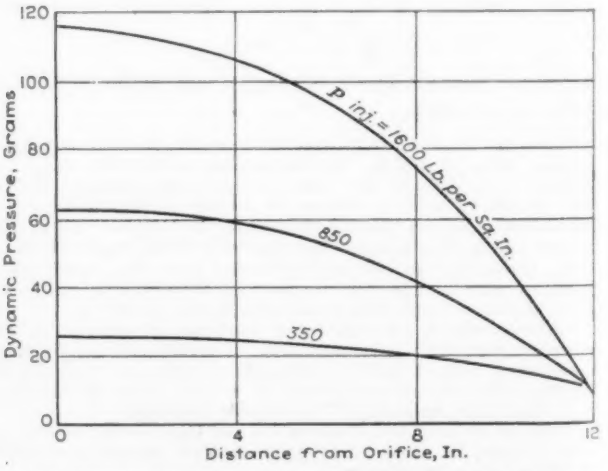

FIG. 6 RIEHM'S CURVES SHOWING RELATION BETWEEN DYNAMIC PRESSURE AND PENETRATION
(Orifice diameter, 0.305 mm.; orifice length, 1.0 mm.; chamber pressure, 300 lb. per sq. in.)

is the cam profile. If the peak pressure on the indicator card is too high, a more gradual rise is given to the cam profile. The cam profile has absorbed a disproportionate amount of attention from the designers and has diverted it from other important factors.

Through close measurements it was found that the cam profile is not responsible for many things attributed to it.

In Fig. 3 the upper curve shows how the needle of the cam-actuated spray valve would have moved had it followed the cam. The rate-of-discharge curve and the muzzle-velocity curve, both of which were determined experimentally, show that the valve opened about 17 deg. later and closed about 17 deg. earlier than it was supposed to, and the valve lift was also correspondingly smaller. This discrepancy was traced to the elastic compression and expansion of the valve stem. Fig. 4 shows schematically the spray-valve mechanism. The rocking arm, etc., was found to be sensibly rigid, and the outer end of the valve stem closely followed the cam. The trouble is that the valve end of the stem does not follow the other end. Under pressure the valve stem compresses like a spring, then it expands again. This change in length is far from being negligible. Initially the valve has to be pressed on the seat so that the high oil pressure shall not make it leak. This compression, for 6000-lb. injection pressure, amounted to about 0.004 in. Now when the cam begins to open, the valve stem expands, and until this initial stem compression is taken up no discharge will take place. Incidentally, this dead motion of the valve stem, during which the outer end of the valve stem moves outward and the inner end stands still, takes up more than half of the legitimate valve lift. This causes a delay in valve opening. The valve also closes earlier because the expanded valve stem reaches the seat sooner. The influence of the valve elasticity on the timing and metering varies with the injection pressure.

The elastic compression of the valve stem in the course of the injection was computed, and the dotted-line curve was obtained for 3000-lb. injection pressure as the theoretical valve lift. It sufficiently checks with the observations.

The beginning of the rate-of-discharge curve is significant. Instead of starting at zero, it starts at a high rate of discharge, indicating that the valve opened suddenly rather than gradually, the cam profile being a gradual curve. What caused the sudden opening? Before the valve opens, the oil pressure acts on a ring surface which is between the stem diameter and the seat diameter. When the valve opens, the oil gets behind the seat and exerts an additional pressure on the valve stem. This increase in pressure is practically instantaneous and causes a sudden push-back of the valve stem with a corresponding sudden discharge. This push-back is quite appreciable even with mechanically operated valves unless the valve stem is rather rigid. With the valve used, it figured as 0.0005 in. at 3000-lb. pressure, as shown in Fig. 3, and offers a partial explanation for the sudden initial rise in the rate-of-discharge curve. With spring-loaded valves this push-back of the stem should be more pronounced and suggests an explanation for a common annoyance in connection with solid-injection Diesel engines. Attempts to eliminate undesirable high maximum pressures by changing the fuel-cam profile did not meet with much success. Making the seat smaller and the valve more rigid is likely to produce the desired effect.

Injecting

For proper atomization, injection is not considered satisfactory unless the jet breaks up instantly upon leaving the spray nozzle. This requirement holds for the narrow cone sprays used in conjunction with precombustion chambers as well as with direct spraying. In order to have the spray already atomized when leaving the nozzle, a spray-tip velocity is needed of not less than about 120 ft. per sec. or an injection pressure of not less than about 1000 lb. per sq. in. for gas oil and accordingly more for heavier oils. If the injection pressure is insufficient, there is a solid core of a certain length, which is undesirable. If the injection pressure drops at the end of the injection, there is after-dripping.

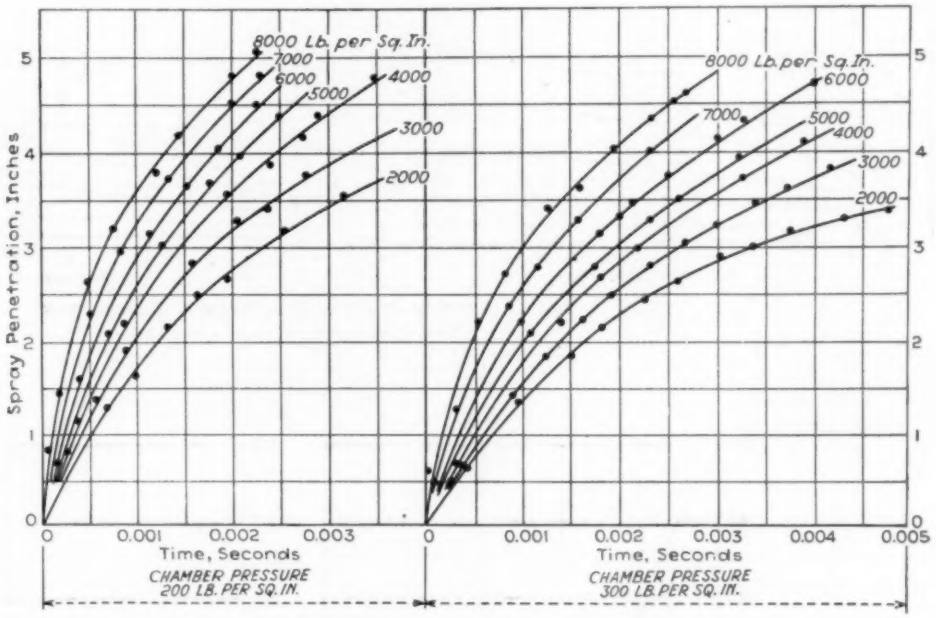

Fig. 7 N.A.C.A. Curves Showing Effect of Injection Pressure on Penetration

In direct-spray injection the jet should not only be broken up, but atomized into sufficiently small globules. According to Dr. Sass, to have good combustion in the A.E.G. engines, 20 per cent of the globules should be not larger than 0.0002 in., 30 per cent not larger than 0.0006 in., and preferably none larger than 0.002 in. Such an atomization can be obtained with an injection pressure of 4000 lb., a chamber pressure of 150 lb. (cold), and an orifice diameter of 0.024 in.

The globule sizes decrease with an increase in injection pressure. The number of globules per unit weight of fuel seems to be in direct proportion to the injection pressure, as shown in Fig. 5, most of the increase being in the small droplets. The average globule diameter for 3000 lb. is about 0.001 in., which is a good figure to remember. For other pressures it may be calculated from the relation mentioned. The drop sizes also decrease with smaller and shorter orifices or with centrifugal nozzles, but not very appreciably. For high-speed engines or engines with little or no turbulence a finer atomization is needed to accelerate combustion. The proper way to obtain it is by increasing the in-

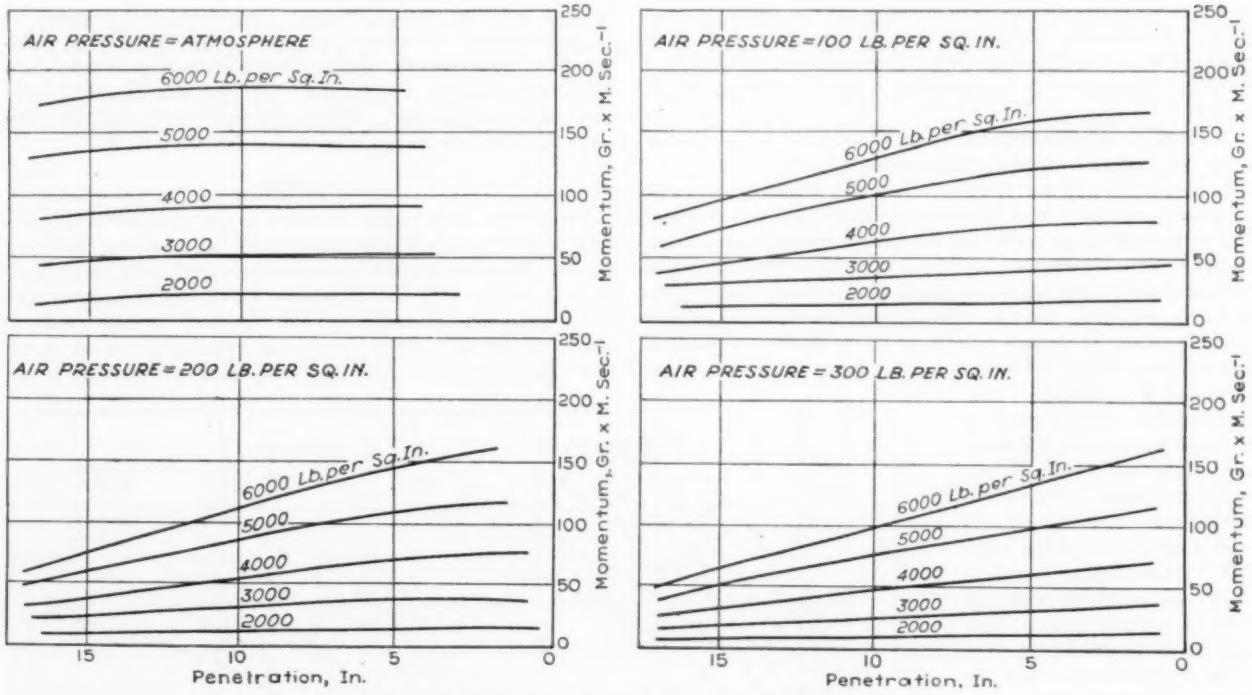

FIG. 8 RELATION OF SPRAY MOMENTUM TO PENETRATION
(Momentum = mass × mean velocity.)

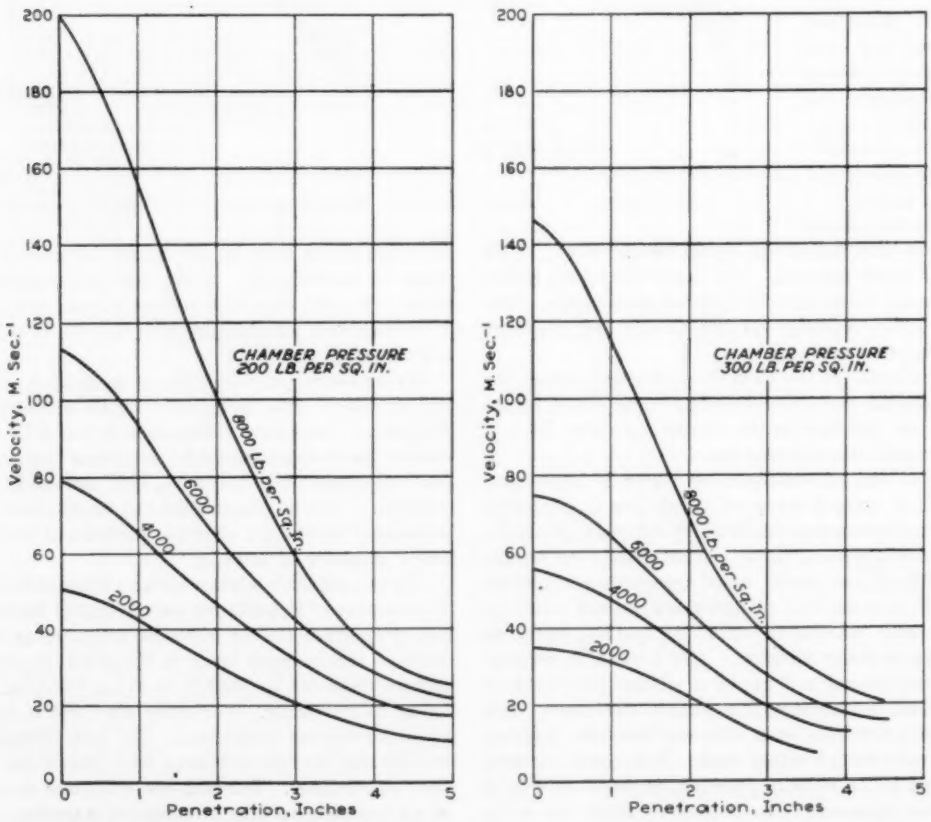

FIG. 9 N.A.C.A. CURVES REPLOTTED SHOWING DECREASE OF VELOCITY WITH PENETRATION

jection pressure. Heavier oils require higher injection pressures to produce the same atomization.

Spraying

If there is no turbulence, the oil spray has to fit the combustion chamber; if there is turbulence, it has to suit the turbulence.

An oil spray of 6000 lb. injection pressure in 200 lb. cold air (the density of which corresponds to 450 lb. hot air) will travel 28 in. With 1000 lb. injection pressure the penetration is about the same. In atmospheric air that spray shoots across the laboratory.

The fact that the spray penetration, precisely the total length of a horizontal spray, is independent of the injection pressure was discovered by Dr. Riehm six years ago (see Fig. 6). The Langley Field experiments, on the other hand, showed the penetration to increase with the injection pressure. That is at least the common interpretation given to the N.A.C.A. data, as shown in Fig. 7. Dr. Sass in his book pointed out the apparent discrepancy between Dr. Riehm's results and those of the N.A.C.A. and believed the former to be incorrect.

In the author's experiments intermittent injection was used instead of continuous injection, which was the strongest objection against Riehm's tests. The momentum of the spray (mass times velocity) was measured at various distances with the De Juhasz recording ballistic pendulum. A sample set of curves is shown in Fig. 8; the others are similar. It will be seen that the momentums drop off about in proportion to the distance, very rapidly at 300 lb. chamber pressure, but unnoticeably at atmospheric pressure. It will be seen that the momentum lines for various injection pressures intersect the horizontal axis practically in the same point. The distance of zero spray momentum, which is nothing else than the total penetration, is 23 in. at 300 lb. chamber pressure, 25 in. at 200 lb., 29 in. at 100 lb., and very long at atmospheric pressure, but the injection pressures does not seem to have much of an influence. The explanation is that the high-pressure spray is atomized into much finer droplets and the higher initial velocity is counteracted by higher air resistance.

These tests vindicated Dr. Riehm. Are, then, the N.A.C.A. tests incorrect? They are not, if interpreted correctly. The N.A.C.A. penetration curves are plotted against time. If by drawing tangents to the penetration curves, velocity is plotted against penetration, the curves shown in Fig. 9 are obtained. They appear quite convergent. It is conceivable that the curves for different injection pressures would have met on the abscissa axis if the Langley apparatus had been suitable to follow them so far. That checks with Dr. Riehm's and the author's results.

The difference in the curvature of the curves between Riehm's, Langley Field's, and the author's experiments can be explained easily. Riehm worked with a continuous spray, and the air set in motion kept the jet from losing much speed near the nozzle; therefore the curves are convex. At Langley they photographed the spray tip, the velocity of which is in the beginning slower, and later faster than the mean spray velocity. Therefore the curves start out convex and later become concave. The author measured what amounts to the mean velocity of an intermittent spray and obtained approximately straight lines.

High-pressure sprays and low-pressure sprays travel about the same distance in compressed air, but the high-pressure sprays travel faster. Therefore to obtain deeper penetration the increase of the injection pressure will not help much, but an increase in orifice dimensions will. However, in case of a high-speed engine the total penetration distance does not tell the whole story. The spray should penetrate and penetrate quickly. In order to make it penetrate more quickly and also to ignite more quickly an increase in injection pressure is quite in order.

Dispersion

To secure good combustion the space distribution of the spray is most important. In a non-turbulent type of combustion chamber the ideal is to distribute the oil in the combustion space so that it reaches every oxygen molecule. On the other hand, every part of the spray should be kept from hitting any surface which is below a certain temperature where it could coalesce or crack. In a turbulence type of combustion chamber the spray has to be directed so that it meets the air flow systematically.

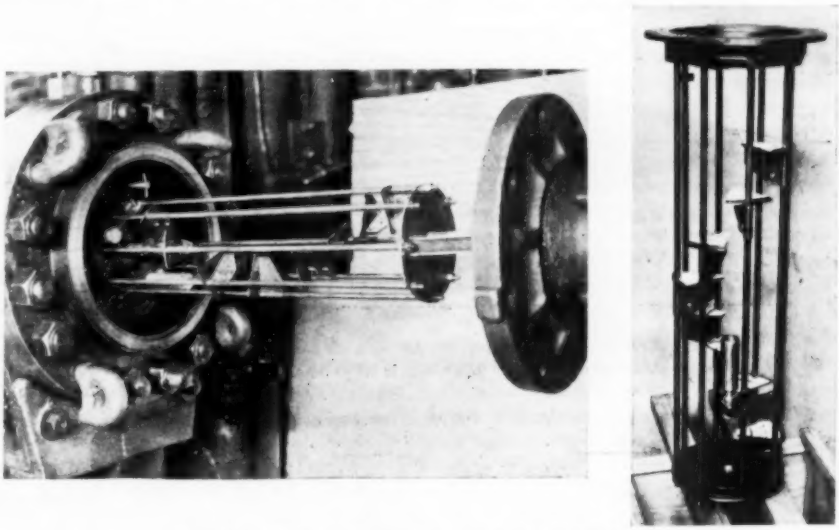

Fig. 10 "Spiral Stairway" for Dispersion Tests
(On the left, in place, before closing the pressure chamber; on the right, removed for weighing the segments.)

Little information was available on spray dispersion when the author started his experiments. At the suggestion of Professor De Juhasz, to determine the spray distribution various parts of the spray were caught in a cage holding segments of blotting paper located at various distances and angles like the steps of a spiral stairway. Weighing the blotting paper before and after injection, the difference indicates how much fuel passes the area represented by the blotting paper. Fig. 10 shows the "spiral stairway" with eight segments. The cage is placed in the pressure chamber, and one single shot gives the fuel distribution in the entire space.

Results obtained by the dispersion tests show that the spray is much wider and shorter in dense air than in the atmosphere, with simple cylindrical nozzles. In atmospheric air at a distance of 12 in. from the nozzle, 57 per cent of the total discharge is still within a 1-in. circle, while in 200-lb. air this percentage is only 8.7. Dispersion tests in the atmosphere have little value.

Fig. 11 gives a clear idea of the spray in compressed air. This refers to a Diesel oil spray at 4000 lb. injection pressure, 200 lb. chamber pressure, and atmospheric temperature, which is produced with a 0.025 by 0.050 in. orifice. A similar picture can be drawn for any spray nozzle and any operating condition. The author's spray is about 20 in. long and has a cone angle of about 25 deg. The heavy lines connect points having the same flux or angular density. If the oil particles would neither evapo-

rate nor be deflected by gravity, the flux lines would be straight and represent the path of flight of the particles. The envelope of the spray would then be a cone like Fig. 12, which shows the same spray in atmospheric air. With the actual spray in dense air this is approximately true near the nozzle, for about 8 in. distance with the author's spray. Then the gravity and evaporation make themselves felt more. The particles on the periphery evaporate or drop and the spray begins to "converge." It also becomes less and less dense and in slightly more than 20 inches it vanishes.

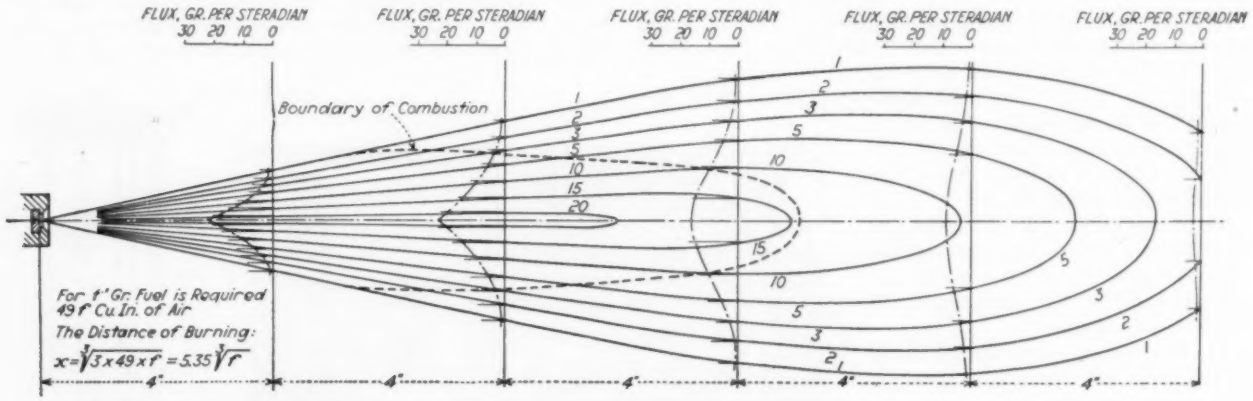

FIG. 11 SPACE DISTRIBUTION OF AN OIL SPRAY INJECTED INTO COMPRESSED AIR, EXPERIMENTALLY DETERMINED
(Orifice = 0.025 in. diameter by 0.050 in.; p oil = 4000 lb. per sq. in.; p air = 200 lb. per sq. in.; n = 202 r.p.m.; Diesel fuel oil.)

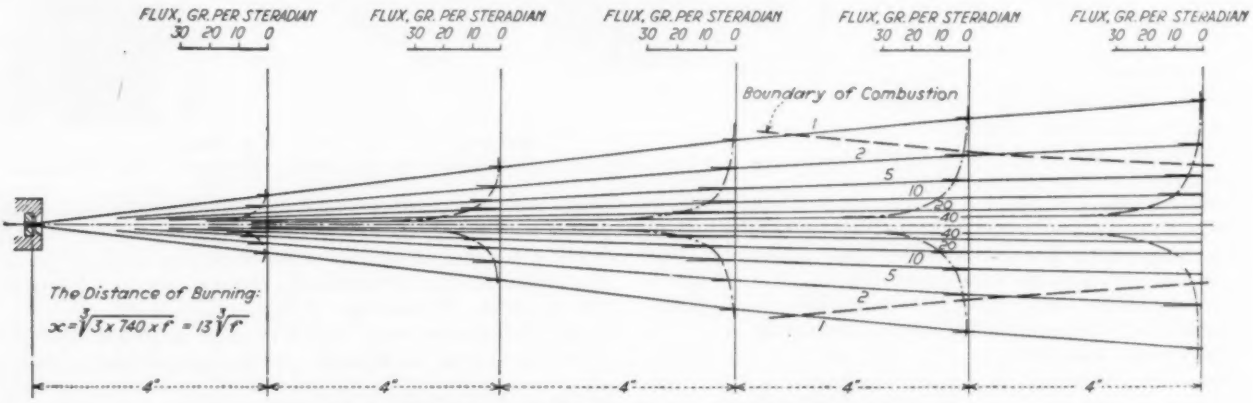

FIG. 12 SAME SPRAY AS SHOWN IN FIG. 11, IN ATMOSPHERIC AIR
(Orifice = 0.025 in. diameter by 0.050 in.; p oil = 4000 lb. per sq. in.; p air = atmosphere; n = 202 r.p.m.; Diesel fuel oil.)

The spray illustrated has a total weight of $^1/_{230}$ lb. and contains, according to Dr. Sass's measurements, 525 million droplets of from 0.0002 to 0.0015 in. diameter, which together have a total surface of 5.4 sq. ft.

It should not be inferred that the spray as shown represents the actual spray formed in the engine. The lighter portions will undoubtedly be torn apart by some turbulence. Some particles will burn before they get very far. In a low-speed engine a good portion of the fuel burns before the injection is over.

When traveling in hot air the oil particles burn. The dotted line marked "boundary of combustion" indicates the distances traversed before all of the oil burns. The adjacent oxygen is just sufficient to combine with the respective layer of oil, under the assumption that combustion begins at the nozzle with zero ignition lag and proceeds in a stagnant air free of turbulence. Therefore the rotational surface corresponding to the "boundary of combustion" is the "theoretical combustion chamber," the envelope of a theoretical combustion. But from a theoretical combustion chamber practical conclusions may be drawn. Spray interferences in a multi-spray engine should be avoided in or near the boundary of combustion if one does not want the drops to starve for the lack of oxygen. Farther away a spray interference is not so objectionable.

Discussion

OLIVER F. ALLEN.[3] Professor Schweitzer is to be congratulated for calling attention to the prime importance of accuracy and uniformity in the manufacture of injection nozzles. The nozzle is of necessity a precision instrument, and its normal and regular functioning is inseparable from good Diesel-engine performance, especially with solid injection.

Equal care should be exercised in the selection of material

[3] New York, N. Y. Mem. A.S.M.E.

for the nozzle itself and for the valve seat, valve disk, and valve stem of the shutoff device.

The author mentions the elasticity of the moving parts. The matter of their weight is quite as important. Both affect the timing. In the mechanism shown diagrammatically by the author a very considerable cam travel is required for relieving the compression in the valve stem, disk, and seat when starting injection and again when closing the valve. The best results as to fuel economy seem to be obtained when the mechanism is such that the speeds of the parts while opening and closing the valve are as high as possible so as to reduce to a minimum the ill effects of the compression, expansion, and surging of both the moving and stationary masses. That is to say, injection should be started and stopped as quickly as possible.

In such engines as the Packard Aircraft Diesel the rate of acceleration of the pushrods, pump plunger, and valve parts is carried far beyond past performances. This is only possible with very light-weight parts of carefully selected materials, accurately and uniformly manufactured.

As the rotative speed of the engine, and consequently the number of cycles per minute, increases, the problem of metering becomes more difficult. With open nozzles and a considerable length of pipe line between the pump or controlling valve and the nozzle, as frequently occurs in slow-speed engines, the breathing of the pipe line, serious pressure surges, and perhaps other variables make the timing of both the beginning and the ending of injection somewhat uneven, especially with changing loads. The manufacturers try to shape and time the cams to compensate for such features. Fortunately at the slow speeds heretofore employed there is time for some irregularity in the injection control.

But what happens when the rotative speed is increased as required for automotive services such as rail cars, locomotives, buses and aircraft? The time available for the functioning of the fuel injection system becomes mighty short.

At, say, 200 r.p.m., a stationary engine, 10 deg. angular movement of the shaft, corresponding roughly to the injection period in a solid injection engine, represents about 0.009 sec. If an equal time is allowed for taking up lost motion, relieving compression in parts, etc., the total time for cam action is about 0.018 sec., if the release is instantaneous at the end of injection, but considerably more if the parts follow through according to the cam profile.

Assuming accuracy of timing of 3 deg. is required for good combustion control, the timing tolerance is of the order of 0.003 sec.

Considering the aircraft motor and assuming twice the angular movement for total cam action, up to the end of injection, and 5 deg. tolerance for good combustion control, at 2000 r.p.m. the time for cam action corresponding to 40 deg. angular movement is only about $^1/_8$ of that of the slow-speed engine. In other words, the total time for cam action of the aircraft motor corresponds to the tolerance of about 0.003 sec. for the accurate timing of the slow-speed machine. In the aircraft engine a 5-deg. tolerance represents about 0.0004 sec. This gives us a fair idea of the accuracy of manufacture, assembly, and adjustment required for the efficient results which have been accomplished with multicylinder injection-type high-speed heavy-oil engines.

To facilitate this result the tendency seems to be toward individual pumps for each cylinder, with the pump, valves, and nozzle all brought as close together as possible.

A. G. GELLALES.[4] The author is to be complimented for the presentation of this paper with such a wealth of information on the effect of nozzle design and test conditions on the spray produced. It represents a serious effort to clear some vexing problems on the subject. Further explanation, however, is in order if some points in the paper are to be fully interpreted.

One of the points is the application of the viscosity correction to the coefficient of discharge equation when a large orifice length to diameter ratio is used. The application of this correction is necessarily limited for a laminar type of flow through the throat of the orifice. This is possible only at the lower range of Reynolds' number with flows of small head difference and high kinematic viscosity. Information is lacking on the critical velocities and head losses for liquid flow through the diameter orifices used with high-speed compression-ignition engines; but if assumed that the critical velocities, through the orifices are similar to those in a parallel tube of the same diameter, and if the equation for critical velocities (Reference 1) established for tubes of $^1/_8$ in. and larger be employed, it will be found that for the Diesel oil, the throat velocities and other conditions identifying these injection-valve orifices, a laminar type of flow through the orifice is a rare occurrence. Take, for example, parallel tubes of 0.010 in. and 0.040 in. internal diameters, which represent about the smallest and largest orifice diameters used with high-speed oil engines. For other conditions, take an injection pressure of 5000 lb. per sq. in., Diesel oil having the properties of that used at the laboratories of the National Advisory Committee for Aeronautics, and oil temperature of 80 deg. fahr. Computations by the above method show the critical velocities to be 250 and 60 ft. per sec. for the smaller and larger tube diameters, respectively. The velocities through the throat of the orifice, unless of an excessive length, are always higher than these values, the ideal velocity with no orifice length being above 900 ft. per sec. From this it is seen, therefore, that before applying the correction suggested by the author of this paper, it should be ascertained whether or not the velocities through the orifice are below the critical region.

The National Advisory Committee for Aeronautics is extending the research on coefficients of discharge to include nozzles with maximum length to diameter ratios of 10. These nozzles will be tested for coefficient of discharge and spray penetration and dispersion. It is hoped that, at the conclusion of these tests, information will be obtained regarding the extent of head losses in the throat of the orifices of varying depths, and whether or not the equations for the larger sizes of tubes are also applicable to these conditions.

The fact that a length of orifice up to about four times the diameter has no effect on the coefficient of discharge, as given by the author, has been confirmed by tests concluded recently by the committee for a 0.014 in. diameter orifice for lengths between one and four times the diameter.

It is regrettable that Doctor Sass should have misinterpreted the results obtained by the National Advisory Committee for aeronautics spray photography apparatus on the ultimate penetration of the spray at different injection pressures. What the National Advisory Committee for Aeronautics spray photographs have shown was the development of the spray with time. The penetrations shown in the curves published in the various reports were those of the spray tip up to a maximum penetration of about 6 in. and at 0.004 sec. after the start of injection at the latest. That there is a difference in penetration with changes in injection pressure during this interval was clearly shown by these photographs. A set of curves of velocity against time, published in a report of the committee by Joachim and Beardsley (Reference 2), has shown the velocity of the spray tip to be the same at 0.002 sec. after the start of injection, regardless of the injection pressure.

[4] Assistant Mechanical Engineer, Langley Memorial Laboratory, Langley Field, Va. Jun. A.S.M.E.

ROBERTSON MATTHEWS.[5] Discussions of oil-engine nozzle design used to refer to the item of the compressibility of the fuel. Professor Schweitzer in his paper refers to the compressibility of nozzle valve stems. Owing to the increasing attempts to operate compression-ignition engines at higher and higher r.p.m., this attention to nozzle valve stems is commendable.

In Professor Schweitzer's paper considerable attention has been given to jet penetration and atomization. It is to be hoped that during the coming year those companies who are supporting this research will encourage by financial support research on directed turbulence in oil engines. The Hesselman engine, the Doxford, and the latest reported work of Ricardo, with his sleeve-valve engine, all have had as a primary item of consideration attention to provision for directed turbulence.

The fuel economy of all those engines is excellent. It is just possible that we have reached the useful peak of attention to fuel injection and penetration. It may be that in using the term oil engine we are concentrating too much on one substance. Though the term would be too indefinite for general use, it might open up new avenues of thought if once in a while, when we are in conference on oil-engine research, we apply to our baby the term "air engine."

As the nucleus of an item in research on turbulence, the writer should like to suggest consideration of the following presentation: Fig. 13 represents a conical jet projected into air, either

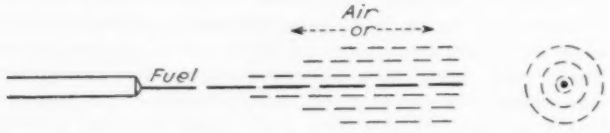

FIG. 13

stagnant or else moving somewhat parallel, either against or with the jet. Consider this jet as a cone made up of layers of fuel particles and fuel vapor.

Now let ignition occur. Combustion will begin not within the cone, where the mixture will be extremely rich, but will be at the boundary layers, and with an increase in pressure. Instead, however, of combustion causing dispersion of the cone of fuel through the surrounding air, the cone may be subjected to compression on all sides and, at least momentarily, suffer contraction. In such a case the benefit of the most desirable atomization could be considerably annulled.

Let Fig. 14 represent a body of whirling air passing a jet as in

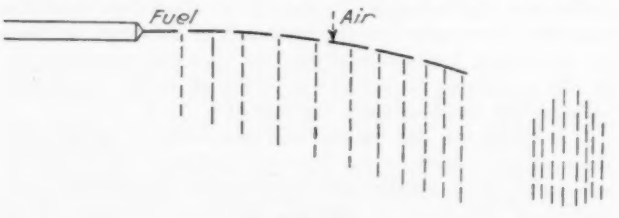

FIG. 14

the Ricardo sleeve-valve compression-ignition engine. As the jet becomes less dense, we may assume the air whirl bends it. But it does more. Instead of developing a cone of spray, the scrubbing action will develop elongated layers of spray and air which, when combustion occurs, will tend to spread out. If the Ricardo engine behaves as he states, that is, the air makes one complete whirl while the fuel-injection valve is open, the aforesaid layers should practically extend entirely around the combustion chamber.

[5] Detroit, Mich.

Turbulence probably explains why different experimenters have obtained good fuel economy with sprays of widely different fineness. That there is room for research on turbulence may be gathered from a comparison of statements concerning the Ricardo and the Doxford engines. Allowance must be made, of course, for the great difference in size and r.p.m. Ricardo speaks of fuel moving toward the center of the chamber because of a lower air pressure there. Regarding the Doxford engine, it is stated that there has been overheating of the cylinder walls due to fuel being thrown toward the walls.

Regarding what Professor Schweitzer says of the workmanship on orifices and proportioning orifices for different fuels, it may be well to consider whether for high-speed operation we are wise in attempting to use heavy fuels and residuals. Where would the automobile industry be today if it had been satisfied to attempt to use fuels that were simply left-overs on the market? This item may prove more significant if we remember that the day of spark ignition is not yet passed.

When with spark ignition and a concocted fuel an engine can be made to yield at 3300 r.p.m. a brake m.e.p. that no oil engine can touch, and—note this carefully—with a volumetric compression ratio of *ten*, there is room for thought.

Should development continue with spark plugs and such high compression, it will be interesting to see how soon the lay mind, with a cramped vocabulary, will be terming such engines near-Diesels.

It is doubtful wisdom for engineers to encourage the lay mind and salesmen to apply the term Diesel regardless of the cycle followed to every engine if it uses compression-ignition. What should we think if to every engine and turbine using vapor expansively some engineers insisted on applying the term Watt?

If the present loose use of the word Diesel continues to be applied to engines of all cycles, it will not be long before every test code, report, periodical, and patent specification, in order to make clear reading, will have to use a reference and footnote whenever the word Diesel is introduced.

The A.S.M.E. has already had much entertainment from such terms as boiler horsepower, efficiency ratio, and total heat. Why add to them? Our engineering diction, as in other professions, should grow with our achievements. It is not common knowledge as yet that compression-ignition for making fire a originated in Asia at some unknown date.

It is hoped such research as Professor Schweitzer represents will eventually give us a *combustion* indicator; something more in keeping with our research on oil engines than is the present engine indicator originated for work on steam engines.

AUTHOR'S CLOSURE

Mr. Gellales of the N.A.C.A. believes that the viscosity correction suggested by the author ought to be applied only in case of a laminar type of flow through the orifice, which is a rare occurrence. It is the opinion of the author that the suggested viscosity correction could be applied to advantage not only to laminar flow, but also to turbulent flow in the vicinity of the laminar region. No error would be caused even from using the formula far away from the laminar region, because the viscosity coefficient so calculated is very close to one for a large Reynolds number and small l/d ratios.

Neither can the author accept the view that a laminar flow in spray nozzles is a rare occurrence. It is rare with the N.A.C.A. because they are using a very thin oil. The viscosity of the N.A.C.A. Diesel oil (see Technical Notes No. 315) is less than the minimum of the A.S.M.E. tentative standard for light high-speed fuel oil. The A.S.M.E. tentative standard for heavy-duty Diesel engines is 10 times as viscous as the N.A.C.A. oil. On the basis of Mr. Gellales' figures with this oil, the critical

velocities are 2500 and 600 ft. per sec., which shows that with A.S.M.E. heavy-duty Diesel oil we actually are having laminar flow in the orifices. The Gulf black oil with which most of the Penn State tests were conducted is more than twice as viscous as the A.S.M.E. tentative standard, and still more viscous Diesel oils are in use. Laminar flow in Diesel orifices is rather normal than a "rare occurrence."

As intimated before, if one is in doubt whether a viscosity correction for the flow calculation would be in order, it is safe to apply the viscosity correction. It will do no harm, because the correction is insignificant in the turbulent region.

Mr. Allen's remarks emphasize the importance of the accuracy of the manufacture of Diesel injection parts and fully coincide with the views of the author.

Mr. Matthews recommends research on turbulence. Such an investigation is very desirable. The N.A.C.A. has done some work lately on this subject. The author would like to call the writer's attention to the fact that equally good results were obtained with turbulent and non-turbulent types of engines. While a familiarity with the characteristics of the oil spray is more important for the designer of an engine using limited or no turbulence than the other type, it is useful to both.

PET-52-1

Automatic Control of Oil-Pipe-Line Stations

First Report of the A.S.M.E. Special Research Committee on Automatic Pipe-Line Pumping Stations

By J. B. FORD,[1] J. B. McMAHON,[2] AND T. D. WILLIAMSON,[3] TULSA, OKLA.

This paper describes a fully automatic oil-pipe-line pumping station built by the A.S.M.E. Special Research Committee on Automatic Pipe-Line Pumping Stations. The station is in operation at the grounds of the International Petroleum Exposition at Tulsa, Okla., and is being used as an experimental laboratory to complete the development of automatic pumping and to fully test out and coordinate the equipment units used in its construction. When this development is completed, the committee will make a final report indicating all changes, and will give a description of the piping and electrical circuits finally resulting from this research.

THE transportation of crude oil as a step in its transformation into the refined gasoline and lubrication oil sold at filling stations is so remote from the consciousness of the layman that it is taken for granted, if indeed it is even given a thought. Oil pipe lining, however, has made great progress since the 1860's, when oil was transported in kegs on horseback and sold for medicinal purposes only under the now legendary name of "Seneca Oil," after the Seneca Indians of New York State who first used it, until today oil pipe lines extend into every section of the United States.

JAMES B. FORD

J. B. McMAHON

T. D. WILLIAMSON

These oil pipe lines reach out from the oil fields of the Mid-Continent and deliver their streams of crude to the Gulf Coast, the Great Lakes cities, and the centers of population on the Atlantic Seaboard. Similarly, the oil fields of California are connected with the West Coast cities by a system of pipe lines extending from southern California to Oregon.

Briefly, the oil is taken from the wells in fields by gathering pipe lines, which may be gravity-flow or pumping systems. From these gathering lines it is delivered into the trunk-line stations, where it is put into the lines under high pressure and sent on its way to the distant refineries.

Oil trunk lines are subject to all of the hazards of the seasons, and due to the dangerous nature and value of their burden, any failure on the line must be checked and repaired immediately. Changes in temperature result in tension and compression strains, and while the lines are protected against these by bends and expansion joints, a weak collar or weld occasionally will give way. Also there is the ever-present menace of river and creek crossings, which result in large breaks. Most oil lines cross the large rivers on the bottom, and shifting bars, quicksands, high water, caving banks, etc., all put strains on the crossing which might result in a break. The pumping-station operators have to be very vigilant and watch the flow charts carefully to detect any breaks and to take the proper steps to prevent excessive loss of oil.

This paper deals with some recent developments in the fully automatic pumping of oil by a system of electrically operated and remotely controlled pumping stations. While the automatic pumping of oil is an accomplishment much to be desired, the protection of the line and station in the event of a line break and the master control and remote supervision of the pipe-line pumping stations has to be developed along with it. In American pipe-line practice the average main trunk line is of 8-in. pipe size and operates at approximately 800 lb. per sq. in. working pressure. In recent years, however, a number of 10-in. and 12-in. lines have been built, and of course there are a number of short 6-in. lines working at pressures as high as 800 lb. per sq. in. The lengths of these trunk lines vary; some are 1600 miles in length, with pumping stations spaced about 40 miles apart along the line. Field gathering lines consist of pipe 2, 4, and 6 in. in diameter and work at more moderate pressures.

Individual pipe-line companies have used to some extent automatic pumping stations with emergency safety devices,

---

[1] Tulsa Branch Manager, Chapman Valve Company. Mem. A.S.M.E. Mr. Ford was born in Georgetown, British Guiana, in 1896. He was graduated from the Massachusetts Institute of Technology in 1921 as Bachelor of Science in Naval Architecture. From 1922 to 1925 he was engaged in aeronautical engineering and research. He became associated with the Chapman Valve Manufacturing Company in 1925, first as mechanical engineer and later as branch manager. For the past four years had charge of their oil-field activities in the Mid-Continent area, with headquarters at Tulsa. He has been active in the standardization of oil-country equipment and the application of improved valve equipment to oil-field practice.

[2] Assistant Sales Manager, The Foxboro Company. Mr. McMahon was graduated from Carnegie Institute of Technology in 1921. He has had two years in selling pumping equipment and machinery to the oil industry and seven years in selling instruments to all phases of the oil industry. He assisted in the layout and design of the preliminary A.S.M.E. experimental station. He has been associated with the Research Committee on Automatic Pipe-Line Pumping Stations since its inception and now is Chairman of the Sub-committee on Instruments.

[3] President, The Petroleum Electric Company. Mr. Williamson was graduated from the University of Arkansas in 1909 and received Master's Degree in Electrical Engineering from the University of Arkansas in 1928. He has been actively engaged in selling electrical equipments and contracting electrical installations for the oil industry since 1917. He assisted in selecting equipments for the first automatic pipe-line station installed in the Mid-Continent field. He has been associated with the Research Committee on Automatic Pipe-Line Pumping Stations since its inception and now is Secretary of the committee. He designed the electrical system for the demonstration station.

Presented at the National Petroleum Meeting, Tulsa, Okla., October 6 to 8, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

such as high- or low-pressure shutdown, and there have been at least two attempts at fully automatic pumping; but these efforts have been hampered and were not complete due to a number of unavoidable handicaps extraneous to the problems of automatic pumping. The present developments under the auspices of the A.S.M.E. and through the cooperation of the International Petroleum Exposition at Tulsa have been brought to a successful completion by the unstinted contribution of experience and ideas by the engineers of the oil companies, the electric-power companies, and the pipe-line equipment companies. All of the work has been done cooperatively by committee action, and the station is set up and operating on the grounds of the International Petroleum Exposition at Tulsa for experimental development and further research. A less complete station was built and exhibited at the 1929 Oil Exposition, and the present very complete installation is being exhibited at the 1930 Exposition in October.

The trend to the use of electric motor drive for oil-pipe-line pumping stations has turned the thoughts of pipe-line engineers to the possible use of automatic control for the electrical stations. Improvements in deep-drilling methods and rapid oil production have resulted in raising large quantities of oil from high productive pools, with a consequent rapid decline of each new pool, and this competition in production has made it necessary to move large amounts of oil rapidly with hardly enough time to build new lines or even to loop the old lines.

The pipe-line companies, in order to keep pace with the rapid production of oil in the new pools, have been forced to add booster stations quickly to established lines in order to increase their capacity, although in many cases loops have been added paralleling old lines. Similarly, in the gathering lines in the field, the gathering stations have had to be large, and yet their usefulness at maximum capacity in any given field does not exceed three to five years. This condition has necessitated the use of equipment which is readily movable to new locations and of low first cost, even though the operating cost might be somewhat higher than more expensive equipment. Accordingly, the pipe-line companies have gone to the use of electrically driven centrifugal and reciprocating pumping units, to cope with the urgency of cheaply and quickly moving the excessive quantities of oil being produced in the flush oil fields. There is a trend also to the use of electrically driven units for main-line pumping stations. This use of electrical pumping has made possible the application of automatic operation and control to the pumping units, and there is every indication that the next few years will see numerous automatic installations.

In the cases where electricity is being used for pipe-line power, the pipe-line companies are looking hopefully to automatic operation for greater economy of power and labor. At an increased cost of approximately 40 per cent electric pumping stations can be made fully automatic and remotely controlled, and this applies equally as well to reciprocating pumping stations, electrically driven, as to centrifugal stations. At this time there is approximately 130,000 electric horsepower in use for oil pumping in the Mid-Continent and Southwest oil districts alone, and this development has practically all occurred since 1926. Nearly all gathering units which take the oil at the end of the gravity lines are now electrically driven, and although not automatic, there is every prospect that a number of them shortly will be made automatic. Also, a number of the main trunk lines carrying oil from the Mid-Continent north and to the seaboards through distances up to 1000 to 1200 miles are interspersed with electrically driven booster stations between the old oil-driven reciprocating pumping stations.

We will now enter into a general description of the Tulsa Automatic Pumping Station, its operation, and the means of accomplishing the things which it does. This unit has been designed for 7000 bbl. per 24 hours at 350 lb. working pressure, and by the operation of certain gate valves and switching from one electric circuit to another it will operate as one or the other of three types—first, as a main-line booster station, using centrifugal discharge pump; second, as a main-line pumping station, using suction pump on the field gathering lines and separate discharge pump into the main line; and, third, as a simple field gathering station, using reciprocating pump, putting the oil into the station tanks.

In the first case, as a main-line centrifugal booster station, the centrifugal pump draws the oil from the station tanks and discharges through the "line" to the tanks at the next station beyond. The reciprocating suction pump in this case is always idle until a break in the line occurs, when due to the increased discharge velocity through a flowmeter, the centrifugal main-line pump is shut down and closed off from the line by the electrically operated gate valves, while the reciprocating pump is started and thrown on to the line, drawing the oil back from the break and emptying it into the station tanks.

In the second case, the centrifugal pump is still used as the discharge pump through the "line," but is supplied by a reciprocating suction pump which draws the oil from the field gathering lines. In the event of a pipe-line break, the discharge pump is shut down automatically and the suction pump is transferred by means of the electric manifold valves to the broken line and withdraws the oil from the break, back into the station tanks.

In the third case, the centrifugal pump is not used. This case represents a simple electrically driven reciprocating pumping station such as is used for field gathering lines. The reciprocating pump picks up the oil and discharges it to the tanks at the main-line station, except in the event of a line break, when the pump is shut down by a low-pressure tripping gage. At the same time the electrically operated manifold valves are switched so that the pump will place suction on the discharge line to withdraw the oil from the break. The reciprocating pump is then automatically started again and runs until the line is emptied.

In all of the three foregoing cases the main-line pumps are started by high oil level in the station tanks. Twin tanks are provided, and the suction is switched automatically from the empty tank to the full tank as soon as one tank is pumped down to the pre-established low level. When both tanks are pumped down to the low level, it automatically shuts the station down and closes the proper valves to isolate the pumps from the oil-filled lines.

Regarding shutdown for line breaks, this is accomplished in the first and second cases (centrifugal discharge) by means of a flowmeter and velocity-actuated switches rather than by a low-pressure tripping device. The velocity-actuated shutdown is necessary for centrifugal pumping because it is possible in the case of a break at some distance from the station for the pressure to be maintained or even increased at the pump discharge. This would make a pressure-actuated shutdown inoperative. However, even though the pressure be maintained at the discharge of a centrifugal pump delivering into an open line, the velocity will always increase rapidly, depending of course upon the size of the break. Similarly, if the centrifugal pumps were operating against a closed gate or otherwise obstructed line, the pressure would be maintained, but the velocity would be reduced, and this would shut the station down.

In the third case, in which the reciprocating pump acts as a discharge, a high and low pressure operated trip is used, because in a reciprocating pump the discharge pressure drops immediately the head on the discharge line is removed, and, conversely, the pressure is increased for an obstructed line. In addition to protection against breaks and line stoppage, there are provided a

number of additional protective features such as shutdown for hot bearings, shutdown for excessively high temperature in station (fire hazard), and other details to be described later. All of these protective features are interconnected with the master control system, which indicates instantly on the central control panel the nature of the stoppage and the cycle of the operation occurring at the station during and after the shutdown.

Mention should here be made of the master control system, although this will be described in considerable detail later. The isolated location of pumping stations and the fact that they operate night and day and independently of weather conditions make it necessary that a system of remote supervision and control be provided. The stations are designed to operate entirely without manual attention, and if a station be automatically shut down and taken off the "line," due to line break, hot bearing, fire, or other trouble, it is necessary that this be known immediately and the cause of shutdown indicated to the line supervisor so that proper steps can be taken to place it back on the line.

The master control system that was developed for the Tulsa Automatic Station will permit of transmitting 80 or more operations and indications simultaneously in either direction over a two-wire copper or iron telephone circuit, or it can be handled equally well over a phantom circuit. It has not been found necessary to use more than ten or a dozen indications in the Tulsa station, but in a fully automatic main trunk line with twenty or more multiple-unit pumping stations, this master control system would doubtless be used to capacity.

The types of pipe-line pumping stations, which have just been briefly described, were selected by the pipe-line representatives, members of this research committee, as practical examples for the applications of automatic controls. The operating conditions and the emergencies which required protection were also outlined by these members. Thus, the automatic pumping station which has been built at the exposition grounds represents the practical operating conditions which will actually be found in gathering and pipe-line stations.

With this paper are flow charts and outlines of the sequence of operations for the types of stations previously described. Reference to these will give a clear understanding of the arrangements of the equipments and the function which each has been selected to perform.

A previous paragraph refers to the several types of protective devices which have been selected, corresponding with characteristics of the equipment with which they are to be used. These selections were made after a considerable amount of investigation, in which all available facts were secured from pipe-line operating superintendents as well as from engineers representing the equipment companies.

Other features of protection for station equipment which are not peculiar to this problem were found necessary. One of these is the starting of centrifugal pumps against closed gate valves, since a serious overload is thrown on the pump motor when the pump is started against an open line. Provision is made that the centrifugal pump will never start except against a closed gate, which is opened in steps by electrical relays through a definite time interval, after full operating pressure has been built up against the gate.

It should be emphasized at this point that it has not been found necessary to build any special equipment for this station. Every piece of equipment selected has been used successfully on other applications. For instance, the motor-operated valves are of a standard make with positive-limit switches on both opening and closing, so that jamming of the valve or the seat to shut down the valve motor is unnecessary; at the same time, if jamming occurs due to foreign material becoming lodged in the valve body, an overload relay protects the valve motor. These valves are illustrated in Fig. 9.

The liquid-level gages used are of standard makes, with ordinary high and low electric contacts. These are illustrated in Fig. 6 at *K* and *LL*. Diaphragm boxes are used. A test was made using a small flow of air continually being bled through the liquid, and the pressure on the air line, which is equal to the liquid head, being transmitted to the gages, which was found unsatisfactory, due to pulsation of instrument needles.

In the following part of the paper reference is made to the flow charts (Figs. 1, 2, and 3) and the diagram of the layout (Fig. 4), the photographic illustrations (Figs. 5 to 11) and Tables 1, 2, and 3, describing the operations in Cases 1, 2, and 3.

The station referred to as Case 1, and shown in Fig. 1 and Table 1, functions as a main-line booster, receiving fluid by gravity or pressure into the station tanks *T*-1 and *T*-2, either from field lines or another booster station. Two tanks are provided enabling the fluid to be received into one while being pumped out of the other. This automatic control is operated by means of liquid-level instruments *LL*-1 and *LL*-2; when a tank is filled to the level setting of the instrument, the motor-driven valves *A*-1, *A*-2, *A*-3, and *A*-4 are operated to so change the pipe connection that the fluid is pumped from the filled tank and flows into the one which is partially emptied. Should either tank be pumped to a predetermined minimum level, as indicated by the liquid-level instruments representing lack of fluid coming into the station, the centrifugal pump is stopped. When the fluid reaches the high-level setting in either tank, the pump is automatically started, and the station continues to function under normal conditions. A centrifugal pump is used to discharge fluid from the station, and protection against broken pipe lines is provided by means of a flowmeter *FM*-1, as previously described. When a break occurs, the centrifugal pump is stopped, motor-driven valves are operated to change the pipe connections, and a reciprocating pump, controlled by a definite time relay, is started, to draw fluid from the broken line and return it to one of the station tanks. At the end of the time for which this relay is set, the reciprocating pump is stopped, motor-operated valves are closed, and an alarm is sounded. The flowmeter *FM*-1 serves also to measure the volume of fluid delivered into the pipe line by this station and to check with the volume received at the next station. Flowmeter *FM*-2 is used to show the delivery to the next station, and operates an electric alarm when a predetermined decreased flow occurs, which would indicate line-break conditions between these two stations. The meter also makes it possible to measure the amount of liquid lost in the break.

Tank *T*-3 represents the receiving tank at the next station. The pumping station represented by Case 2, and shown in Fig. 2 and Table 2, is identical in every way with the station of Case 1, with the exception that tank *T*-3 represents a field storage tank, and the reciprocating pump is used to deliver fluid from this tank to the station tanks *T*-1 and *T*-2. This operation is controlled by means of an electrically wound time switch, equipped with mercury-tube electrical contacts. The period of time during which this reciprocating pump is to operate is set in this time switch. Motor-driven valves are operated to make proper piping connections, and the reciprocating-pump motor is electrically interlocked with the valve *A*-6 on the discharge side of this pump to start the motor when the valve is fully open.

In this case tank *T*-3 serves the double purpose of field tank, from which fluid is being withdrawn by the reciprocating pump, as well as receiving tank at the next station, into which the centrifugal pump discharges.

In case of a pipe-line break, the duty of the reciprocating pump

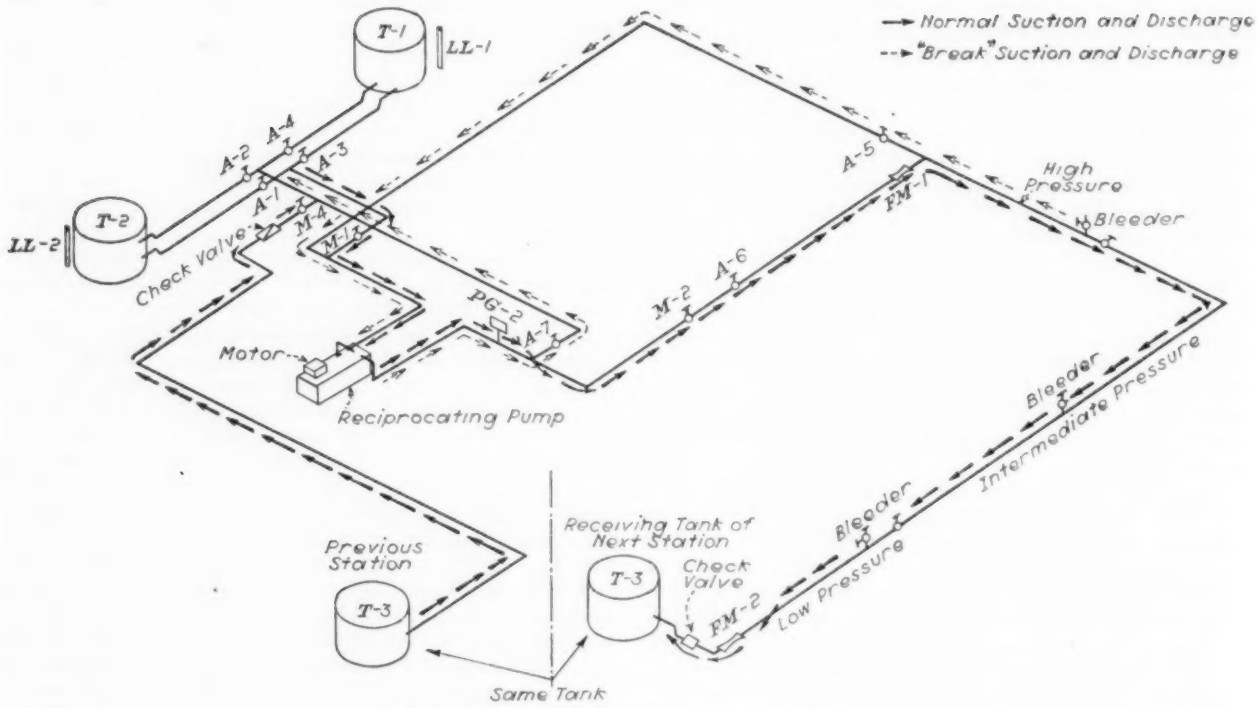

FIG. 1 FLOW SHEET COVERING OPERATION OF CASE 1

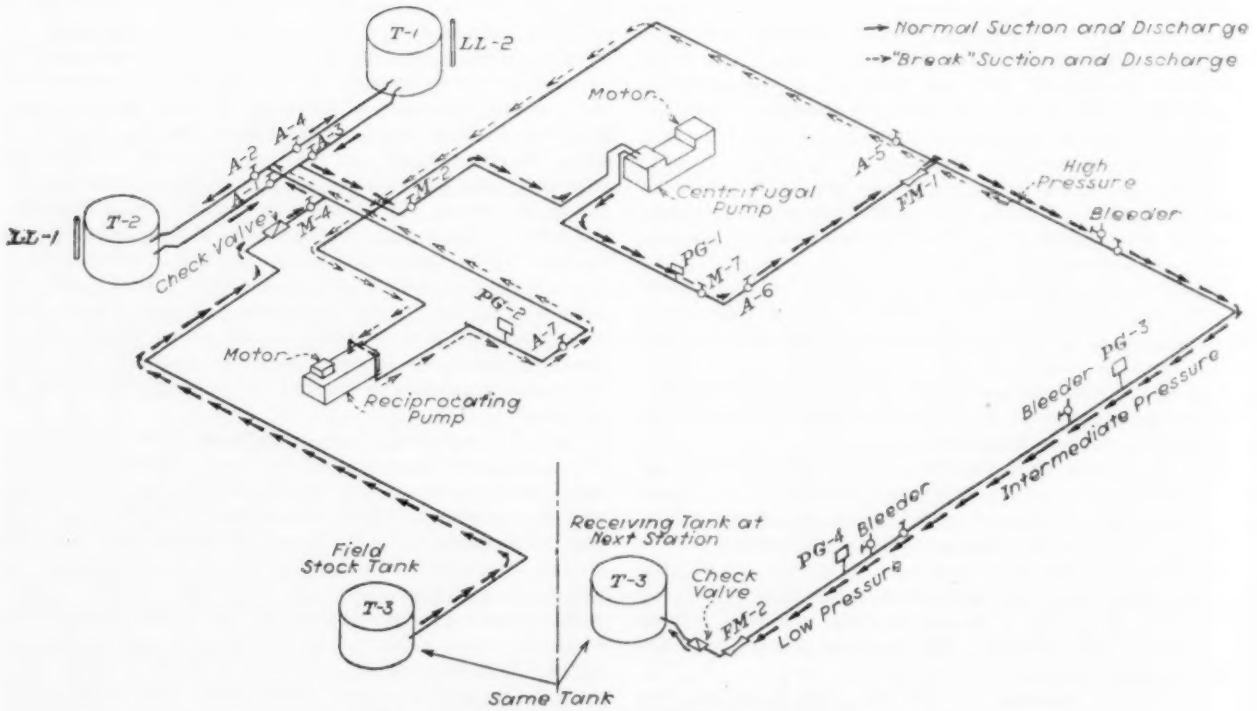

FIG. 2 FLOW SHEET COVERING OPERATION OF CASE 2

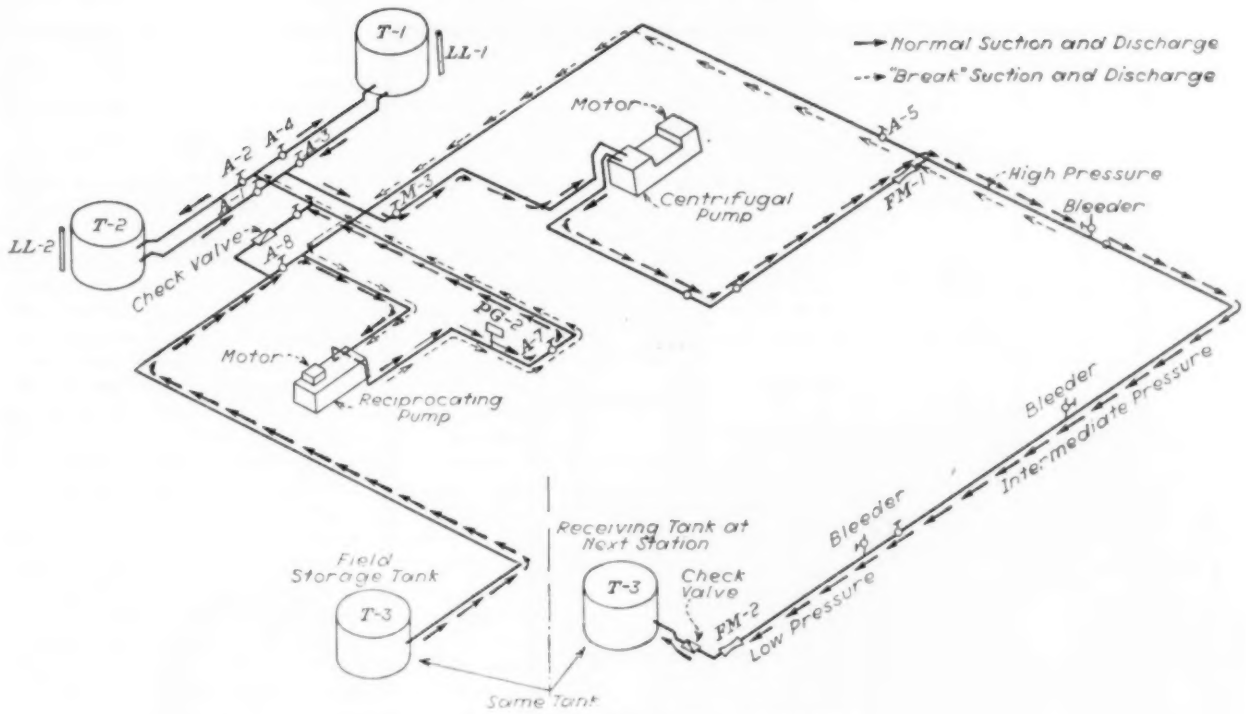

FIG. 3 FLOW SHEET COVERING OPERATION OF CASE 3

TABLE 1 OPERATION OF CASE 1

Centrifugal pump as discharge pump delivering through the "line" to tank *T*-3. Suction pump idle except in event of break.

A-1, *A*-2, *A*-3, and *A*-4 automatically "switch" the tanks, and all operate at the same time and are controlled by the high level in either tank. *A*-2 and *A*-3 close as *A*-1 and *A*-4 open, when *T*-2 fills up; and vice versa when *T*-1 is full.

Position of manual valves to produce this Case 1: *M*-1 closed, *M*-2 closed, *M*-3 open, *M*-4 closed, *M*-7 open.

Automatic valves before cycle starts: *A*-5 closed, *A*-6 closed, *A*-7 closed, *A*-8 closed.

Starting Cycle:

Cause: High level in either tank *T*-1 or *T*-2, caused by opening *M*-4.

Starts centrifugal pump, and when normal operating pressure is reached, as indicated by *PG*-1, *A*-6 starts to open intermittently through a definite time relay, and when *A*-6 is fully open, the electrical circuit on *FM*-1 is energized, which then causes *FM*-1 to function for abnormally high flows.

Normal Operation:

A-6 is fully open, *A*-5, *A*-7, and *A*-8 remain closed.

Normal Shutdown:

Cause: Shutting *M*-4, which causes low level in either *T*-1 or *T*-2.

Centrifugal pump stops. *A*-6 closes.

When a Break Occurs:

From the abnormally high flow through the flowmeter *FM*-1, a relay is operated, which starts *A*-6 closing, stops centrifugal pump, opens *A*-5, opens *A*-7, and (when *A*-7 is fully open) actuates a definite time relay which starts the suction pump and runs it for a definite set time.

At the end of this period, *A*-7 starts to close, stopping the suction pump, and *A*-5 closes.

NOTE: *FM*-1 will be used in this case for not only measuring volume, but also for control work when abnormally high volumetric delivery occurs. *FM*-2 will be used in this case on the receiving end for measuring volumes as well as giving an alarm when a predetermined decreased flow occurs, and measuring amount of liquid lost in break.

TABLE 2 OPERATION OF CASE 2

Centrifugal pump as discharge pump discharging through the "line" to tank *T*-3. Suction operating from tank *T*-3 and instead, in the event of a break, on the discharge end of the line only.

A-1, *A*-2, *A*-3, and *A*-4 automatically "switch" the tanks, and all operate at the same time and are controlled by the high level in either tank. *A*-2 and *A*-3 close as *A*-1 and *A*-4 open, when *T*-2 fills up; and vice versa when *T*-1 is full.

Position of manual valves to produce this Case 2: *M*-1 closed, *M*-2 closed, *M*-3 open, *M*-4 closed, *M*-7 open.

Automatic valves before cycle starts: *A*-5 closed, *A*-6 closed, *A*-7 closed, *A*-8 closed.

Suction Cycle:

Starting: Cause—Time clock or relay or manual switch. *A*-7 and *A*-8 open. When *A*-7 is fully open, suction pump starts.

Stopping: Cause—Time clock or relay or manual switch. *A*-7 starts to close, suction pump stops, and *A*-8 closes.

Starting Discharge Cycle:

Cause—High level in either *T*-1 or *T*-2 or manual switch. Starts centrifugal pump, and when normal operating pressure is reached, as indicated by *PG*-1, *A*-6 starts to open intermittently through a definite time relay, and when *A*-6 is fully open, the electrical circuit on *FM*-1 is energized, which then causes *V*-1 to function for abnormally high flows.

Normal Discharge Operation:

A-6 fully open, *A*-5 closed; *A*-7 and *A*-8 are both open if the suction pump is running; *A*-7 and *A*-8 are both closed if the suction pump is shut down.

Normal Discharge Shutdown:

Cause: Low level in either *T*-1 or *T*-2 or manual switch.

Centrifugal pump stops and *A*-6 closes.

When a Break Occurs:

From the abnormally high flow through the flowmeter *FM*-1, a relay is operated which starts *A*-6 closing, stops centrifugal pump, opens *A*-5, opens *A*-7 (if not open), closes *A*-8, and (when *A*-7 is fully open) automatically transfers the control of the reciprocating pump from the time clock to a definite time relay which starts the reciprocating (suction) pump (if it is not running) and runs it for a definite set time.

At the end of this period (the time set on the relay), *A*-7 closes, the suction pump stops, and *A*-5 closes.

NOTE: *FM*-1 will be used in this case for not only measuring volume, but also for control work when abnormally high volumetric delivery occurs. *FM*-2 will be used in this case on the receiving end for measuring volumes as well as giving an alarm when a predetermined decreased flow occurs, and measuring amount of liquid lost in break.

TABLE 3 OPERATION OF CASE 3

Centrifugal pump eliminated. Reciprocating pump as discharge pump delivering through the line to tank *T*-3, except in the event of a break, when it puts suction on discharge end of line.

A-1, *A*-2, *A*-3, and *A*-4 automatically "switch" the tanks, and all operate at the same time, and are controlled by the high level in either tank. *A*-2 and *A*-3 close as *A*-1 and *A*-4 open, when *T*-2 fills up; and vice versa when *T*-1 is full. When break occurs, however, *A*-1 and *A*-3 both close, while *A*-2 and *A*-4 continue to alternately open and close.

Positions of manual valves to produce this Case 3: *M*-1 open, *M*-2 open, *M*-3 closed, *M*-4 closed, *M*-7 closed.

Automatic valves before cycle starts: *A*-5 closed, *A*-6 closed, *A*-7 closed *A*-8 closed.

The control circuit for Case 3 is now transferred to a separate system of wiring than in Cases 1 and 2, by a double-throw switch.

Starting Cycle:

Cause: High level in either *T*-1 or *T*-2 or caused by opening *M*-4.

A-6 starts to open, and when *A*-6 is fully open, reciprocating pump starts.

Normal Operation:

A-6 is fully open; *A*-5, *A*-7, and *A*-8 remain closed. The reciprocating pump runs continuously.

Normal Shutdown:

Cause: Low level in either T-1 or T-2 due to closing M-4 or manual switch.

A-6 starts to close, and reciprocating pump stops.

When a Break Occurs:

From the abnormally low pressure at the gage *PG*-2, a relay is operated which starts *A*-6 closing, shutting down pump, opens *A*-5, opens *A*-7, closes *A*-1 or *A*-3, whichever of these two valves happens to be open so that the pump is prevented from continuing to take suction from the tanks *T*-1 and *T*-2, and (when *A*-7 is fully open) automatically transfers the control of the reciprocating pump from normal operation and shutdown to a definite time relay which starts the pump and runs it for a definite set time.

At the end of this period, *A*-7 starts to close, stopping the suction pump, and *A*-5 closes.

NOTE: *FM*-1 will be used only to record the volume in this case. *FM*-2 will be used on the receiving end for giving an alarm when a predetermined decreased flow occurs.

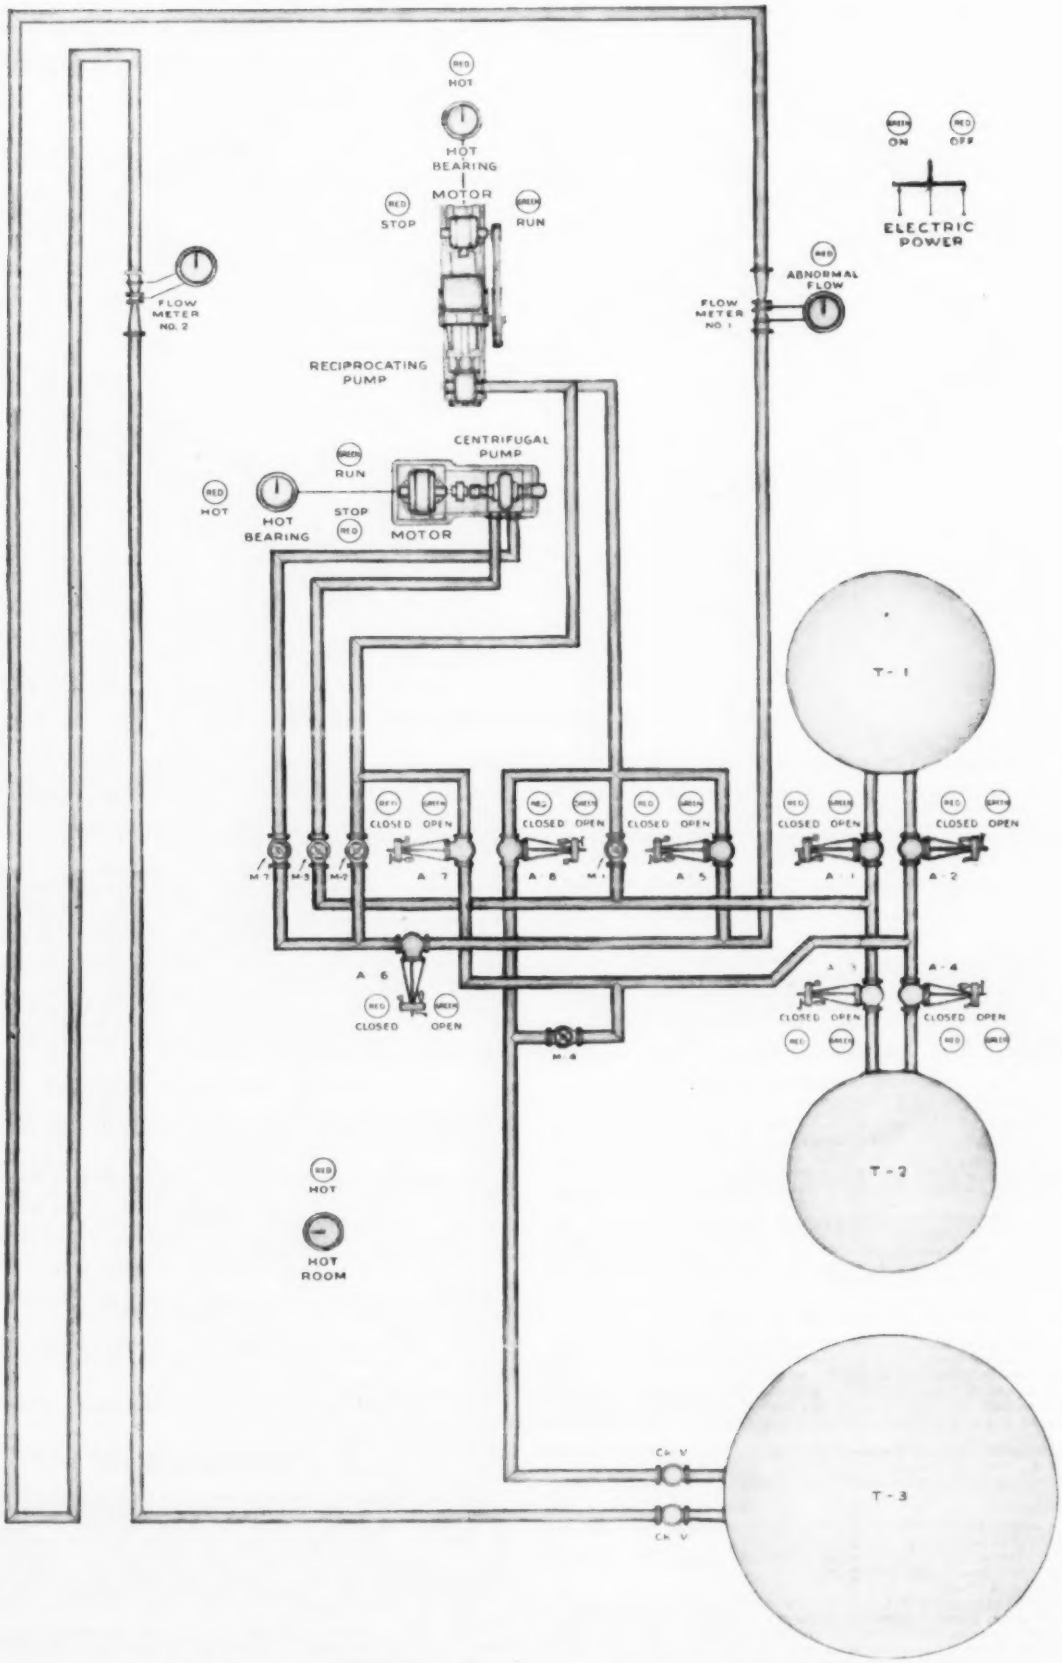

FIG. 4 DIAGRAMMATIC LAYOUT OF AUTOMATIC PIPE-LINE PUMPING STATION

is transferred from that of a field-line pump to a suction pump, to draw fluid from the broken line and deliver it into the station tanks *T*-1 and *T*-2. Necessary changes in the piping connections are automatically made by motor-operated valves.

The pumping conditions represented by Case 3, and shown in Fig. 3 and Table 3, are those of a simple reciprocating-pump station, such as is used for field gathering lines and small booster stations. The centrifugal pump is not used. The reciprocating pump delivers fluid from the station tanks *T*-1 and *T*-2 through the pipe line to tank *T*-3 of the next station. In case of a line break, motor-driven valves are operated to change the piping connections, and the operation of the reciprocating pump is reversed, drawing the fluid from the pipe line and returning it to the station tanks.

In the operation of this station the flowmeter *FM*-1 is used only to record the volume of fluid being pumped and flowmeter *FM*-2 to record the volume being received at the next station. The difference between these two records represents the fluid lost due to a break in the pipe line. Flowmeter *FM*-2 is so equipped as to give an alarm when a predetermined decreased flow, which would indicate a line break, occurs.

The operation of the liquid-level instruments *LL*-1 and *LL*-2 is identical with that described in Cases 1 and 2.

The mechanical equipments and devices described in the preceding paragraphs, such as flowmeters, motor-operated valves, liquid-level instruments, etc., serve as the direct means of accomplishing the automatic operations in this pump station. In order to properly correlate these operations, to tie them together in their proper sequence, and to provide such features as

Fig. 5 Outside View of Automatic Pumping Station

time delay and remote control in their operations, we have employed electrical energy. In this section we will describe the various electrical equipments used, their functions, and the sequence of operations.

The previous section has described in detail the three types of pump stations for which automatic equipments have been applied. Supplementing this description of the mechanical equipments and their operations, the electrical devices used in conjunction with them will be described for each type of station, in the order previously given.

Case 1. The electrical equipments and devices used in this type of station are illustrated in Fig. 6, and may be briefly described as follows:

(*a*) The mercury-type time-delay relays operate on the basis of a solenoid, when energized, pulling up plungers. The time delay is accomplished by means of a cup filled with mercury, having a small hole in the bottom through which the mercury escapes, the maximum time delay obtainable being three minutes.

(*b*) The motor-type time-delay relay, driving through a train of gears, operates contacts the maximum delay of which is 30 min.

(*c*) The electrically rewound time switch, with mercury-tube contacts, serves to energize and de-energize electrically, certain equipments at predetermined times.

(*d*) A mercoid-type pressure switch closes an electrical contact when the pressure setting of the device has been attained.

(*e*) The control stations for the motors of the automatic valves consist of push buttons to "open," "close," and "stop" the valves, with lamps to indicate when electric power is available and also the position of the valves, whether fully opened or fully closed.

(*f*) As shown in Fig. 7, a large number of relays serve to transfer the electrical energy between equipments and to so interlock them as to insure the proper sequence of operations. These relays consist of both the "single pole" and "double pole"

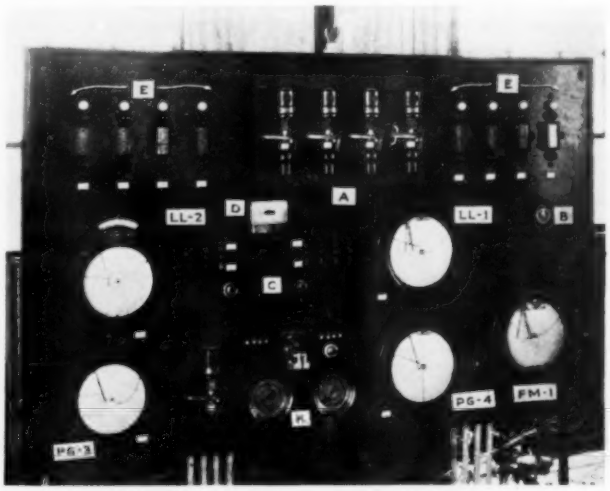

Fig. 6 Front View of Control Panel

types, as well as "single throw" and "double throw," as required to perform their function.

(*g*) The control equipment (Fig. 8) for the 25-hp., 440-volt motor driving the reciprocating pump consists of magnetic-operated contacts installed under oil, to insure safety when used in a gaseous room. Overload protection is provided in thermal-type overload relays which, when operated, actuate a mercury tube, opening the holding-coil circuit for the main contacts and allowing them to open. The motor is controlled at any number of points by opening or closing this holding-coil circuit.

(*h*) The control equipment for the 60-hp., 440-volt motor driving the centrifugal pump is identical with that used in the control of the 25-hp. motor, except for the larger capacity.

(*i*) The motor used for driving the reciprocating pump is standard squirrel-cage type, rated 25 hp., 440 volt, three phase, 60 cycle, 1200 revolutions.

These circuits connect with the electrical contacts which are provided in the various meters and instruments previously described and which become a part of the electrical system.

Operation of Station

The starting of the discharge pump is accomplished when the liquid level in either of the station tanks *T*-1 or *T*-2 reaches a predetermined setting, as indicated by the liquid-level instruments. The closing of the electrical contacts in these instruments, through a system of interconnecting relays, energizes the holding coil of the motor control, and the 60-hp. motor and centrifugal pump are started. This pump operates as long as there is fluid in either station tank *T*-1 or *T*-2, and is stopped when the fluid in either tank reaches a predetermined minimum

level as indicated by the liquid-level instruments. In this case the electrical contacts in these instruments, closing the circuit through relays, de-energize the holding coil of the motor control, and the motor and pump are stopped.

As outlined in the previous section in connection with the operation of the station, certain motor-operated valves are opened or closed to accomplish the desired results. These operations are performed electrically, by interconnecting through relays the allied equipments with the "open" or "close" buttons of the valve-control stations. The results obtained are similar to an operator having closed the corresponding button of the motor-control station.

An explanation has been given of the several reasons for starting a centrifugal pump against a closed valve, which should be opened

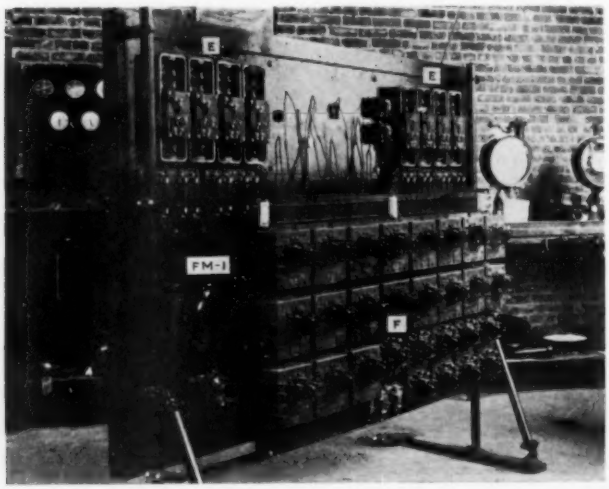

FIG. 7 BACK VIEW OF CONTROL PANEL

gradually, allowing the pressure to build up on the discharge side of the valve, equal to that between the pump and the valve. This result is accomplished automatically by means of a mercury pressure switch (item *d*) and three mercury-type time relays (item *a*). The mercury pressure switch is connected in the main pipe line between the pump and motor-operated valve. Referring to Fig. 6, when the circuit is closed, energizing the coil of relay 1, this closes within one second, energizing the opening contact of the valve control. At the same time the coil of relay 2 is energized and within ten seconds closes contacts which causes the valve to "stop." At the same time the coil of relay 3 is energized, and within twenty seconds the "open" contacts of the valve control are energized, and the valve starts to open. At the same time the coils of both relays 2 and 3 are de-energized and automatically reset. The coil of relay 2 is again energized, and within ten seconds causes the valve to "stop." Thus this sequence of operations, opening for ten seconds, stopping for twenty seconds, is continued until the valve is fully open, when the limit switch in the valve mechanism causes the coils of all three relays to become de-energized, and they are reset, ready for another opening operation.

Should a break occur in the line beyond this station, the sequence of operations would be performed as previously described in detail. The electrical functions in this connection are outlined as follows: Excess flow of fluid through the flowmeter *FM*-1 closes an electrical contact, which, connecting through relays, energizes a motor-driven-type time relay. This relay is set to operate for a maximum time which would be required to empty the pipe line. The motor-operated valve on the discharge side of the centrifugal pump is closed by automatically operating the valve-control station, and those on the suction and discharge sides of the reciprocating pump are opened by similar means. When the motor-operated valve on the discharge side of the reciprocating pump is fully open, a relay is closed by the limit-switch mechanism in the valve, thus allowing the contactor in the motor-control equipment to close, starting the reciprocating pump to operate. This pump will then operate to draw the fluid from the pipe line, discharging into the station tanks, for the period of time set in the motor-operated time relay. At the end of this time the motor is stopped, and all of the motor-driven valves on the discharge side of the station are closed. At the time a break occurs, followed by the foregoing sequence of events, an alarm relay is also closed, to notify the superintendent or pumpers, at distant points, of the trouble. Also a relay is actuated which prevents the station from again starting automatically until the break has been repaired and the relay reset by hand.

Case 2. The operating conditions of this station are similar in every way to those of Case 1, with the exception that the reciprocating-pump unit is called upon to serve a double purpose. In addition to evacuating the pipe line in case of a break, the operation of which has been described under Case 1, in this case the reciprocating pump is to be used to "boost" fluid into the pump-station tanks from field or flow tanks. The latter operation is to be performed during certain fixed hours of the day or night. For this control an electrically rewound time switch (item *c*) is utilized. When this pump is to be used for

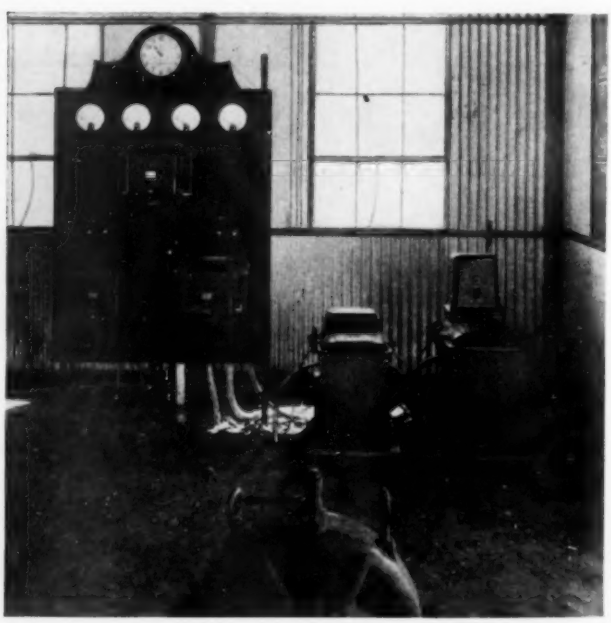

FIG. 8 MOTOR-CONTROL PANEL AND MOTOR-STARTING EQUIPMENT

bringing fluid from the field tanks, the electrical contact in the time switch having closed, motor-operated valves on the suction and discharge sides of the pump are automatically opened. When the valve on the discharge side of the pump is fully opened, a relay operated by the limit switch of the valve mechanism causes the contacts in the motor control to close, and the motor and reciprocating pump are started. At the end of the time set in the time switch, the valves on the suction and discharge sides of the reciprocating pump are automatically closed. When the valve on the discharge side of the pump starts to close, a relay actuated by the valve-limit switch causes the contacts of the

motor control to open, and the motor and reciprocating pump are stopped.

In case of a break in the pipe line, control of the reciprocating pump and motor is transferred from the time switch to the motor-operated time relay, and at the end of the service of emptying the pipe line, the entire station is shut down until the trouble is cleared and a relay reset by hand. All other operations and automatic controls are otherwise identical with those described under Case 1.

Case 3. In this station the centrifugal pump is eliminated from all operations, only the reciprocating pump being used.

Normal starting and stopping operations are performed from the same causes and by the same means as described under Case 1.

In the section covering mechanical equipment, a detailed explanation is given of the equipment required to protect reciprocating-pump stations against broken pipe lines. A description of the electrical equipment follows. It must be understood that this is a fully automatic station, without operators; hence a different type of equipment is required from that used in stations where operators start the pumps, and the protection required is semi-automatic.

As explained in a previous paragraph, a break in a pipe line operated by reciprocating pumps causes a very rapid drop in pressure; hence successful protection may be accomplished by means of pressure gages.

This protective equipment consists of two pressure gages with scales corresponding to the normal line pressure, each having two electrical contacts and two relays, one of which latter is hand reset. This equipment is illustrated in Fig. 6. When the automatic station is first started, the pressure of the discharge side of the pump is zero. In order to prevent the tendency of the motor to shut down by low pressure before the station is started, two pressure gages are necessary, one of which is called the "setting" gage and the other the " tripping" gage. The operation of these gages is as follows: The high-pressure contact point of the "setting" gage is adjusted to the normal line pressure of the pipe line. When pressure is established on the discharge side of the pump, the needle making contact with this setting energizes the

FIG. 9 MOTOR-OPERATED GATE VALVES

coil of a relay, which, when closed, connects the electrical contacts of the "tripping" gage. Then if while the pump is running there should be a break in the pipe line, the needle of the "tripping" gage makes contact with the low-pressure setting, energizing the coil of a time-limit hand-reset relay, which opens the holding-coil circuit of the motor control, stopping the motor and closing the electrically operated valves on suction and discharge, and at the same time closing an alarm circuit notifying the pipe line office, some distance away, that trouble has occurred. A time-delay relay is used, as it is found that in starting a reciprocating pump there is a tendency for the pressure to build up and then to drop back to a low point for a few seconds, finally establishing the operating pressure. If an instantaneous operating relay were used, the motor would be stopped during this period of momentary low pressure. In case of a plugged pipe line or the closing of a valve on the discharge side of the pump, the needle of the "tripping" gage would make contact with the high-pressure setting terminal, operate the time relay, and stop the motor and pump as outlined.

A hand-reset relay is used to prevent restarting of the pump and motor.

MASTER CONTROL SYSTEM

The pump station described in this paper is fully automatic, capable of taking care of every emergency condition which might arise, and to fully protect all of the equipment. However, pipe-line engineers and superintendents have definitely decided that it is necessary for an operator at some point to be fully conversant with the conditions which exist in these automatic stations, so that in case of line breakage or trouble having developed in the machinery, repair crews could be dispatched immediately.

FIG. 10 FLOWMETER *FM*-2 ON DELIVERY END OF PIPE LINE

This master control system has therefore been designed to fulfil the requirements outlined and to supplement the automatic operation of pipe-line pumping stations.

Briefly, this system, used in conjunction with any two-wire telephone circuit, serves to signal from the automatic station to the central control point the exact conditions which exist as regards open or closed valves, stopped or running pumps, hot bearings, etc., and to enable the operator at the central control point to have complete control over the operation of the equipments at the automatic stations. A summary of the operations to be performed by the master control system is as follows:

To be signaled from automatic station to central control point:

(1) Open or closed position of all motor-operated valves
(2) Running or stopped motor-pump units
(3) Electric power "on" or "off"
(4) Temperature of pump or motor bearings when reaching a predetermined maximum value
(5) Pump-room temperature when reaching a predetermined maximum value (indicating a fire)
(6) Station shutdown due to loss of suction pressure
(7) Station shutdown due to excessive flow of fluid through pipe line (indicating broken line in reciprocating-pump station
(9) Indication of normal suction pressure
(10) Indication of normal discharge pressure
(11) Additional indications may be provided to meet operating conditions.

Control which may be provided from central control point to automatic station:

(1) Opening and closing of motor-operated valves
(2) Starting and stopping of motor-pump units
(3) Opening and closing of main electric service switch
(4) Listening-in connection for telephone in pump room of automatic station, enabling operator to hear what is taking place
(5) Repeater service, enabling operator to have repeated a signal which was not received satisfactorily
(6) Any automatic operation at the pump station may be directly controlled by means of the master control system.

Method of Operation

This control is accomplished by means of impulse switches operating impulse relays in conjunction with polarized, lockout,

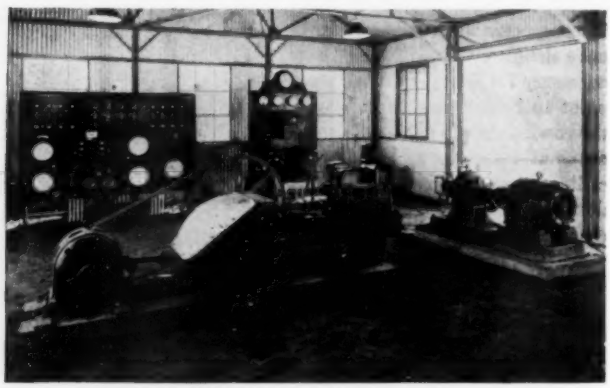

Fig. 11 Inside View of Automatic Pumping Station

and interconnecting relays. Signaling from the automatic station to the central control point is accomplished by means of a small motor driving through reduction gears, rotating the impulse switches, all of which with the exception of the operation to be signaled, are "locked out" of the electrical circuit.

A pair of telephone wires, preferably copper, serve as the electrical connections between the automatic station and the central control point. Seventy-eight operations may be dispatched over these two wires in either direction, and a signal may be sent in both directions at the same time without interference.

Control Switchboards

The control panel at the central control point consists of a metal etching mounted on an ebony asbestos panel representing an actual picture of the equipment and arrangement in the automatic station. The piping, valves, pumps, motors, etc., are shown in their actual relations to each other; red and green signal lights are located directly above the equipment the condition of which is to be indicated, and control switches are located directly below the equipments to be operated. This is all shown in Fig. 4. Thus the operator at the central control point, by glancing at this panel, knows the actual condition of all the equipments, and if any dangerous condition arises, such as a hot bearing, an alarm is sounded, in addition to the turning on of a red light.

The instrument board at the automatic station contains the thermal indicators, flowmeter, pressure gages, and other instruments and various types of relays used in connection with the master control system.

Electrical energy is supplied from 130-volt batteries, and either primary cells or storage batteries may be used.

Actual tests have been made proving that signals may be successfully transmitted over an equivalent of 800 miles of No. 8 (B. & S. gage) copper wire, simplex and phantom circuits, and with a high-resistance ground connection to the circuit.

Experiments are being conducted in connection with the use of a gas indicator device to signal the condition of an oil leak in the automatic pump station, the accurate gaging of tanks from distant points, and the transmission of pressure readings from that automatic station to the central control point.

It is always difficult to sustain a reader's interest in a detailed technical description. In entering into the details of the Tulsa station, we have done so realizing that the pipe-line industry is seriously interested in these experiments, and if the details have lessened the readability of this paper, we trust that it may be pardoned for that reason. In closing, we wish to point out that the work described has only been in progress twelve months, and while the A.S.M.E. Special Research Committee on Automatic Pipe-Line Pumping Stations feels that much has been accomplished, there is yet a great deal to be done.

One of the penalties accompanying the use of automatic equipment of any sort is the occasional failure of some minor part which interrupts the whole system. The only solution for such failures is continual improvement of the failing parts, until they are as serviceable as all other parts. There are doubtless a number of weak links in the Tulsa station which would develop failure only after actual continuous operation in a pumping line. Further application of this system to main lines, with a corresponding development of the equipment, is here suggested, and it is the expectation of this committee to continue this work. There are at this time two major pipe lines using parts of this system on their loops.

There are still two other branches of the pipe-line industry which have not been touched in these experiments, but which can be improved by automatic operation, and they are the pipe-line transportation of refined gasoline and the piping of natural gas from the Mid-Continent gas fields to the Eastern and Northern centers of population. The natural-gas pipe lines are becoming one of the nation's important public utilities, and it is already evident that pure competition and the necessity for reducing the cost of piped natural gas are going to force the natural-gas companies to automatic operation. We will leave the subject here. It has been said that no good work is ever fully completed, and that is true in this case. If we have left with those who are connected with the oil and natural-gas industries a desire to carry on these efforts in their own organizations or in collaboration with this A.S.M.E. committee, our efforts will have been amply rewarded.

PET-52-2

Lubrication of Power Cylinder of Diesel Engines and Causes of Cylinder Wear

By J. B. HARSHMAN[1] and JOHN M. McGREGOR,[2] TULSA, OKLA.

To determine methods of reducing Diesel cylinder-liner wear and to establish reasons for great differences in the rate of wear, a series of tests and experiments, extending over a period of four years, were carried out by the authors. The cost of the renewal of liners on a large pipe-line system is very considerable, but it is only a portion of the total losses. Added to liner-renewal expenses are the troubles likely to accrue from contamination of the oil in the crankcase, from loss of power, etc., which add greatly to operating costs.

In this paper the authors attempt to show how liner life may be lengthened with a resulting greater economy in the operation of the Diesel engine. Methods adopted for applying the cylinder oil and other causes allied to poor lubrication are discussed. The tables in the paper show what can be effected by changing the grade of oil in use and by correct treatment of fuel oil and the air.

SUCCESSFUL operation of a Diesel engine depends largely upon how efficiently it is lubricated. There are a number of factors, other than lubrication, that must be considered before the best of lubricants can give satisfactory service. After careful thought and many tests the authors are forced to the conclusion that many important details have been overlooked by the majority of engine manufacturers, and they will try to show some of the means that might be adopted to give better economy and better service when operating oil engines, whether they be used on pipe lines or other service.

Method of Checking Cylinders

To determine the rate of wear in liners a system of checking was adopted and standardized throughout the entire system. No matter what method be used it must be such that it is simple yet at the same time accurate, otherwise the results secured will be useless. The manner in which checks were made is as follows:

Starting at the flywheel side of the cylinder and directly above the crankshaft a mark is made on the top face of the liner and called zero deg. The liner face is measured carefully every 45 deg. and is marked with a center punch; these points are called 45, 90, and 135 deg.

In order that the micrometers may be located exactly at the same point each time a T-square is used. This consists of a piece of $1\frac{1}{2}$ in. angle iron about 15 in. long, riveted or brazed to which is a strip of metal 1 in. by $\frac{1}{4}$ in. A series of holes are drilled in the strip, the top of which registers with the center of the top ring when the piston is at its inner position. A punch mark is made on the angle iron so that, when it is laid across the top of the liner, this mark will register with the marks made on the liner face. Other holes can be drilled in the metal strip, the position of these depending on the length of stroke and type of engine. During the tests holes were drilled every inch down from the top hole, and measurements were usually taken for the top 6 in. of the cylinder, and at the four points previously named. With certain engines, however, it was thought necessary to go further down; this would apply more to two-cycle engines such as that used in this example. In passing it might be noted that the results of the checks show that, whereas the majority of two-cycle engines wear to what might be termed barrel-shape, the four-cycle engine wears in the form of a taper with the largest diameters at the top.

In order to make the checks the T-square is laid into the cylinder with the angle iron resting on top of the liner and the strip with the holes hanging down inside. The mark on the angle iron is brought into line with the several marks on top of the liner and the measurements are taken by placing the point of the micrometers in the drilled holes. By adopting this, or some similar method, it can be readily seen that no matter what time elapses between checks one can always be sure of going to exactly the same point. This is essential, as a difference as great as 0.012 in. has been found by moving the micrometer round the cylinder wall only 15 deg.

In submitting the following tables showing actual measurements made on a 17-in. by 25-in. two-cycle engine, it should be explained that much work was carried out on engines of this type as liner life was extremely short. The stars opposite some of the figures denote the point of greatest wear in each case, and it is this point that is taken to determine the rate of wear, for should it be necessary to bore out the cylinder it is to this point that one would have to work to make a correct job.

A log is kept for each engine, and the hours it runs is noted and brought up to date each day. The total number of hours the engine or liner has run is divided by the greatest wear and the result listed as so many hours run for every 0.001 in. wear.

In making checks the same micrometers should be used on the same engine as considerable discrepancy has been found to exist on different instruments, and further, the cylinders should be at, or near, the same temperature each time a check is made.

Grade and Quantity of Lubricating Oil

The proper grade and quantity of lubricating oil to be used is of primary importance. The authors recently carried out a series of tests on different oils and found that the difference in results was surprising. It is an extremely difficult matter to state just what kind of oil or how much should be admitted to the cylinder, but to a large extent successful lubrication will depend on these determinations.

As conditions vary so much in different types and sizes of engines there will be no attempt made to lay down any hard and fast rule. It has been found over a large number of units that practically each condition must be studied from its own particular viewpoint. It has been found frequently that by a change from a light grade of oil to a heavy grade, or vice versa, the liner and ring life can be materially increased.

Choice of the correct oil is doubtless the leading factor in proper lubrication. Most reputable oil companies manufacture oils that will give satisfactory service, but it has been found

---

[2] Sales Engineer, Byron Jackson Pump Company. Formerly Pipe-Line Representative, Standard Oil Company of Indiana.

Presented at the National Petroleum Meeting, Tulsa, Okla., Oct. 6 to 8, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

that even they are sometimes liable to err. Cases have been found where a change from an accepted standard brand of oil to a new oil made by the same company resulted in very considerable improvement. This was done when making the tests, the results of which are shown in accompanying tables. It is impossible to state how much a cylinder will require; even cylinders of the same size will vary in the correct consumption, and this can only be determined by the men responsible.

Method of Application

The method of application of the cylinder oil appears to have been given insufficient attention by the engine builders. The

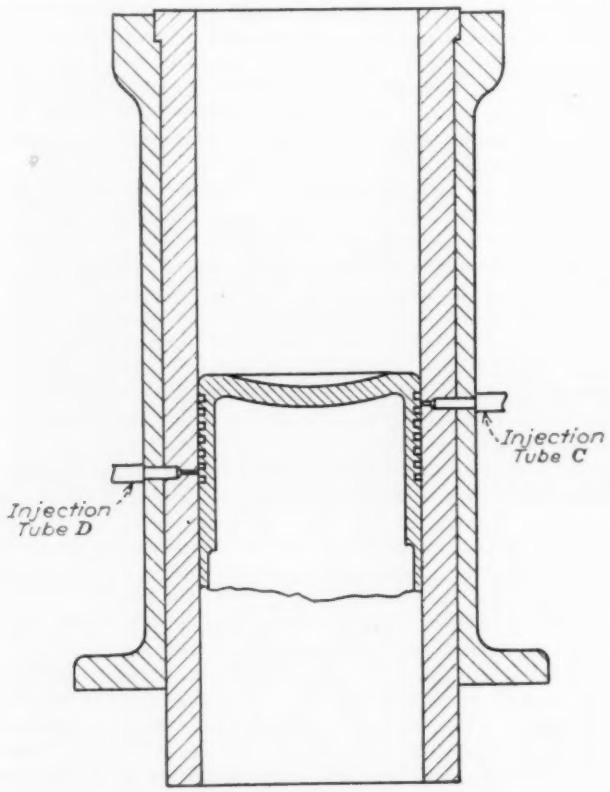

Fig. 1 View of Cylinder
(Showing correct and incorrect methods of locating injection tubes in relation to piston rings with piston at lower end of travel.)

piping system and position of the points of entry of the oil-injection tubes vary according to the opinion of the average manufacturer or it might even be said of some cases that the lubricating system has been added to the unit without any consideration of its importance. That the position varies greatly can be seen from the fact that in some cases the oil enters at a point registering with the bottom of the piston rings, and in others even ahead of the top ring when the piston is on outer center. This is illustrated at *D*, Fig. 1.

It has been found that the ideal position for the point of entry of the oil is between the first and second rings counting from the head end of the piston, as shown at *C*, Fig. 1. The injection tube should be of such a type that the end discharging the oil will extend through the liner to the inner wall, and should have a valve or some form of restrictor as near the inner side of the liner as possible. A tube of this type is illustrated in Fig. 2.

By so doing the oil will be prevented from dribbling and the suction of the piston will not have the same tendency to whip the oil from the tube when the piston rings travel over the end of the oil tube. With this continual whipping or dribbling action, the majority of the oil is pulled out on to the piston skirt with the result that the parts most requiring lubrication are more or less totally ignored.

The open-type injection tube so commonly used is very undesirable as it permits the hot gases from the cylinder to enter the tube, and, coming in contact with the oil, renders it practically useless from the point of view of lubrication. It has been found that where the open-type injection tube is fitted, the check valve, if any be fitted, being well outside the cylinder, the oil is changed from a good clean lubricant to a contaminated oil. Fig. 3 shows such a type of tube. Samples have been collected and have been found to be extremely dark in color, and a great deal higher in viscosity than the oil in the mechanical lubricator.

Table 4 shows the characteristics of two new oils as supplied to the lubricator. Samples of each of these oils were drained from the feed lines leading from lubricator to cylinder. Tables 5 and 6 are presented to show the decomposition of the oils after coming into contact with the hot gases blown back from the cylinder into injection tubes and feed lines. Table 5 is analysis of oil No. 1 and Table 6 is analysis of oil No. 2. This experimental work was done by Mr. W. O. Northcutt and was presented in a paper read at the regional meeting of the A.S.M.E. held in Kansas City, April, 1927.

Further, entrance of hot gases to the oil lines carbonizes the oil, and will have a tendency to block some of them completely should the piping system be composed of branch lines coming from one line from the lubricator, as shown in Fig. 4.

Reference to Tables 1 and 2 will show that the improvement is very marked. During the period covered between the two checks a different brand of oil was used. In the original installation a lubricator was fitted on top of the cylinders and two feeds were supplied to each cylinder, each feed being split through a tee giving four points of entry for the oil. However,

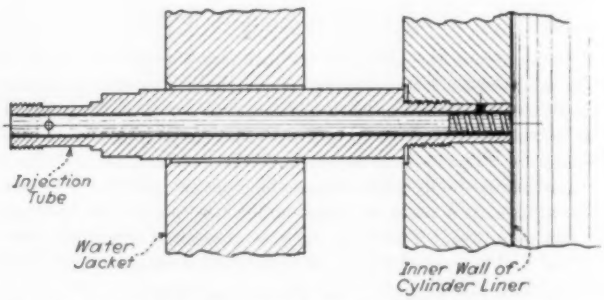

Fig. 2 View of Injection Tube to Power Cylinder
(Fitted with restrictor at inner wall of cylinder liner.)

it has been found that neither of these conditions can give good lubrication. The lubricator should be placed below the point of entry of the oil and each point of entry of the oil should have a feed direct from the lubricator, as illustrated in Fig. 5. If this be done the difficulty of lines becoming blocked with carbon will be overcome. It is further suggested that all cylinders of 75 hp. and over should have four individual feeds direct from the lubricator to the cylinder.

With a lubricator mounted on top of the engine and with faulty check valves, and these are far from being rare, the lines are very likely to be drained of oil whenever the engine is shut down. It has been noted that after the engine has been shut down for a considerable time it requires several minutes of hand priming to fill the line. Were the unit to be started up without

priming and completely filling the lines, piston seizure or excessive wear would very likely take place.

Many engines are equipped with lubricators of an obsolete type that pump a great amount of air with the oil; this results in pockets of air being formed in the lines. The air is forced through at varying intervals, sometimes two or three minutes apart, and carries a quantity of oil with it leaving several inches of the line empty of oil. Tests on engines equipped with lubricators of this type have shown that in engines of 24-in. stroke and running at 200 r.p.m. more than 2 miles are frequently covered by the piston before it receives a fresh supply of oil. A lubricator that will pump oil free from air will overcome this difficulty.

Effect of Piston-Ring Pressures and Design

The type of piston ring used in an engine is a very important factor in the life of the cylinder liner. Excessive ring pressures increase the amount of liner wear greatly. This point is readily noted by referring to Table 2 and examining the difference between the wear in cylinder No. 1 and that in the other three cylinders. As was noted at the foot of the table, a new type of ring was tried out in cylinder No. 1 and the old rings were left in position in the other three cylinders. The rings tried were $^1/_4$ in. wide, and the average wear was such that the liner life equaled only 170 hr. per 0.001 in. wear against the average for the other three cylinders of 904 hr. In the cylinders giving the long average wear, rings $^1/_4$ in. wide were used. The narrow rings were tried with a radial thickness of three different sizes, but with no better results. A wide ring with the radial thickness of approximately two-thirds the width gave the best results.

In order that observations might be made regarding the conditions under which rings had to operate a cylinder of 17-in. bore was accurately measured every 15 deg., and the results are shown in Table 3. The measurements were taken at points registering with the middle of the top ring when it was at the inner end of its travel. Despite the short space between the points that were checked, the difference in wear is considerable

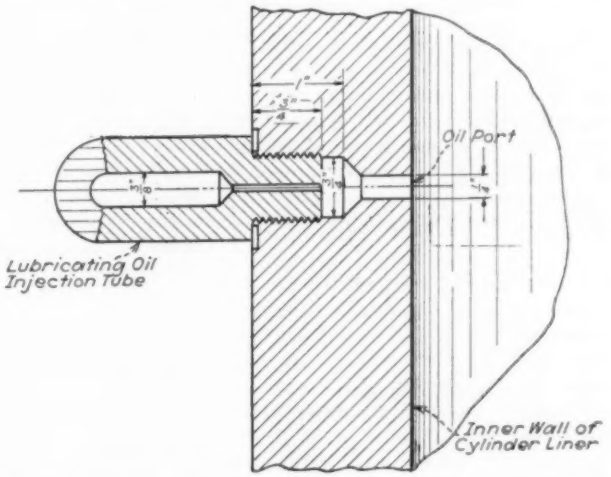

Fig. 3 Sectional View of Cylinder Liner and Injection Tube
(Showing open pocket at inner end of injection tube.)

in some instances. With new or stiff rings especially, and considering the shape of the liner to which the ring is supposed to conform, it is not surprising that there is considerable leakage. Theoretically, the ring is supposed to act as a seal for the gases by pressing against the wall of the cylinder, but it would appear that such a condition is nearly impossible. In fact, it seems reasonable that instead of the gases assisting the rings to form

a seal by pressing behind them they will have a tendency to press on the face of the ring and further accentuate the loss of power due to leakage.

Abrasive Material in Intake Air

The subject of lubrication covers a very wide field and it must be considered from several points. The intake air and the fuel oil have each a bearing on the matter. In passing, it is desirable to point out that no matter what type or quantity of lubricating oil be used it cannot give satisfactory service unless all other points are considered, and when difficulties are encountered that they be dealt with. The cleaning of air is one essential. The modern automobile manufacturer attempts to eliminate, as far as possible, entry of abrasive material into the motor. Air filters are just as essential on a Diesel engine as on an automobile, especially when a plant is in a dusty vicinity. Naturally, engines of different designs and sizes take different quantities of air. However, the ratio of the foreign matter to the total quantity of air under similar circumstances will be the same. From one to four grains of dust are found in every 1000 cu. ft. of what is considered fairly pure air. With a displacement of 2000 cu. ft. per min. a unit would draw in from $1^1/_2$ to 6 lb. of dust every week. Such a quantity of dust should be eliminated, for any considerable amount entering the cylinder is likely to mix with the lubricating oil and make the latter a first-class abrasive instead of a first-class lubricant as it was intended to be.

(Showing two separate lines from mechanical lubricator to lubricating-oil injection tube.)

Abrasive Material in the Fuel Oil

It appears that one should reasonably expect to get a fairly clean fuel no matter from what source it may be obtained. Yet, all contain a certain amount of foreign matter, much of which would act as a cutting compound if it were permitted to enter the cylinder. It is not alone the liners and rings that suffer, but probably as great if not greater damage will be done to such parts as fuel-pump plungers, injection valves, etc., where an oil containing a considerable percentage of solid matter is used without cleaning it in some effective matter. Extensive tests have shown that no matter what fuel be purchased, care should always be taken to see that it is cleaned either by heating and settling or by the use of a centrifugal machine.

There is a machine for almost any size of installation and although the first cost may be considered high it is believed that such an installation will pay for itself in a very short space of time. The use of the centrifugal machine is being more and more adopted in pipe-line systems and so far the authors have never been able to find an instance where the centrifugal machine has not proved its worth. After passing the fuel oil through the centrifuge it is practically cleared of all solid matter and all water is removed. Ash content is almost entirely eliminated and the sulphur content may be considerably decreased in some instances. The flash point of the fuel is raised and the calorific value is increased considerably. Mysterious pitting on the surfaces of the metal in the unit may often be traced to the presence of sulphur in the fuel. It is questionable whether any appreciable amount of the sulphur can be removed by centrifuging; there are some who maintain it can, and some who maintain it cannot. However, if it can be, so much the better argument in favor of the adoption of the centrifuge machine, more especially when engines are stopped and started frequently, giving rise to the almost inevitable presence of moisture. Fuel oil with a high sulphur content, unless it can be cleaned perfectly, should be avoided as the sulphur burns, forming sulphur dioxide, which, reacting with any water that may be present, will form an acid and give rise to a condition frequently blamed on poor lubrication.

There is no doubt that the amount of foreign matter in fuel varies greatly, but figures taken from a number of main-line stations give an average of one pound of solid matter removed from every five barrels of fuel treated by means of a centrifugal machine.

Instances have been noted where, by the introduction of treating methods for the fuel, the liner life was lengthened by more than twice and also valve grinding and valve renewal, pump plunger replacement, etc., were very considerably lessened. The introduction of such an accessory need not prove expensive nor need the arrangement be complicated, and should soon pay its way. At first sight it might appear that air filtration and fuel-oil cleaning have no bearing on the subject, but the introduction of dirt with the air or with the fuel oil will readily multiply any efforts made to secure perfect lubrication. Space does not permit discussion of other points such as design and cleanliness of water jackets, misalignment of parts, and poor metal, but all enter into the question of liner life, and often are the real causes of poor lubrication.

Conclusion

The authors have attempted to describe the more important

conditions affecting the lubrication and life of power cylinders of Diesel engines. From their observations the causes of excessive cylinder wear are in most cases a combination of several of the aforementioned conditions, and it is suggested that the purchasers of a Diesel engine would do well to present specifications to the manufacturer demanding that the engine to be purchased be equipped with lubricators that will not pump air and that they be mounted below the cylinders, pumping upward, and supplying oil to each point of application to the cylinders through an independent line from lubricator to injection tube.

The injection tube should be of a type that will prevent the blowback of hot gases from the cylinder into the tube and not permit the suction of the piston to draw the oil out of the lines. The injection tube should be located preferably between the first and second rings from top of piston and not lower than between the second and third rings when the piston is at bottom.

Discussion

A. E. Flowers.[3] The paper shows evidence of a carefully planned, well-conducted, and thoroughly reported investigation. The results are well represented by the tables and illustrations shown.

It is to be hoped that the authors will have added to the sketch of the lubricating-oil injection tube, shown in Fig. 3, a line sketch showing the location and type of check valve they have found suitable in avoiding burning oil left in the tube by the hot gases.

It is stated that Tables 1 and 2 show the wear results upon change of oil, but it appears that the method of feeding oil was also changed. It would be well if the authors would clarify these statements, for if both conditions were changed simultaneously, there is little basis for proof that one oil was better than the other. It would be helpful if the authors would give the full set of physical tests of each oil used and state in the heading of Tables 1 and 2 which was used during each test.

It is suggested that in Fig. 1, showing the proper and improper location of lubricating oil tubes, the words "Improper Location" be inserted under the words "Injection Tube D" and the words "Proper Location" be inserted under the words "Injection Tube C."

For some reason Table 6 does not include test values for acidity and for total sediment, as Table 5 does, so that the comparison is not as complete as the authors intended it to be. Headings for Tables 5 and 6 might well be added stating Oil No. 1 and Oil No. 2, respectively, and the words "Samples Collected From the Ends of Lubrication Tubes," to show at a glance the character of the material.

The authors' observations on the reduction of wear as a result of centrifugal purification of the fuel oil agree with the statement made by Mr. L. R. Ford in his paper last year before the A.S.M.E. meeting at State College, Pennsylvania, in regard to marine Diesel engines.

The authors' observations of the effect of sulphur are interesting, as well as the possible effect of centrifuging. It is well known that free sulphur dissolves in oil and while dissolved cannot be centrifuged out, but there seems to be a special affinity between such free sulphur and metal or other particles, so that the sludge collected in a centrifuge bowl will show a higher sulphur content than the oil. It is possible that sulphonated compounds are present in oils which would separate or stay with the oil depending upon whether they were in solution or present as pitchy, semi-solid, heavy compounds, as the latter could be removed by centrifuging.

[3] Engineer in Charge of Development, De Laval Separator Company, Poughkeepsie, N. Y. Mem. A.S.M.E.

E. H. Hillman.[4] The authors have presented many useful points which should be of value to Diesel-engine builders and operators. Their comments on the position of the lubricator and the need for separate feeds to each point are particularly valuable. The writer has noted several instances where one of the two split feeds from the same lubricator pump was stopped up after comparatively short runs. It is only natural that this would occur when it is considered that the same amount of oil will not be pumped through each injection tube. The tube receiving the least oil will naturally choke up somewhat faster, and this choking will still further reduce the feed, which in turn will permit a faster accumulation of deposits. On the other hand, all the oil which does not go out of the partially choked tube will go out of the other tube, which thus will be swept clean of all deposits. It may be doubted, however, that four individual feeds are necessary except for large engines.

The data on deterioration of cylinder oil, due to blow-back of hot gasses into the lubricator tubes, should be of interest to check-valve manufacturers; but this blow-back would not necessarily make the oil unfit for use. It is obvious that such blow-back, when it occurs, will not subject the oil to such severe conditions as it will find on the cylinder walls and rings, where it will come in contact with gases which have not been appreciably cooled. An oil which will lubricate the cylinders satisfactorily could hardly be deteriorated to a dangerous extent by gases blowing into the lubricator tubes.

The rate-of-wear data point to a branch of Diesel lubrication which has been inadequately studied. The effect of viscosity and other variables should be determined separately. If this were done, it is suggested that a regular change in rate of wear with change in viscosity would be found, the rate being different, of course, for different engine types and operating conditions.

The authors suggest that cylinder wear be measured by comparing only the points of greatest wear. This method will show the effect of mechanical irregularities, such as misfitting rings, irregular liners, or piston slap which might cause a great deal of wear at certain points during one inspection period, but little wear during the next period.

In any study of cylinder wear, one is of course primarily interested in the effect of conditions such as load, temperature, design, or lubrication, which will cause substantially uniform wear. One is not interested in mechanical misadjustments which might cause localized wear or scoring, except to know that they exist, and to effect a remedy if possible.

Thus in comparing the wear obtained with different types of rings or with different lubricants, it is suggested that always the average wear be determined. All measurements taken on the upper part of the cylinder covered by the ring travel should be averaged at the start of the test and at the end of the test. The difference will give a much clearer picture of the rate at which wear is taking place, and will normally show less wear than that obtained by the maximum diameter method. If all the top nine measurements in Table 1 are averaged and compared with a similar average for Table 2, the hours per 0.001 in. wear will be 884 instead of 721, as shown. The rate of wear by the average method will naturally be slower than by the maximum diameter method, since it minimizes localized excessive wear due to mechanical difficulties. It might even occur in some instances that no wear would be shown when comparing maximum diameters, since a broken ring or other mechanical defect might cause severe scoring at one point which would remain the maximum diameter during several inspections.

While it may be admitted that a determination of the maximum diameter will show the machine shop the size to which the cyl-

[4] Standard Oil Company, Chicago, Ill.

inder liner should be rebored, yet it would appear to have no bearing on a comparative study of Diesel-engine designs or lubricants.

The writer has had the privilege of working with the authors in making cylinder-diameter measurements as described in their paper, and has found them to be accurate and necessary for reliable results. In his own paper the writer has presented data showing the great extent to which diameters may vary from one point to another in the cylinder. This shows the necessity for a method to accurately standardize the points at which measurements are taken.

FRED THILENIUS.[5] Having known both the authors of this paper for some time and having discussed with them many times the points involved, it is easy to agree with them on all of the arguments put forth. It happens that, as assistant master mechanic of the Prairie Pipe Line Company for five years and as superintendent of that company's Panhandle line for three years, the writer was able to collect much of information on the operation of Diesel engines. This information includes several thousand measurements of liner wear taken over long periods, and the results obtained agree very closely with the points brought out in the paper. The writer is pleased, therefore, to confirm several points with additional information and stress a few other points with additional arguments.

On the pipe line mentioned, accurate measurements over a period of six years were recorded to obtain the liner wear for every Diesel-engine cylinder on the main line which included two- to six-cylinder engines in horsepower of 300 to 665 per engine and which involved several hundred cylinders. Measurements were made exactly as described, except that only two measurements were taken, at two positions on each liner. The first position was at the top of the top ring travel and the second was at the half-stroke position of the top ring, and in each case one measurement was taken parallel with and the other at right-angles with the crankshaft. As pointed out it was difficult to obtain accurate measurements without an instrument similar to the one described for a guide, and as mentioned it was found absolutely necessary to use the same micrometer on the same liner each time. Even with these precautions, it was found necessary to check the results obtained at each reading with several other readings over long periods to secure a true indication of what the wear was per thousand hours, for it often happened that a liner would show several thousands of negative wear over a period of several months, due probably to the different temperatures of the liners and micrometers.

It is interesting to note that the measurements shown in Tables 1, 2, and 3 are exactly like 90 per cent of the measurements obtained on the Prairie system in that the zero positions are from 10 to 20 thousandths greater than the 90-deg. positions. This indicates that liners wear more in the direction of the length of the crankshaft than crosswise, and this condition maintains with horizontal trunk-type piston engines as well as verticals. This is interesting because it is generally thought that the side thrust of the connecting rod has much to do with liner wear. At least it was argued by the first vertical-engine builders that the liner wear would be a great deal less than in a horizontal engine, for in the vertical engine the weight of the piston was not carried on the liner. This condition indicates that the forces acting on the liner due to end play of the shaft or misalignment of the connecting rods is as a rule greater than those caused by the side thrust of the rod or the weight of the piston. And this is another point that the manufacturers should take into consideration in the design of their engines. There have been cases where this difference was as much as 50 or 60 thousandths.

As for the application of the lubricating oil to the cylinders it is also the writer's belief that too little thought has been given to this important feature by the manufacturers. It is almost inconceivable that a designer should expect a drop of lubricating oil to have enough intelligence to split itself exactly in half when it comes to a tee in the line as pictured in Fig. 4. And he heartily agrees that a dependable check valve located on the inner end of the injection tube is an essential thing. The writer has disconnected many lubricating lines between the lubricator and the cylinder on engines that had no check valves or faulty check valves and has found the lines full of particles of carbon, as far back as the lubricator. The presence of this carbon in the line is not nearly as important as the condition it indicates. It could only get there by blowing back, which could only happen when the line was partly empty. With no check valve on the end of the line, the oil can run out into the cylinders in slugs, which leaves the line empty until the lubricator can again fill it. With the injection tubes 8 or 9 in. long and bored out to $^1/_4$ in. it is possible for several thimblefuls of oil to run out at one time, and with the lubricator feeding only 4 to 6 drops a minute, there might easily be periods of 15 or 20 minutes during which the piston received no oil at all. This is possible when the lubricator is located at a lower elevation than the injector tubes. When the lubricator is above the tubes, the entire line can drain, and unless it is primed, which is rarely thought of, an engine might run for half an hour after starting without receiving a drop of oil. This condition has been noted many times in the field. Although it is of course essential to have the proper oil for efficient operation and to obtain a minimum amount of liner wear, it can be said that improper application or lack of application at periods accounts for more liner wear than a slight variation of the oil.

As mentioned, it is important to have both clean air and clean fuel, but of these two the fuel seems to be the more important. This is probably due partly to the fact that dust that enters the cylinder through the air is more finely divided and it is dry, and therefore it is more easily carried out again with the exhaust, whereas the grit in the fuel oil is wet and will adhere more readily to the walls of the cylinder and the top of the piston. There is also a much greater quantity of dirt carried into the cylinder by the fuel than by the air. Roughly, each pound of fuel combines with about 15 lb. of air in the cylinder, but there is perhaps twice this amount of air passing through the cylinder. Using the average dirt content given for both air and fuel, this figures that there is roughly 4 lb. of dirt brought into the cylinder by oil for every pound of dirt brought in by the air. This is borne out by the observation that on a large main-line station that was located very close to a cement plant, where the air was thick with dust much of the time, the wear on the liners was found to be only slightly excessive as compared to other stations on the line that were favored with fairly clean air, whereas it was found on another station that the liner wear was cut exactly in half by centrifuging the fuel oil as compared to six other similar stations on the same line using fuel from exactly the same source, even though at the other six stations the fuel was thoroughly settled after heating in twin fuel tanks before it was used on the engines.

PET-52-3

Service Tests on Carbon Formation in Diesel Engines

By E. H. HILLMAN,[1] CHICAGO, ILL.

Testing methods and technique applicable to field conditions are described. Data are presented which have been secured as a result of such tests under service conditions. Laboratory tests designed to measure the carbon-forming tendencies have little relation to results secured in service. At present the only satisfactory proof of merit is service or simulated service tests, but the procurement of reliable data is difficult. Cylinder wear is shown to affect lubrication by preventing proper ring seal.

WHEN a new Diesel engine is placed in operation, the owners and operators are confronted with the task of selecting the lubricants. Most manufacturers of the equipment seldom are in a position to give helpful suggestions. As a matter of policy many hesitate to make specific recommendations and, as a matter of fact, with few exceptions have not run tests sufficient to compare various oils in a quantitative way. They usually offer only the most general specifications or a long list of approved oils without comment as to their respective merits. Heretofore, the refiners also quite generally have not adequately discussed the methods of lubricant selection and the characteristics of suitable oils. The result frequently is considerable doubt among operators as to the factors which should be considered in the selection of lubricants.

Laboratory Tests

Laboratory tests are of limited value for the evaluation of Diesel cylinder oils, the Conradson carbon or carbon-residue test being the only commonly accepted method for measuring the carbon-forming tendencies of an oil in service. Where the same type of lubricating stock and method of refining is used, this test may check up fairly consistently with carbon formation in the engine, but in other instances the results appear to be not at all comparable with engine performance. The operator should therefore place no reliance on this test, since he has no means of knowing the source and methods of refining used on the products offered for purchase. Table 1 shows clearly the lack of relation found between the laboratory test and field results. It would seem that there is no adequate test to show the carbon-forming tendencies other than running in an engine as outlined farther on.

Many factors indirectly affect the cylinder lubricant, such as engine size, speed, type of cycle, combustion characteristics, fuel-injection method, piston-cooling method, cylinder cooling, type of fuel, piston-ring type, and air condition.

Undoubtedly the resultant of these various factors, together with the exact method used in applying oil to the cylinder walls, will for any given operating condition result in a definite oil-film temperature on the cylinders, piston walls, and rings which, if known, would be of major importance in selecting the proper lubricant. Such film temperatures would take into account design factors, operating factors such as load and cooling-water temperature, and condition factors such as ring wear and blow-by.

It would be helpful to know the actual operating temperatures on the lubricated surfaces of Diesel-engine pistons for various conditions. This information should be of great assistance in selecting proper lubricants. Temperatures around the piston rings ranged from about 200 to over 300 deg. fahr. in a few tests made with special equipment to measure temperatures of the oil film at such points.

Unfortunately, we find on the one hand that laboratory tests give an inadequate clew as to the deterioration of oil in service, and on the other hand data on oil film temperatures or their underlying causes are not available in sufficient quantity to work out a lubrication theory or to permit the application of a theory to individual cases. In the study of cylinder-oil deterioration we were therefore restricted to tests under service conditions.

Engine Carbon

Two-stroke-cycle crankcase scavenging engines seem to form carbon more rapidly in the exhaust passages. In all Diesel engines, gumming and sticking of rings causes more or less trouble and loss of time from shutdowns. Since measurable amounts of these deposits form after comparatively short runs, we have been able to work out methods for reliable comparisons of various oils in a comparatively short time.

Carbon deposits are found in two main locations: (*a*) in the exhaust passages and (*b*) around the piston rings. In the first case, they cut down the scavenging efficiency of the engine, and if allowed to accumulate may cause serious loss of power or overheating. The tendency of deposits to form in this location varies to quite a large extent with the design of the engine and is not serious in many cases. In the second case, pistons must be pulled and cleaned more often than would be necessary if carbon deposits around the rings could be avoided. These deposits retard the free action of the rings, with consequent decrease in their sealing efficiency. Eventually they become stuck, especially the top ring, with an even greater loss in efficiency, increased blow-by, and accelerated oil deterioration.

Fig. 1 and Table 1 show how the weight of carbon deposits in exhaust passages of a two-stroke-cycle engine varies for several oils. It will be noted that as the exhaust-gas temperature increases, the weight of deposits decreases. This is undoubtedly due to the fact that higher exhaust-gas temperatures dry out the deposits so that more are blown away by the force of spent gases. The table also shows the viscosity and the carbon residue value of several oils. The lack of correlation is evident.

[1] Technical Division, Standard Oil Company (Indiana). Mr. Hillman was graduated in chemical engineering from Purdue University in 1923 and shortly afterward entered the employ of his present firm, being assigned to the lubrication department. In recent years his work has been mainly with the development and testing of new lubricating products, especially Diesel oils. He is in charge of this work in the Technical Division of the company.

Presented at the National Petroleum Meeting, Tulsa, Okla., October 6 to 8, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

TABLE 1 OIL RATINGS IN DIESEL TESTS

Deposits in Diesel-Engine Exhaust Passages[1] (From Curves)

Oil	Conradson carbon residue[4]	Viscosity at 210° F.	Exhaust-gas temperatures 420° F. (Grams)	Exhaust-gas temperatures 440° F. (Grams)	Piston order of merit[2]	Oil used, gal. per hr.[3]
A	0.09	65	0.75	0.50	1	0.274
B	0.05	61	1.50	0.80	3	0.264
C	0.32	57	1.80	1.20	5	0.228
D	0.10	56	2.55	1.85	2	0.246
E	0.49	64	2.8	1.90	4	0.235

[1] The figures show the average weights of deposits formed in standardized areas of the exhaust passages of a 240-hp., two-stroke cycle, port-scavenging, four-cylinder Diesel engine, during 55 hours' operation, with the average exhaust temperatures and with lubricating oil as shown.

[2] Based on carbon found back of rings, tightness and oiliness of rings, and general observations of piston and ring condition.

[3] Lubricator feeds were the same in all tests. Reason for variation not known.

[4] Conradson carbon test.

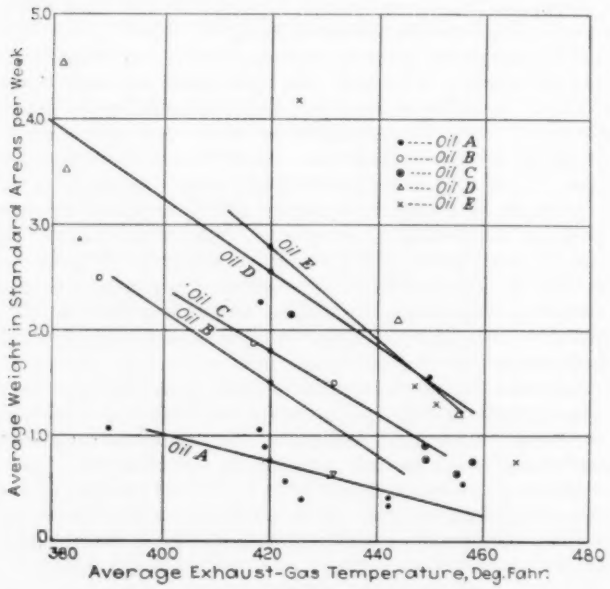

FIG. 1 DEPOSITS IN EXHAUST PASSAGES

(Two-cycle crankcase-compression port-scavenging solid-injection Diesel engine.)

Table 1 also shows ratings based on piston and ring lubrication and ring carbon.

TEST METHODS

During most of these tests, deposit samples were taken from two standardized areas in each exhaust passage each week. Thus, eight samples from the four cylinders in the test engine were averaged to get the carbon-forming tendencies of the oil for the weekly period. Samples as above were compared with the average exhaust-gas temperature for the week. Since the number of hours which the engine operated varied from week to week, it was necessary to correct the weight of deposits to what would have been obtained in a standard week, assuming carbon formation to proceed at a uniform rate.

Tests on the foregoing plan were usually run for four weeks with each oil. At the end of each run No. 1 piston was pulled, and the cylinder was carefully examined to determine the quality of lubrication. Notes were made of the extent to which the rings were stuck, gummy, dry, or well lubricated, and the location of gummy or carbonaceous deposits between rings or on piston skirts. All the carbon which adhered to the back of each ring was saved for weighing. Inasmuch as many fewer samples were available, the results of these weight determinations are not as clear cut as in the case of carbon in the exhaust passages, but they rate the oils similarly in most instances.

HEAVY-DUTY LUBRICATION

Table 2 shows the result of several tests made along the foregoing lines in a larger two-cycle Diesel engine where it has been found necessary to use an extra heavy grade of oil. In these tests additional information was secured by taking close-up pictures of pistons and cylinder walls. These formed a permanent record which amplified the notes and memory of the investigator for his final rating of the different oils. The more striking of these pictures are shown in Fig. 2.

The ratings in Table 2 based on piston charts[2] are entitled to considerable weight. These charts are illustrated in Fig. 3, and were found to be a convenient means of recording in logical fashion the position and size of carbon deposits, dry spots, gummy oil, etc., on pistons, rings, and cylinders for permanent reference in comparing oils. It was found that minimum reliance must be placed on memory in any careful comparison of lubricants.

The column headed "oil used" in Tables 1 and 2 is of interest as showing the variations which will occur for unknown reasons without readjustment of the lubricator.

The foregoing data are presented as illustrating the methods which were found necessary to select the best out of several oils which were under consideration for use in two-cycle engines. In many instances four-cycle engines do not give trouble from

[2] These were designed in cooperation with Messrs. W. G. Heltzel and J. B. Harshman, of the Sinclair Pipe Line Company.

[4] Estimates from detailed notes of piston and cylinder lubrication at time of inspections. Principal emphasis on oiliness of rings.
NOTE: All tests ran for close to 500 hours. Oil consumption and weights of carbon are corrected to a 500-hour basis. Engine was 750-hp., four cylinder, two-stroke cycle, port-scavenging, with piston-cooling. Weight and observations were from piston No. 1 only.

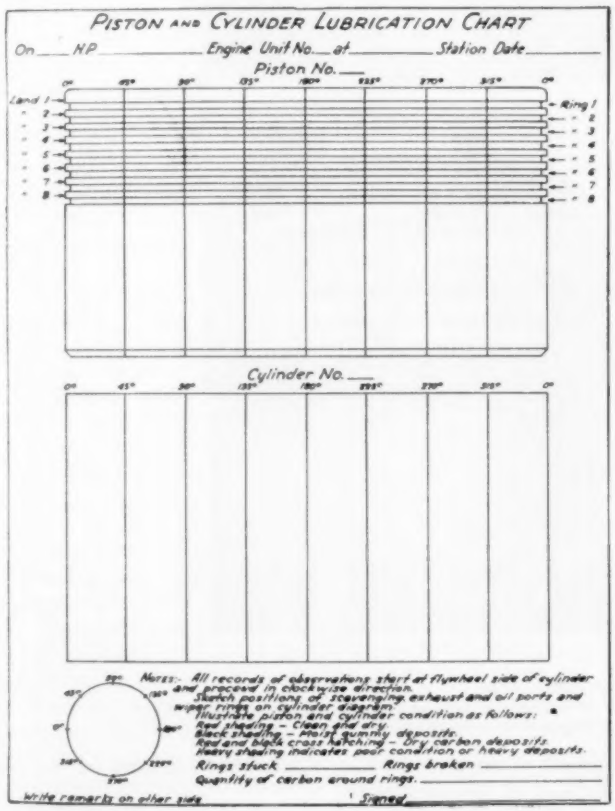

FIG. 3 CHART SHOWING RECORD OF PISTON AND CYLINDER LUBRICATION

deposits around the exhaust valves or passages, so that deposits on pistons and rings only need be considered.

WEAR OF FRICTION SURFACES

The feeling is prevalent that wear decreases as oil viscosity is increased within moderate limits.

This opinion seems reasonable, but is not adequately supported by available experimental data and should be the subject of further investigation. Excessive wear does not ordinarily show up in the bearings because the lower temperatures of such surfaces almost always permit even moderately light oils to lubricate properly. Oil films of suitable thickness are built up in the bearings, except of course under abnormal conditions. Cylinder and ring wear is, however, of considerable economic importance, and its measurement is being covered in detail in other papers. Such wear causes increased blow-by, with resultant loss of power, especially when the engine is on heavy load. The blow-by results in more severe heating and more rapid deterioration of the oil. Fig. 4 shows clearly the extensive gumming and carbonization taking place in the path of escaping hot gases at the ring gaps.

ROUNDNESS OF DIESEL CYLINDERS

The measurement of cylinder wear is not a test to be undertaken without careful consideration and preparation. The methods to be used to avoid errors in measurement and to avoid errors due to operating conditions are described elsewhere.

Diesel-engine cylinders differ in their degree of roundness. There is a pronounced corrugated effect in many cylinders, so that measurements within a few degrees of each other may differ by 0.001 in. or more. Table 3 shows marked differences in the degree of roundness of three Diesel-engine cylinders, expressed as the average difference in diameter from one position to the

FIG. 4 BLOW-BY AT RING GAPS

next when measuring the diameter every 15 deg. around the circumference. This emphasizes (*a*) that considerable blow-by and oil deterioration may be due to irregular cylinder walls and (*b*) that every possible precaution should be taken to standardize the point where cylinder diameters are measured in wear tests.

In addition to these variations as the micrometers are rotated around the cylinder, there are also more pronounced variations as the micrometers are lowered into the cylinder. Some Diesel cylinders wear to a regular taper from the top down, the greatest diameter being at the top. Others are barrel shaped, showing the greatest diameter from 4 to 8 in. from the top. In all cases there is very little wear at the bottom.

Fig. 5 shows pictures of the same pistons whose measurements are shown in Table 3. It will be noted that the amount of apparent blow-by is proportional to the extent to which the cylinders are irregular.

OIL CONSUMPTION

As in the case of motor oils, higher viscosities usually also result in lower oil consumption. In the case of engines which are in poor mechanical condition or overloaded, this saving may be quite important, but under ordinary conditions the difference may not be great.

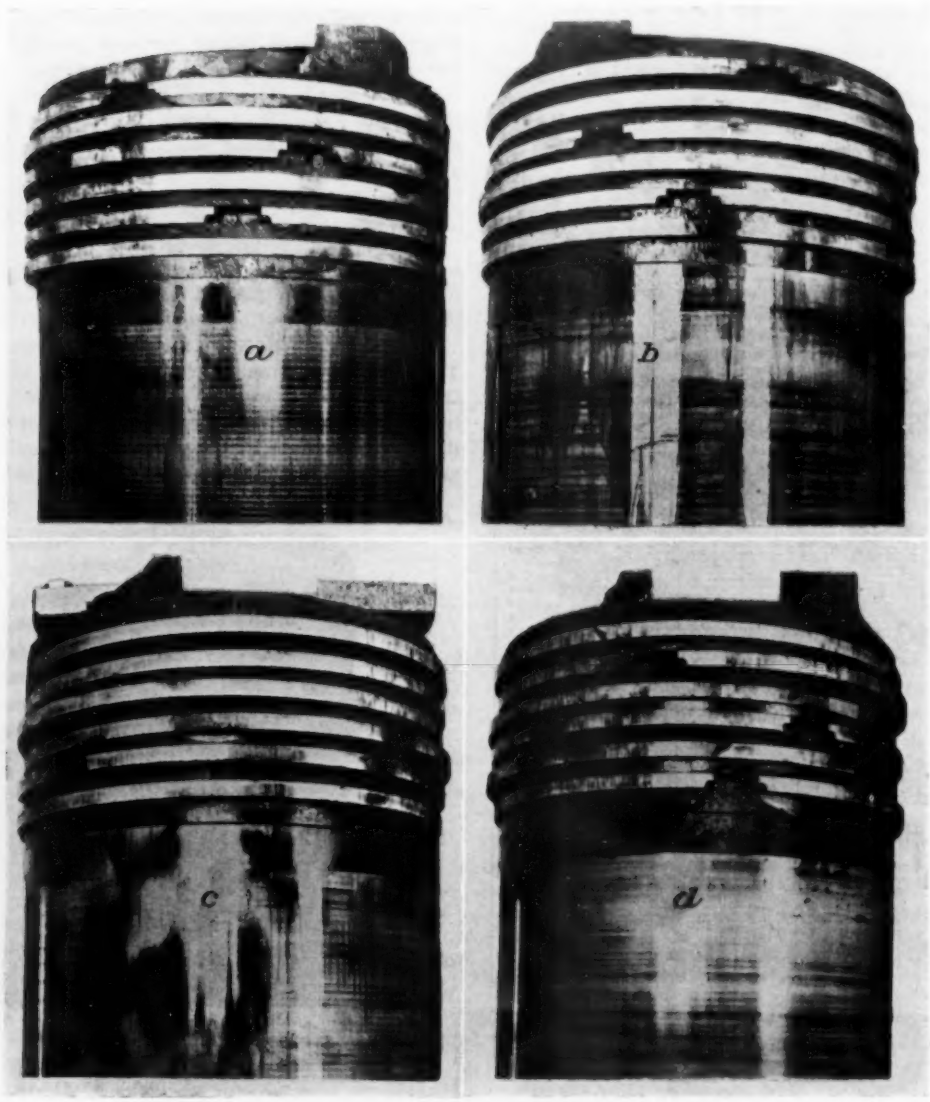

FIG. 5 BLOW-BY ON RING FACES

TABLE 3 DEVIATIONS FROM ROUNDNESS OF DIESEL-ENGINE CYLINDERS

Location	—Differences in diameter, in inches— Engine 4, Cylinder 4	Engine 3, Cylinder 3	Engine 3, Cylinder 4
Average 1 in. from top	0.0038	0.0042	0.0054
Average 2 in. from top	0.0033	0.0033	0.0059
Average 3 in. from top	0.0028	0.0032	0.0038
Average 4 in. from top	0.0028	0.0020	0.0037
Average 5 in. from top	0.0028	0.0017	0.0043
Average 6 in. from top	0.0028	0.0013	0.0018
Grand average	0.0030	0.0026	0.0042
Visible blow-by	Little	None	Much

Engines were 440-hp., two-cycle Nordbergs, running at 225 r.p.m., with valve-scavenging and port exhaust. Cylinders were 15 in. in diameter, and stroke was 20 in. Diameters were measured at 15-deg. intervals around the circumference. Differences in diameter from one point to the next are shown.

Compare the average deviations from roundness with piston pictures showing blow-by (Fig. No. 4).

Because of possible reduction in wear and, frequently, a reduction in oil consumption, there is a trend to the use of heavier oils for Diesel-cylinder lubrication. This has an analogy in the automotive field where the use of heavier oils is quite often carried to extremes because of smoother operation as well as reduced oil consumption.

PRACTICAL FIELD TESTS

Where Diesel oils are compared in service tests, too much emphasis cannot be placed on securing the same operating and mechanical condition for both oils. In this work it appeared that the following points should be considered:

Cylinder and Ring Wear. This affects the ring gap, which in turn will affect the amount of blow-by, with resulting piston fouling and loss of power.

Cylinder and Ring Conditions. When either are materially out of round or scored, the oil being used is obviously subjected to a disadvantage. Dark spots on outer faces of rings or on cylinder walls may indicate blow-by due to irregularly worn cylinders or rings.

Cooling-Jacket Scale. If this is allowed to accumulate, it will subject the oil to more severe conditions which will not be indicated from the other operating characteristics of the engine.

In extreme cases cracked cylinder heads may result from accumulations of scale. Conditions should be sufficiently uniform if in each test the engine has run the same length of time and with the same water supply since the last thorough cleaning.

Cooling-Water Inlet and Outlet Temperature. It would be desirable, although less important, to keep the inlet-water temperature and the flow in gallons the same as for all of the tests.

Load on the Engine. This should average the same for each test.

Timing and Fuel Distribution. With some engines this can be determined approximately from exhaust-gas temperature, which should be kept uniform between the different cylinders while in other engines it may be necessary to take indicator cards or to check the engine very carefully to insure that timing and load distribution remain uniform.

Exhaust-Gas Temperatures. In some types of Diesel engines where carbon accumulations in the exhaust passages are serious this is a most important consideration. In some cases, as already shown, comparatively small variations in average exhaust-gas temperature will cause quite large variations in the amount of carbon deposit in exhaust passages.

Procedure for Field Tests

Where it is possible to secure comparable operating conditions, as just outlined, either by testing the oils in similar engines running at the same time or in the same engine alternately, the various observations described in the preceding sections may be made.

In some cases it even may be necessary, because of the impossibility of following the tests closely, to eliminate certain parts and observations, but it is believed that by so doing the accuracy of the results is decreased. It was found that reliable comparisons were best secured when carbon samples were obtained quantitatively at regular intervals and weighed.

Frequently, helpful data may be secured by observing the presence and location of deposits or sludges which may drop into the crankcase from the cylinder or accumulate on the bottom or sides of the crankcase. The comparative amounts of these deposits should be estimated as closely as possible. Where possible, the sludges, if any, may be saved for later comparison of amount and composition.

Examination of the filter or centrifuge at regular intervals may show the relative amounts of sludge or deposits which accumulate from the same quantities of oil.

In most cases it will be very difficult to determine the relative fuel consumption for an engine when operating on two lubricating oils, since the error in making such fuel tests except under laboratory conditions is usually larger than the difference between the oils. Where good lubrication is being secured, there will be only a small difference in power consumption for oils differing considerably in viscosity.

Oil consumption is difficult to compare because of uncertainty as to just how low the feeds should be cut in each case and still secure sufficient lubrication. In any case the oil should be sufficient to maintain a light film of oil on pistons, cylinders, and rings, but anything beyond a reasonable surplus should be avoided.

All consumption records should be kept for the same time of operation in both cases, but unless the feed in each case has been carefully reduced to about the lowest practicable point little weight should be given to the results.

The comparison of Diesel lubricants is a matter of some difficulty, and usually facilities or the time are not available to properly make such tests. It would appear that the procedure cannot be simplified to the point where the respective merits of various oils can be determined accurately and easily.

Discussion

J. B. Harshman.[2] A description of the method used in determining the lubricating-oil film temperatures at the piston rings and a table showing operating temperatures would have been of considerable value to operators of Diesel engines in testing a lubricating oil to determine characteristics under different temperature conditions. It is believed that the amount of carbon formed in the cylinders of a Diesel engine depends largely on the condition of the cylinders. A badly worn cylinder, with gases blowing by the rings, will naturally form more carbon on any oil than if the cylinders were in first-class condition.

Under badly worn conditions, a heavier oil, which might possibly have a greater carbon content, will form a better seal and eliminate a large percentage of the blow-by, thus reducing the amount of oil burned on pistons and rings, and forming less carbon. For this same reason there is a possibility of reducing cylinder wear with a grade of heavier oil, by securing a better seal and reducing the blow-by and formation of carbon.

The author refers to two-cycle engines in which the scavenging air was compressed in the crankcase and with the tendency of the exhaust parts to clog up with carbon. It is believed that more or less trouble will be experienced with this type of engine, regardless of the nature of the oil used. This clogging of parts is due mainly to oil vapor and splash from the crankcase being carried through with the scavenging air into the cylinder. The amount of oil reaching the cylinders in this manner is usually beyond control of the operator.

The author states that an increase in exhaust-gas temperatures shows a decrease in the amount of carbon formation in the cylinder. It would be interesting to know the load that the engine referred to on test was carrying. This reduction of carbon formation with increase in exhaust-gas temperature is believed to be true up to a certain per cent of load due to better combustion. However, it is believed that on engines fully loaded any increase in exhaust-gas temperatures would be detrimental and would probably increase the amount of carbon formation due to burning a greater amount of the lubricating oil, as in the case of an overloaded engine.

The author also states that four-cycle engines do not give trouble from carbon deposits in the valve openings. The writer has found that four-cycle engines will give trouble from this source under various conditions, such as overload, poor quality of fuel, or excessive lubrication.

As to the author's statements in regard to checking up on the crankcase sludges, it is believed that no accurate data could be secured from these deposits as they might easily be caused by contamination or partial breakdown of the oil in the crankcase system and have no definite relation to the cylinder lubrication. It is believed that the author's experiments in the development of an oil with lower carbon content are a step in the right direction for the development of lubricating oils better suited to the various conditions of Diesel engine lubrication.

Author's Closure

The measurement of lubricating-oil film temperatures and the data obtained from several tests will be discussed in a paper which will appear in the near future. A knowledge of the heat condition which oils are subjected to in the various parts of an engine would of course be valuable, but so far as is known, data sufficiently comprehensive to warrant general conclusions are not as yet available.

Operating conditions and the condition of the engine will obviously exert a great influence on the amount of carbon which

[2] Sinclair Pipe Line Company, Tulsa, Okla.

will be formed with any oil, and as a matter of fact carbon formation is usually influenced more by such factors than by differences in the oils. Two-cycle engines were selected for test purposes because of their known tendency to form carbon faster than four-cycle engines, although, as Mr. Harshman points out, adverse conditions will cause excessive deposits even in the latter type.

The decrease in exhaust-carbon formation as the exhaust-gas temperatures increase was found throughout the range of exhaust-gas temperatures studied. It may well be that a reversal in trend would be found at higher temperatures, but these were not available in the test engine which was in regular plant service. The only reason in deriving curves showing this rélation was to permit tests of different oils run at slightly different average exhaust-gas temperatures to be converted back to a standard temperature for comparison.

The value of an examination of crankcase deposits in a study of cylinder lubrication will depend entirely on the type of Diesel engine. The test engine under consideration used the same oil for both crankcase and cylinder lubrication, the latter being supplied with used oil by means of a force-feed lubricator. The excess oil from cylinders drained out into the crankcase, and of course contributed materially to formation of deposits and crankcase-oil deterioration. In other instances where only new oil is used on the cylinders and where there is little opportunity for used cylinder oil to drain into the crankcase system, there would of course be little object in studying the deterioration of a crankcase oil.

PET-52-4

Economics of Pumping Oil at Low Friction Losses

By FRITZ KARGE,[1] LOS ANGELES, CALIF.

A study of California pipe lines and perusal of many articles in magazines of the oil industry indicate that most trunk-line systems are operated at pressures ranging around 750 lb. per sq. in. These pressures result from high friction losses in 8-in. pipe, which appears to be the predominantly favored size. This paper shows that the greater cost of larger pipe lines for pumping oil at lower friction losses will be returned in a comparatively short time by the saving in power cost. It also indicates the way toward a proper estimate of the power-operating costs for new lines.

Application of these principles to the redesign of existing pipe lines is not attempted since the wide variation in the arrangements and characteristics of such lines does not permit generalization. The principles apply nevertheless.

A number of California trunk pipe lines are too small in size. This is particularly evident in winter when the oil becomes cold and viscous. Many of these lines were laid before any definite knowledge had been developed concerning the friction losses in oil pipe lines. It is a more or less common occurrence that while holding the pressure at 800 lb. per sq. in. or higher, the pumps will move less and less oil until the line "freezes." It then becomes necessary to plug it out with light oil. Several means of improving this condition have been under consideration from time to time, such as steam-heating stations and booster stations at intermediate points between pump stations. Electric heaters were tested out on at least two lines. Looping of lines has also been suggested and resorted to more or less. None of these means, however, is entirely satisfactory and most of them cost more than can be justified.

The laying of larger lines to improve pumping conditions has also been thought of, having in view the use of standard line pipe. The cost of such heavy large lines has usually been considered prohibitive. Now changes in the art of making and joining pipe of lighter weight have brought the larger sized lines within economic reach.

WHEN designing a trunk pipe line for a new oil field recently the author made a study of the power costs for pumping at different rates through several sizes of pipe line. The results were so strongly in favor of the large-size low-friction pipe line that it was decided to carry this investigation further and to apply it to light-oil as well as heavy-oil pipe lines.

For the light-oil line a representative light Mid-Continent crude oil was chosen and a length of line of 30 miles, which in many cases is the distance between Mid-Continent pump stations. For the heavy oil a length of line of 15 miles was chosen, which is the customary distance between pumping stations handling such oil in California. The characteristics of the oils are given later. In both cases it was found that the low-friction pipe line would be very much cheaper in operation, and the saving in power would pay off the greater first cost in a few years. An additional saving would result for the larger lines from the wider spacing of pump stations possible because of the lower friction losses per mile. This is also brought out.

General Conditions

It is beyond the scope of this paper to discuss methods for determining the probable period of use and probable rate of pumping of a pipe line or pipe-line system. In designing any kind of a trunk pipe line, however, to run from field to refinery, from refinery to marketing center, or from field or refinery to ocean terminal, an assumption must be made as to the probable period of use of the line and as to the probable rate of pumping. The period would perhaps be shortest for lines carrying crude oil from a single oil field. Experience has shown that the life of an oil field is usually at least 15 years and for many fields very much longer. With this as a basis for the useful life of a pipe line, and in order to be entirely conservative, the operating costs used in this paper include fixed charges equal to 10 per cent per year of the first cost of the line, applied to a wide range of pumping rates.

Since some objection might be raised concerning the use of long, large-diameter lines, it seems desirable to point out that large, thin-walled pipes have been installed and successfully operated in numerous locations throughout the country for gas service, and in a few cases for oil service. Progress has been made in the knowledge of protecting pipes against corrosion, so that the use of light-weight pipe is no longer a matter of experiment.

This paper compares the two largest factors in the annual operating cost of pipe lines of $8^{5}/_{8}$ in., $10^{3}/_{4}$ in., $12^{3}/_{4}$ in., 14 in., 16 in., and 18 in., outside diameter, all of $^{1}/_{4}$ in. thickness. These factors are power cost and 10 per cent write-off. Steel pipe of 70,000 lb. per sq. in. tensile strength was chosen. The maximum allowable pressures were based on a safety factor of four. Mill shipment prices were assumed. The first costs include the cost of the pipe, right of way, ditching, welding, protecting, lowering, testing, and back-filling. The costs were carefully estimated and the figures were checked by a successful California pipe-line contractor. Assuming that only 25 per cent of the length of the lines requires protection because of adverse soil conditions, the cost of protecting such a portion of the lines was included and provides for a coat of priming paint, three coats of asphalt, and two layers of spirally wrapped pipe covering. The lines were assumed to be level, both for the first and power costs. Table 1 gives the main elements which were considered as making up the total cost per mile.

---

[1] Engineer of Transportation, Union Oil Company of Calif. Mr. Karge was graduated in Civil Engineering from Throop College of Technology, now California Institute of Technology, Pasadena, Calif. He has been associated with his present concern since 1915. Until March, 1929, he was in charge of civil-engineering design and since then has supervised the design and construction of pipe lines, pump stations, tanks, reservoirs, and other facilities pertaining to the transportation of oil.

Presented at the National Petroleum Meeting, Tulsa, Okla., Oct. 6 to 8, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

TABLE 1 CONSTRUCTION COST PER MILE

Item	Outside diameter of pipe line—inches					
	8⅝	10¾	12¾	14	16	18
Cost of pipe	$4550.00	$5875.00	$7150.00	$7925.00	$9435.00	$11700.00
Hauling to job site (including stringing)	362.00	448.00	530.00	582.00	662.50	752.50
Ditching and backfilling	362.00	378.00	422.00	482.00	555.00	632.50
Aligning, welding, and lowering (including welding materials)	1025.00	1265.00	1505.00	1690.00	1900.00	2170.00
Inspecting and testing	159.50	193.00	238.00	280.00	331.00	392.00
Protective coating (25 per cent)	356.00	453.00	513.00	585.00	655.00	750.00
Surveying and superintendence	316.00	343.50	370.50	395.00	422.00	452.00
Miscellaneous (valves, fittings, bends, street crossings, railroad crossings, etc.)	357.50	407.50	489.00	553.50	624.50	693.50
Right of way and franchises	725.00	725.00	725.00	725.00	725.00	725.00
Contingencies	422.00	512.00	632.50	682.50	790.00	932.50
Total cost per mile	$8635.00	$10,600.00	$12,575.00	$13,900.00	$16,100.00	$19,200.00

Electric power was assumed because of the greater simplicity of comparison and the fact that an increasing number of pump stations use electric power for their prime movers. A rate of 1½ cents per kw-hr. was taken as being an average cost for electric power for pumping service. For the light-oil line no heating was considered, whereas the heavy oil was assumed to be heated to 150 deg. fahr. The means and the cost of heating are not discussed in view of the fact that steam pumps will usually be chosen where the oil has to be heated and exhaust steam will then be available for heating. If the cost of fuel oil and water are properly figured, the cost of steam power will ordinarily be found to be in excess of the cost of electric power. Using the cheaper electric power therefore for the heavy-oil line places the principle expressed herein in a less favorable light. It is felt that this is a simplification on the conservative side.

Power derived from Diesel engines is usually found to be cheaper than electric power. If the cost of power alone were considered for such installations the lower Diesel-engine power cost would result in a less favorable demonstration of the principle of this discussion. However, it is certain that Diesel engines for high-pressure pumps will cost considerably more than those for low-pressure pumps. This increased first cost for the Diesel engine for high-pressure pumps will partially or perhaps entirely offset the excess cost of the larger line. The great variety of Diesel engines available and the varying costs of their generated power made it inadvisable to consider them in detail.

An overall efficiency of 60 per cent was assumed for motor and pump. This value represents average performance of centrifugal pumps. The assumption of higher efficiency for the low-pressure pumps than for the high-pressure pumps would have been justified, and the resulting power costs would have favored the contention of this paper.

The light oil chosen is a typical Mid-Continent crude oil of the following characteristics:

Temp., deg. fahr.	Absolute (poises) viscosity	Specific gravity	Kinematic viscosity (poises)
40	0.1903	0.8443	0.226
60	0.1303	0.8363	0.156
80	0.0845	0.8283	0.102

The friction calculations were made with the assumption that the light oil would be at 60 deg. fahr. temperature.

For the heavy oil a California crude was used, having an A.P.I. gravity of 13.8. Complete characteristics for this oil are shown in Fig. 4. The heavy oil was assumed to be pumped at 150 deg. fahr. and to cool in the line because of the ground temperature of 60 deg. fahr.

The friction losses in the pipe lines were calculated by the formulas for flow of fluids through pipes as given in Walker, Lewis, and McAdams' "Principles of Chemical Engineering," 1927 edition. The values so computed were compared with those obtained by using the formulas given by R. S. Danforth, of the Kinney Manufacturing Company, in his booklet, "Friction Pressure Loss in Oil Pipe Lines." The friction-loss curves resulting from the two methods are so nearly in agreement that the difference in the ultimate result is negligible. The temperature losses in the heavy-oil line were calculated, using the charts in "Oil Flow Viscosity and Heat Transfer," published by Mr. Danforth.

Again for the sake of conservatism, the cost of pump-station installations for high and low pressures was not considered. The higher cost of high-pressure pumps and motors would partially offset the higher cost of the larger pipe lines for which lower-pressure pumps and smaller motors would be in order. It requires no proof that the low-pressure pumping installations would have a longer life and require less maintenance than high-pressure installations. These features add strength to the conclusions reached. It can further be assumed that low-pressure pipe lines will also require less maintenance.

TABLE 2 FARTHEST POSSIBLE SPACING OF PUMP STATIONS

From Fig. 1					From Fig. 3	From Fig. 1		
Throughput at max. press. small line, bbl. per hr.	Small line 30-mi. long		Next larger line		Years pay-off period	Max. press. permissible larger line, lb. per sq. in.	Longest dist. for larger line at max. press.	
	Size, in.	Lb. per sq. in.	Size, in.	Lb. per sq. in.			Size, in.	Distance, miles
1200	8	1100	10	360	1.2	850	10	71.0
2000	10	850	12	360	1.2	720	12	60.0
3000	12	720	14	445	0.7	650	14	44.0
3750	14	650	16	350	1.0	575	16	49.0
5050	16	575	18	315	1.2	500	18	47.5

The advantage of pumping through large lines at low-friction losses is demonstrated in the charts given herein.

Light Oil Lines

Fig. 1 shows the pressures in lb. per sq. in. required to pump light Mid-Continent crude at 60 deg. fahr. through the different-sized pipe lines, all 30 miles long, at rates from 200 to 6600 bbl. per hour. The dotted line across the top of the curves indicates the maximum pressures which the different pipes can stand with a safety factor of four. The pressures necessary for handling 1000 bbl. per hour, for instance, would be as follows:

Size line, in.	Lb. per mile	Lb. for 30-mile line
8	26.70	800
10	8.67	260
12	3.74	112
14	2.92	70
16	1.23	37
18	0.67	20

The pressure-capacity limit line shows that the maximum rates of pumping vary from 1200 bbl. per hour in the 8-in. line to 6600 in the 18-in. line. For lines shorter or longer than 30 miles the pressures will be proportional, the friction loss per mile remaining the same.

Fig. 2 shows the operating costs in dollars per year per mile for rates of pumping from 400 to 4500 bbl. per hour. The costs include the electric power cost and 10 per cent of the cost of first installation, all reduced to cost per mile. For a 30-mile line,

these figures should be multiplied by 30; for shorter or longer lines by their respective lengths.

It will be noted that at the lower pumping rates the curve for each size pipe line crosses the curves of all smaller-size pipe lines. This indicates that at these lower rates the operating costs are less for small than for large lines. This condition, however, applies only for a short range. The 8-in. pipe, for instance, is cheaper to operate than the 10-in. line only when the rate of pumping is below 500 bbl. per hour. At 1000 bbl. per hour the 8-in. line is more expensive than any of the others, costing about $2600 per mile per year. The cost of operating the other lines at the same capacity is as follows:

Size line, in.	Cost per year per mile, dollars
12	1500

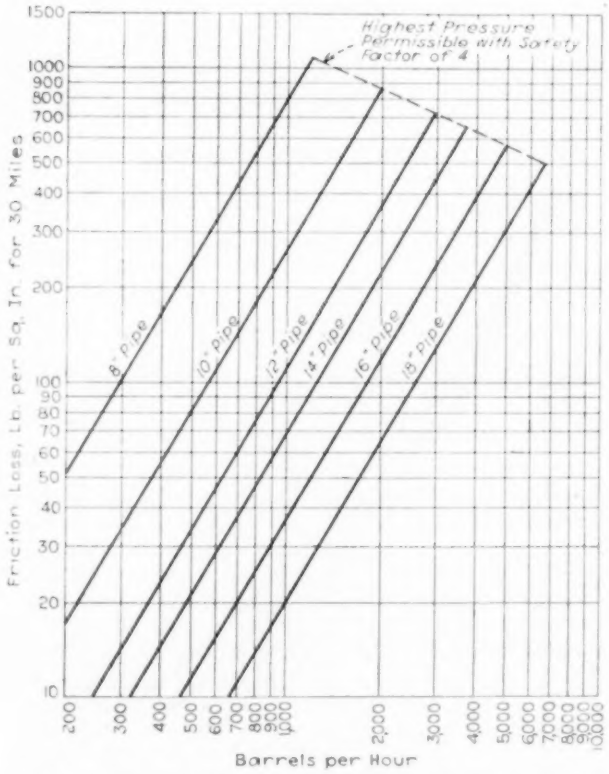

Fig. 1 Pressures Needed to Pump Light Oil Through Pipe Lines of Different Sizes

At 2100 bbl. per hour the cost of operating the 16-in. and 18-in. lines are the same, amounting to $2250 per year per mile. All other lines are more expensive. The upper points on the curves for the 8-, 10-, 12-, and 14-in. lines indicate the maximum rate at which pumping through these lines is possible as determined by the strength of the pipe.

It can also be seen in Fig. 2 that the economic pumping pressures are considerably below the maximum pressures that the pipes can stand, i.e., this is the case in large low-friction lines. As a result such lines not only operate more safely, but will have a large excess capacity available for peak loads due to flush production or emergency movements of oil. To handle such cases it will only be necessary to use the stand-by pumps or to get larger ones. If a system is ordinarily operated at high pressure, i.e., near the pressure-capacity limit of the pipe, peak loads cannot be accommodated. Winter conditions, furthermore, will not affect a large line as adversely as a small one.

Fig. 3 shows the years required for the operating savings in any size line to pay off the difference in first cost between it and the next smaller size line when pumping at different rates. When pumping at 1000 bbl. an hour for instance, the 10-in. line will pay off the difference between its first cost and the first cost of the 8-in. line in two years. At 2000 bbl. per hour, the 12-in. line will return its greater cost over the 10-in. line in about 7 months, and the 14-in. line will return its greater cost over the 12-in. line in about a year and seven months. If a period of 10 years is taken in which to effect a saving equal to the difference in first cost, it is readily seen that this can be accomplished with relatively low pumping rates.

At this point a few remarks relative to the economic spacing of pump stations seem in order. Table 2 gives the pay-off periods required for the savings in operating costs in any size

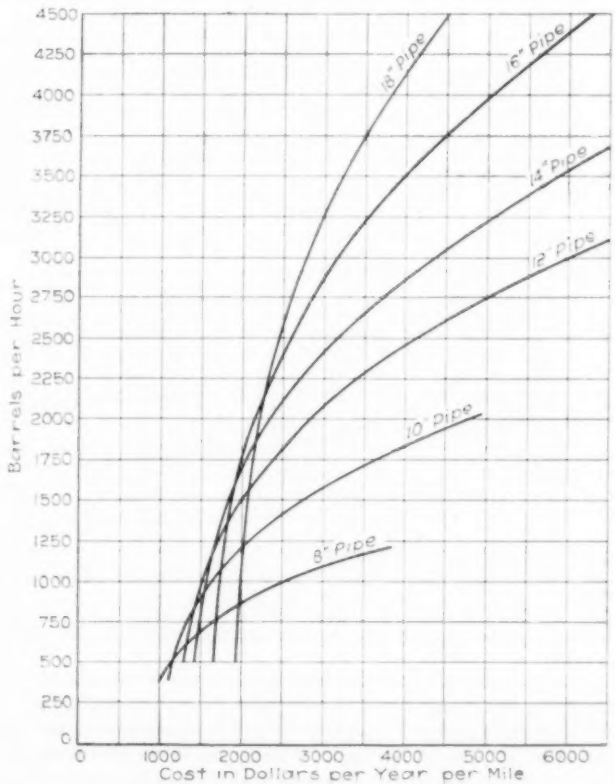

Fig. 2 Operating Costs for Different Rates of Pumping

line to pay off the difference in first cost between it and the next smaller size line when pumping through 30 miles of line at the rate producing in the smaller line the highest pressure consistent with a safety factor of four. The highest permissible pressures are also tabulated. The last column gives the distance through which the oil can be moved through the larger of any two lines under consideration, if the pressure were brought to this highest value, and if the rate of pumping were maintained that produces the highest pressure in the smaller line. This means that the pump stations in the larger of any two lines could be placed very much farther apart than in the smaller line of 30 miles length. In practice, pumping at the highest allowable safe working pressure may not be admissible. Nevertheless, an appreciably wider spacing of pump stations would be entirely

in order, and would result in an additional saving of considerable magnitude.

Heavy-Oil Lines

The consideration of the heavy-oil line is based throughout on a pumping rate of 1000 bbl. per hour. This rate was chosen since it is one aspired to, but seldom reached, in similar lines in California. It seemed inadvisable to develop these diagrams for different rates of pumping because of the many kinds of heavy oils of different characteristics and the varying limits of heating and cooling encountered in practice. The one example offered will demonstrate the principle.

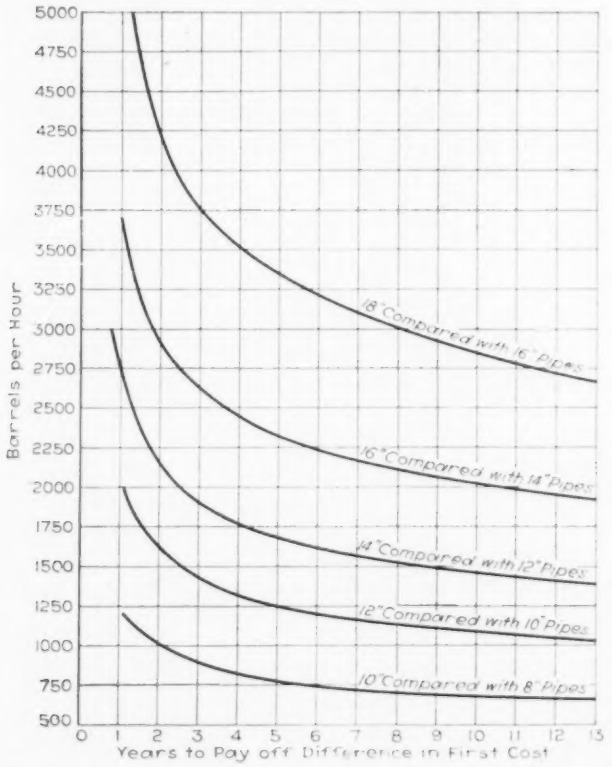

Fig. 3 Time Needed for Savings to Pay Off Difference in First Cost Between Any Line and the Next Smaller Size Line

The characteristics of the heavy California crude oil used to illustrate the design for a 15-mile pipe line are given in Fig. 4. To find the kinematic viscosity at any temperature of the oil, the chart is followed horizontally along the desired temperature to an intersection with the curve, and thence vertically to an intersection with the specific gravity corrected to the temperature. From this point a position parallel to the diagonal guide lines is followed to the upper scale where the kinematic viscosity may be read.

Temperature gradients in the different size lines when pumping 1000 bbl. per hour, initial temperature of 150 deg., ground temperature 60 deg. fahr. are shown in Fig. 5. The line was divided into one-mile sections, and the temperature drop for each section computed from Danforth's heat-loss charts.

It can be seen that the larger the line the better the oil retains its heat for the same rate of flow. This has been demonstrated in tests and in practice. In consequence, in the larger line the oil is pumped at a lower average viscosity, and its higher temperature will keep down solidification of wax, if this substance should be present in the oil.

The friction loss per mile of line when pumping the heavy oil at a rate of 1000 bbl. per hour is shown graphically in Fig. 6. The friction losses are given for the viscosities corresponding to the temperatures within the limits of the temperature gradients shown in Fig. 5.

TABLE 3 PAY-OFF PERIODS FOR THE HEAVY-OIL LINE FIFTEEN MILES LONG

		1304	46,500	35.6
18	35,336			

[1] The 8-in. and 10-in. lines are not listed since they cannot handle the oil for 15 miles at 1000 bbl. per hour rate.

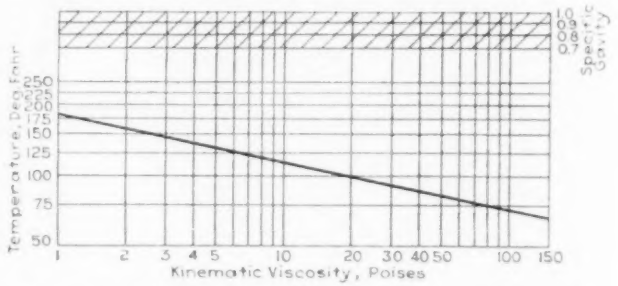

Fig. 4 Characteristics of Heavy California Crude Oil

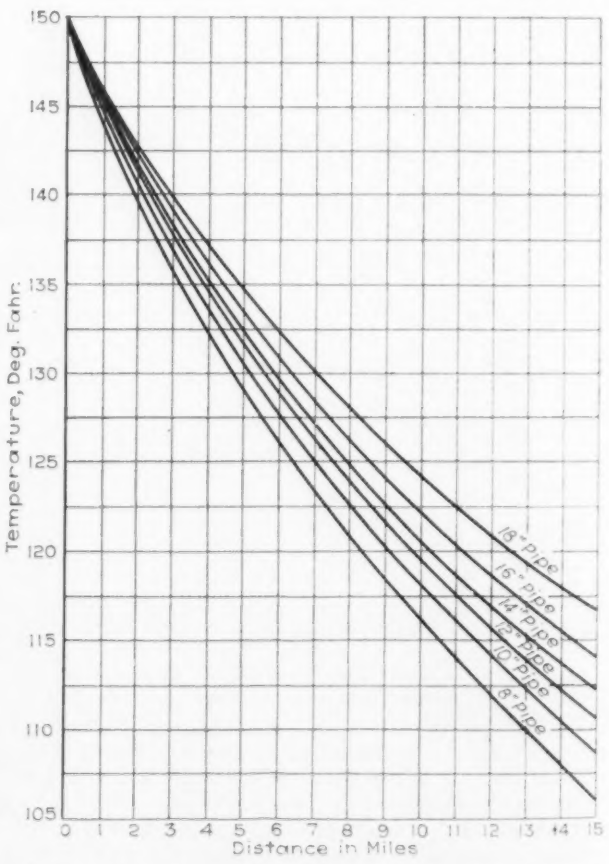

Fig. 5 Temperature Gradients in Different Size Lines

Fig. 7 shows the operating costs per year for pumping 1000 bbl. of heavy oil per hour through lines of lengths from 1 to 15 miles. The procedure used in drawing up this form of chart is as follows:

From Fig. 5 the mean temperature is obtained for each successive mile of the pipe line. From Fig. 4 the kinematic viscosities are determined of the oil for each of these mile sections. Next, from Fig. 6 the friction loss is found for each of the miles and these are added. This gives the necessary pumping pressure. Using the power figure of $1^1/_2$ cents per kw-hr. with an overall

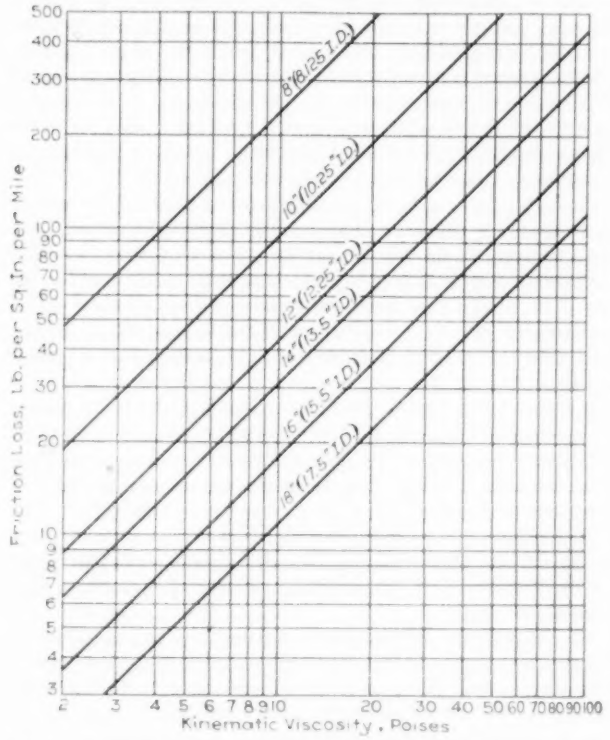

FIG. 6 FRICTION LOSS PER MILE OF LINE WHEN PUMPING HEAVY OIL

efficiency of 60 per cent, the yearly power cost for this pumping pressure may be arrived at. If this power cost is then combined with the fixed charges, which are assumed to be 10 per cent per year of the installation cost, the values shown in Fig. 7 result.

The computations show that the 8-in. line can handle this quantity of 1000 bbl. per hour only through a distance of a little less than 10 miles, and the 10-in. line through 14 miles, when pumping at the highest pressure consistent with a safety factor of four. These limits are beyond the range of the chart.

CONCLUSIONS

From the foregoing analysis it can be seen that the use of large pipe lines at low-friction losses for pumping oil is the most economical arrangement. The use of the figures to solve specific problems is proper only when the oil characteristics are the same. It is, however, possible to study the economics of any proposed pipe line by applying the procedure as set forth in this discussion. Since the spacing of booster stations, the selection of pumping, heating, and other equipment will all be influenced by the size of the pipe line, the necessity for a comprehensive analysis of all factors pertinent to any project is evident.

It seems that many of the old oil trunk lines operate with uneconomically high friction losses. From the foregoing discussion it follows that the oil industry would lessen future oil-pumping costs by laying low-friction lines in all new trunk-line installations. It is probable that in many cases, particularly of lines that are expected to be operated for years to come, appreciable savings would result from a careful redesign and reconstruction with

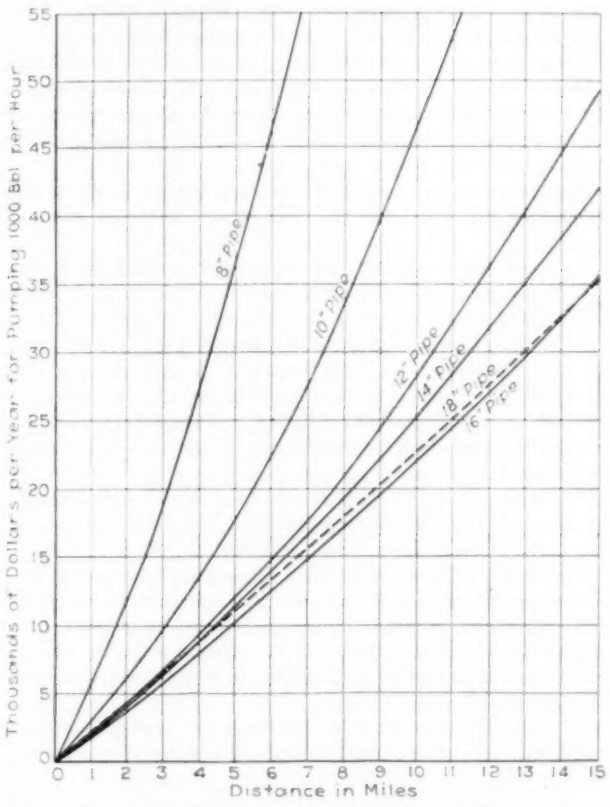

FIG. 7 OPERATING COSTS FOR PUMPING HEAVY OIL THROUGH LINES OF VARIOUS LENGTHS

larger, low-friction loss lines. Some of the large pipe-line companies are now in a position analogous to that of the railroads, in that increased profits must be principally derived from operating economics. These are often possible only after the courageous and well-planned expenditure of money to improve operating conditions.

The author wishes to acknowledge the assistance of L. V. Horne, Mechanical Engineer, Union Oil Company of Calif., and L. M. Miller, Civil Engineer, Union Oil Company of Calif., in the preparation of this paper.

Discussion

R. S. DANFORTH.[2] There has been a tendency among many oil companies owing to the rapid changes in that industry to feel that any expenditure must be repaid in one or two years to justify its installation. On this basis many installations are omitted that would pay good returns on the investment, and the author seems to have called desirable attention to one of these possibilities.

In the paper a number of items favoring the low-pressure line have been intentionally disregarded, but opposing that, the fixed charge of 10 per cent per year seems low if interest on the investment is to be included. Possibly the author intends the saving shown to balance interest on the increased investment.

For temperature drops the charts in "Oil Flow Viscosity and Heat Transfer" were used. These charts were based on accurate data of 8-in. pipe lines of the General Petroleum Company, using recording thermometers for the ground temperatures.

Few test data were available at that time on other sized lines

[2] Pacific Coast Manager, Kinney Manufacturing Company, San Francisco, Calif. Mem. A.S.M.E.

where the ground temperature was accurately known. The effect of variation of size of pipe was deduced by dimensional analysis, and values were suggested pending the availability of more accurate data with known ground temperatures. It would be interesting to know if any tests of other sizes are available at the present time with the ground temperatures accurately known.

The author is to be congratulated on the study given this important subject and the thorough way it has been handled.

W. H. STUEVE.[3] This paper proves in conclusive form that the transportation of crude oil could be made much cheaper by installing larger-sized pipe to reduce friction losses, instead of operating at maximum pressures allowable for a given pipe, but to operate them at lower pressures through a larger pipe line for a like volume of oil pumped, thereby reducing the power requirement cost of station operation, which saving would tend to repay the operating company for increased cost of the larger line required.

It is noted, however, that the curves shown in Fig. 3 are developed by using an electric power cost of 1.5 cents per kw-hr. and "overall" centrifugal pump efficiency of 60 per cent. It is the experience of most pipe-line engineers that a net rate of 1.5 cents per kw-hr. for 100 per cent load factor and for demands of 200 to 500 kw. will not be competitive with oil engines. The curves shown in Fig. 3 are all based on 100 per cent capacity or pumping rates maintained for 8760 hours per year, and hence 100 per cent electrical load factor.

By using the following assumptions to develop an electric rate which will be competitive with oil engines—

(*a*) Oil-engine pump station will cost $3\frac{1}{2}$ times that of centrifugal station, including standby unit of $\frac{1}{2}$ total capacity
(*b*) 15-year life of equipment, 12 per cent total fixed charges
(*c*) Plunger-pump efficiency, 90 per cent
(*d*) Centrifugal-pump efficiency, 70 per cent
(*e*) Motor efficiency, 92 per cent
(*f*) Fuel 0.5 lb. per b.hp-hr. at $2 per bbl.
(*g*) Oil-engine station labor cost 2 times that of electric centrifugal
(*h*) Oil-engine station lubrication 9 times that of electric centrifugal.

From which it is found that an electric rate of approximately the following description will enable electric motors to compete with oil engines as prime movers;

Load factor	Permissible power cost, cents per kw-hr.
100	1.00
90	1.05
75	1.17
50	1.45

All power companies supplying energy for pipe-line pumping in the Mid-Continent oil field have rates of this approximate character.

Referring to curves on Fig. 3, it is noted that when pumping at rate of 1000 bbl. per hour, if 10-in. pipe had been installed instead of 8-in. pipe, the lower power requirements of the 10-in. station would permit it to pay back in two years the difference in installed cost of 10-in. pipe, as against using 8-in. pipe. By using an electric rate of 1 cent per kw-hr. at 100 per cent load factor, it is found that this pay-off period is extended to 3.3 years.

Also, the author should take into account the fact that centrifugal-pump efficiencies will be considerably better when pumping 24,000 bbl. per day in the 10-in. line at 260 lb., instead of a like volume at 800 lb. in the case of the 8-in. line. If this is taken into account, and an overall efficiency of 70 per cent were used, the pay-off period would be three years.

Laying aside the aforementioned difference in pump efficiencies, and assuming that a figure of 60 per cent overall is correct for both 8- and 10-in. volumes and pressures, and again use a value of 1 cent per kw-hr. when pumping at the rate 750 bbl. per hour, it is found that the pay-off period in the case of 8-in. line, as against a 10-in. line, is extended to 11.5 years instead of 5.5 years, as shown on the curves of Fig. 3. This is a long time to project estimated pumping conditions, and therefore the savings effected by using the larger 10-in. pipe may not make much impression on the executives.

As stated previously, all conditions of the developed economic analysis in this paper are based on pumping at the same hourly rates throughout the year for a great number of years to follow.

Experience with known capacities in main trunk lines for the last 4 or 5 years has shown that 100 per cent capacity is not maintained. Trunk lines of three of the largest pipe line companies delivering oil to Chicago and St. Louis have been operating on a 70 to 75 per cent capacity for the last several months and expect to operate at this rate for a period of 6 to 12 months in the future. Therefore some consideration should be given to "capacity factor" over a period of time in making predictions or developing curves to indicate when certain capital expenditures could be recovered if larger lines are installed.

It is suggested that an interesting set of curves, such as shown in Fig. 3, could be developed by using an annual capacity factor of 75 per cent or some such figure as would usually be met with in practice.

The hypothesis in this case would be that pumps would be installed to handle 1000 bbl. per hour and with 60 per cent overall efficiency at that point, but would operate only for 18 hours per day at 800 lb. in case of 8-in. pipe line; therefore, an electrical monthly load factor of 75 per cent is achieved to deliver 18,000 bbl. per 24 hours or 75 per cent capacity factor.

The permissible electric power rate would be 1.17 cents per kw-hr. at 75 per cent load factor. If this condition of hypothesis is maintained for a period of one year or longer, the savings amount to $15,400 per year by using 10-in. pipe as against using the smaller 8-in. pipe, and therefore the increased investment of the larger pipe would be repaid in 3.9 years.

Likewise at 90 per cent capacity factor or electric load factor, when pumping at maximum rate of 1000 bbl. per hour for $22\frac{1}{2}$ hours per day, and using an electric rate of 1.05 cents per kw-hr., the pay-off period is reduced to 3.5 years, for an average delivery of 22,500 bbl. per day.

These figures will hold true only for centrifugal pumps, and a separate study for reciprocating pumps would be necessary, since the most economic method or rate of pumping for 75 per cent capacity factor would be to operate two reciprocating pump units each of 12,000 bbl. capacity per day for 12 hours and one unit for the remaining 12 hours rather than both units for 18 hours, the energy consumption being in this ratio as 77 is to 100.

Another factor not taken into account is the fact that the pressure-volume curves shown in Fig. 1 are apparently based on crude of 80 Universal Saybolt seconds viscosity, and consequent results shown in Fig. 3 pay-off periods, for average Mid-Continent crude.

The annual average temperature for crude flowing in lines in Oklahoma and Texas is approximately 68 deg. fahr. for lines buried 2 ft.

The average viscosity of Mid-Continent crudes at 68 deg. fahr. and 35 deg. A.P.I. gravity will approximate 70 Universal

[3] Oklahoma Gas and Electric Company, Oklahoma City, Okla.

Saybolt seconds or 0.145 kinematic viscosity (poises), and in most cases 50 to 60 Universal Saybolt seconds.

When pumping 1000 bbl. per hour through 30 miles of 8-in. pipe line, the initial pressure required is 720 lb. for 70 Universal Saybolt seconds crude. Likewise when pumping the same amount through a 10-in. line the initial pressure is 240 lb.

The power requirements from the foregoing data, plus fixed costs on the pipe line, again extend the time of recovery of capital expenditure for the difference in first cost between an 8-in. and a 10-in. line from 2 years, shown in Fig. 3, to 2.3 years. Likewise, when pumping 750 bbl. per hour through 30 miles of 8-in. pipe line, the initial pressure is 430 lb. for 70 Universal Saybolt seconds crude oil, and 150 lb. initial pressure when pumping a like amount through a 10-in. line. In this case the difference in capital expenditure for the larger 10-in. line as against using 8-in. pipe will be recovered in 7.3 years, instead of the 5.5 years indicated in Fig. 3, using an electric energy rate of 1.5 cents per kw-hr. and 60 per cent overall centrifugal-pump efficiency in both cases.

As a whole the theories developed in the paper are well proved, but the writer believes that from a practical viewpoint the curves as developed in Fig. 3 should be extended, based on conditions found in actual practice in the field with regard for capacity-load factors and temperate-viscosity changes. Therefore the conclusions reached would carry more weight with practical pipe-line executives, engineers, and designers.

Author's Closure

For the sake of simplicity the figures in the paper were developed for a section of pipe line 30 miles long and only for one set of conditions, which were believed to be average conditions. The necessity for a comprehensive analysis of the factors pertinent to any project was emphasized, since the spacing of pump stations and the selection of pumping, heating, and other equipment would all be influenced by the size of the pipe line. The paper suggests that figures similar to those in the paper, but constructed on the basis of all conditions pertinent to the project in hand, would show that the low-friction-loss line of larger diameter will be the more economical line to build.

Mr. Stueve in his discussion points out the effect on the figures of lower power rates, higher overall efficiency of pumping equipment, and of lower load factor resulting in the extension of the pay-off periods, without, however, vitiating the principles brought out in the paper. The paper itself refers to the lower power rates attained with oil engines and suggests that the saving possible with larger lines by the wider spacing of pumping stations will partially or wholly offset the higher cost of larger lines.

Even with power rates as low as suggested by Mr. Stueve, the larger lines will prove therefore more economical.

Again, for the sake of simplicity the paper made no allowance for this saving in pumping stations. The wide variation in cost of pump stations would have complicated the figures. Sample calculations were made, however, with power rates as low as 1 cent per kw-hr., proving the contentions of the paper.

The paper also states that for any pipe-line project an assumption must be made of the probable period of use of the line and of the probable rate of pumping. Such an assumption must include the consideration of the load factor. Trunk lines are built ordinarily with the expectation of an improving load factor.

It is evident that the trend in pipe-line installation is toward larger lines. The saving in power costs possible through the use of larger lines has of course been always known. The installation of larger lines has become practicable and economically advantageous through the very marked improvements in the art of making and joining large-size thinner-walled pipe.

PET-52-5

Temperature Observations for One Year on Streams of Petroleum Flowing in Mid-Continent Oil Pipe Lines

By BERT MARTIN[1] and WILLIAM G. HELTZEL,[2] TULSA, OKLA.

The designer of an oil-pipe-line system could obtain valuable data on the contraction of the lines if he knew more about the temperature variations of the oil flowing through them. In the transportation of oil over long distances through pipe lines, a change in the temperature of the oil is likely to occur, thus affecting the volume. It is valuable to be able to predict the amount of change in volume for temperature changes over long distances. An important factor is the viscosity of the petroleum, for temperature variations in the oil stream cause the viscosity to vary. The paper shows how these results may be obtained, and gives charts as an indication of the temperature conditions of the oil flowing through the oil-pipe-line systems of the Mid-Continent.

KNOWLEDGE of the underground temperature of oil pipe lines is important, both in the design and operation of an oil-pipe-line system of any length.

Oil pipe lines are laid without expansion joints, and the contraction in the pipe line is provided for by crowding the pipe line into the ditch. It is a rule-of-thumb method in pipe-line practice for providing sufficient "slack" in the line to take care of the contraction. The past history of pipe-line operation is filled with repeated failures caused by the oil pipe lines pulling apart at the joints, especially for the screwed-coupling line, during cold weather or at a time when sudden changes of temperature occur in the ground. It is believed that with information as to temperature variations in these lines, more consideration can be given to the contraction of the lines in designing a pipe-line system.

In the transportation of petroleum over long distances through pipe lines a change in the temperature of the oil is likely to occur, resulting in either a shrinkage or an expansion in the volume of petroleum. It is worth-while information to be able to predict the amount of change in the volume of oil for temperature changes over long distances.

In the design of an oil-pipe-line system, one of the most important factors in the hydraulic calculations is the viscosity of the petroleum, and consequently something must be known beforehand as to the temperature variations of the oil stream in the pipe line; for the viscosity of the petroleum varies widely with the temperature. In order to compute pipe-line pressures, capacities, and horsepower required for a new pipe line, the average temperature of the oil stream should be known, since both the density and the viscosity of the oil are affected by temperature.

It has been pointed out that in the design of oil pipe lines, information as to temperature variations is important in order to provide sufficient "slack" for the contraction in the lines. But since no scientific way of providing for the sufficient amount of slack is used in the construction of oil pipe lines, failures will occur from time to time. Some knowledge as to when minimum temperatures are reached and when the greatest temperature variations occur will aid the men responsible for operation in watching for the failures due to the lines contracting. No trouble, except for leaking couplings, is experienced from the expansion of buried lines. For this reason it is the policy of some pipe-line companies to lay their lines, if possible, during the months of the year when fairly low temperatures prevail.

Purpose

It is the purpose of this paper to present such temperature data for oil pipe lines as might prove helpful both in the design and operation of oil-pipe-line systems in the Mid-Continent area. The average daily temperatures, covering a period of one year, for the oil streams flowing through pipe lines across the various states of the Mid-Continent are presented herewith. It is hoped that these data on average temperatures and the fluctuations in the temperature will prove helpful in the design and operation of oil-pipe-line systems.

Method of Obtaining Temperatures

The temperatures of the oil streams were obtained at four oil-delivery points on a pipe-line system; one near East Chicago, Ind., one in Missouri, one in Kansas, and another at Houston, Tex. A recording thermometer with two bulbs was used for obtaining the oil and the atmospheric temperatures. The one bulb was inserted as a tight fit in a separable steel sock, directly in the stream of the petroleum. The bulb was properly insulated from atmospheric temperature influences. The other bulb was exposed to the atmosphere and protected from unnatural atmospheric temperature variations. Each thermometer was calibrated against a certified mercury thermometer; and at the end of each month, and in some cases every two weeks, the temperature shown on the recording chart was checked with an accurate mercury thermometer by obtaining the temperature of a gallon sample oil drawn from the line.

Once a week the temperature charts were mailed to a central point, and the average temperatures were obtained with a planimeter. Any discrepancies in the recorded temperatures were watched for closely, and any variation from the expected result was checked immediately at the place where the temperature was measured.

Results

These temperature observations are shown in Figs. 1, 2, 3, and 4.

Fig. 1 shows the average temperatures of the continuous stream of oil-received at an oil-delivery point near East Chicago, Ind. These results should be typical of an oil stream flowing in a northeasterly direction across the northern part of Illinois, and likewise across Missouri.

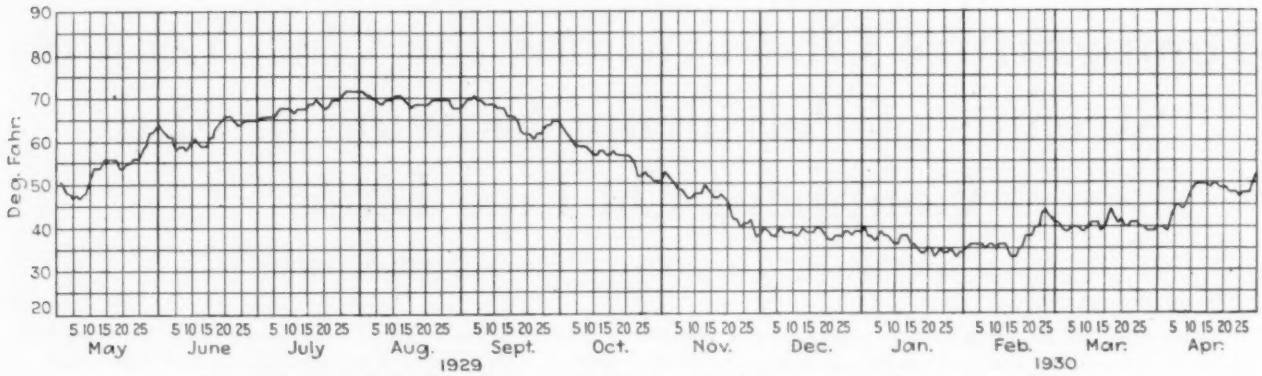

FIG. 1 AVERAGE DAILY TEMPERATURE OF PIPE-LINE OIL STREAM IN THE STATE OF ILLINOIS

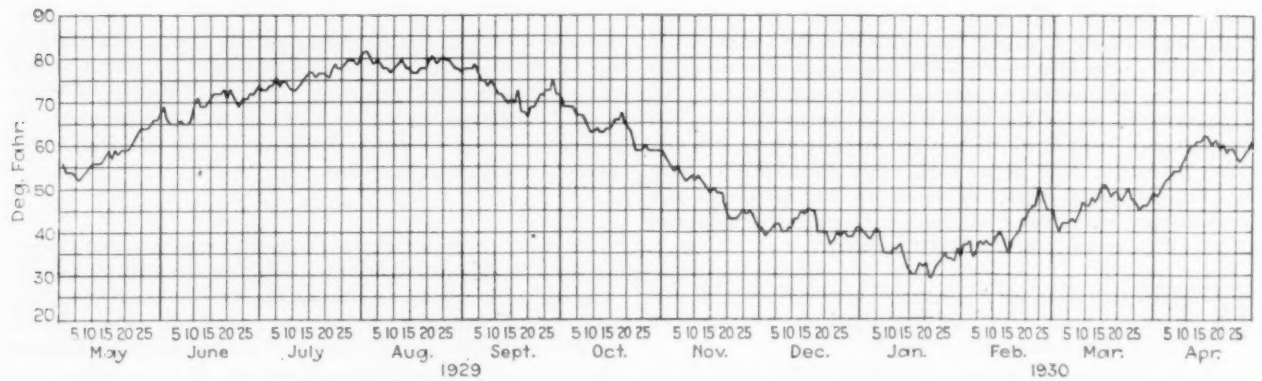

FIG. 2 AVERAGE DAILY TEMPERATURE OF PIPE-LINE OIL STREAM IN THE STATE OF OKLAHOMA

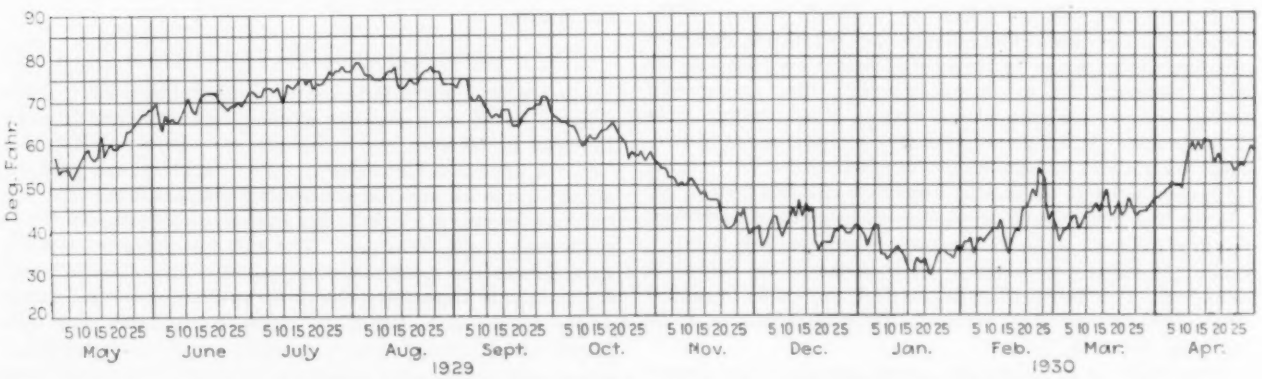

FIG. 3 AVERAGE DAILY TEMPERATURE OF PIPE-LINE OIL STREAM IN THE STATE OF MISSOURI

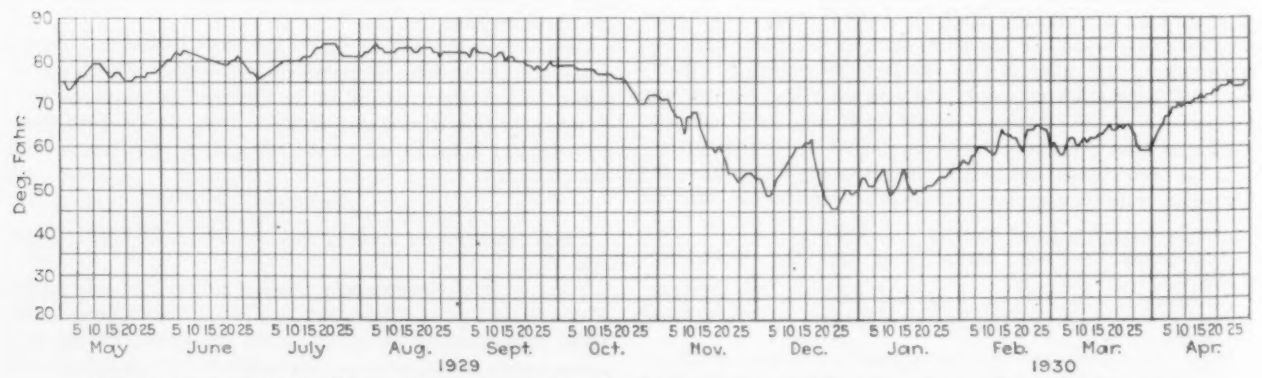

FIG. 4 AVERAGE DAILY TEMPERATURE OF PIPE-LINE OIL STREAM ACROSS THE STATE OF TEXAS, NORTH AND SOUTH

Fig. 2 shows the average temperatures of a non-continuous oil stream received from a trunk line running a little east of north across the central part of Oklahoma and across the southeast corner of Kansas. This curve should give temperatures nearly the same as those that could be expected in oil trunk lines in Oklahoma and Kansas.

Fig. 3 shows the temperatures for an oil stream being delivered in Missouri, near Kansas City. The temperatures on this curve correspond closely with those shown in Fig. 2.

Fig. 4 shows the average daily temperatures for an oil stream flowing through a pipe-line system taking a southeasterly course across the eastern part of Texas and ending at Houston. The temperature shown in this curve should be typical of the oil streams flowing through the principal pipe-line systems of Texas.

Discussion of Results

These temperature observations show that the maximum oil temperatures in pipe lines are reached in Oklahoma, Kansas, Missouri, and Indiana about the first of August and decline to a minimum about the last of January. It appears that the maximum temperature of the oil in the lines in Texas is reached from the middle of July to the first of August, and the minimum temperature is reached about the last of December.

Table 1 shows the maximum and minimum temperatures and the total variation in temperatures from the maximum to the minimum for the various states.

TABLE 1

Location	Maximum temperature, deg. fahr.	Minimum temperature, deg. fahr.	Difference in temperature, deg. fahr.
Illinois and northeast Missouri	71.5	33.5	38.0
Oklahoma and Kansas	79–82	30.0	49–52
Eastern Texas	84	45.5	38.5

The temperatures for the oil stream observed at a point in Kansas and in Missouri are very likely 2 to 3 deg. too high for the maximum and about the same number of degrees too low for the minimum temperature. The reason for these discrepancies is that the stream of oil was not continuous over a 24-hr. period, and consequently during the shutdown period of as long as 16 hours the oil temperature in the line would approach more nearly the ground temperature. The temperature of the oil stream was averaged only for the period during which it was flowing.

These temperature observations show that temperatures as high as 84 deg. fahr. are reached in the oil lines in Texas and that temperatures as low as 45.5 deg. fahr. existed during the last winter (1929–30) in these lines, with a difference of 38.5 deg. fahr. Unusually low temperatures were reached in Texas last winter.

It appears that there is a difference of about 50 deg. fahr. between the maximum and minimum temperatures for the oil streams flowing through the pipe lines in Oklahoma and Kansas, which is nearly 12 deg. higher than the differential for the lines in Texas and Illinois.

The temperature differential for the oil flowing through the lines in Texas is about 38.5 deg. fahr., which is nearly the same for the oil stream flowing through Illinois.

The large drop in the temperature of the oil streams for Oklahoma and Texas on December 17 was caused by the blizzard which set in at this time and which was very unusual for Texas.

These charts show that there are considerable variations in the temperatures of these oil streams over as short a period of time as three to four days. It is during these rapid changes of temperatures in a short period of time that the lines are likely to separate due to the sudden force of contraction.

It is believed that the temperature of the pipe is practically the same temperature of the oil, and this information can be used for studying the contraction of lines.

In no case has artificially heated oil been flowing through these lines during the period of the observations.

There is probably a differential of a degree or two of temperature between the ground and the oil stream.

These curves are presented as an index of temperature conditions for the streams of petroleum flowing through the oil-pipeline systems of the Mid-Continent. These curves show daily averages for only one year. A record for three or four years will be required to establish average annual curves; but these curves should not vary much from the average.

Discussion

F. A. Stivers.[2] As a rough check of data shown in the paper, the writer has compared operating records of temperatures taken in a 12-in. line in Oklahoma, Missouri, and Illinois with readings as shown by these curves. Individual day's readings, of course, show variations from the plotted data, but the general trend of temperatures follows closely enough to indicate that the temperatures shown can be taken as generally representative of other lines in the corresponding states, as well as in the particular line on which readings were taken.

It is interesting to note that oil in the Oklahoma line reached lower winter temperatures than oil in the northern Illinois line, while in summer it reached a peak within a few degrees of the highest temperature found in the line in south Texas. This results in a wider difference between summer and winter capacities in Oklahoma than in Illinois or Texas. For example, in a 12-in. line at 9 lb. per mile friction drop, an oil of about the viscosity characteristic of Seminole crude would flow at a minimum winter capacity rate of $87^1/_2$ per cent of maximum summer capacity in Oklahoma, while under South Texas temperature conditions the minimum winter capacity would be $92^1/_2$ per cent of maximum summer capacity. Due to the lower average temperature throughout the year, the line in Oklahoma would have a total annual capacity only 95 per cent as great as it would have under Texas temperature conditions. On a crude having steeper viscosity curves, such as Oklahoma City crude, the difference between maximum summer capacity and minimum winter capacity would be even more marked than this. These differences must be taken into account in the design of the pipeline system, especially in cases where motor-driven equipment is used, and the information given in this paper should be of much value for such purposes.

In regard to the matter of line breaks, apparently the majority of line breaks due to temperature contraction occur at line temperatures between 30 and 40 deg. and occur at times of relatively rapid temperature changes. It would be of interest in this connection to determine the effect of somewhat greater depth of line burial in smoothing out the sudden temperature changes. The writer would also like to see a line of atmospheric temperatures plotted on the same sheet with the line oil temperatures, so as to know the amount of lag existing in the lines on which readings are made.

Some Operating Data for Electric-Motor-Driven Reciprocating and Centrifugal Oil-Pipe-Line Pumps

By W. H. STUEVE,[1] OKLAHOMA CITY, OKLA.

There is interest among operating officials of oil-pipe-line companies in the costs of electric-motor-driven pumping stations, and the author endeavors to give facts on electric energy consumption for both centrifugal and reciprocating pumps. He reaches the conclusion that centrifugal pumps will pump oil at 700 lb. per sq. in. for 0.335 cent per barrel and that reciprocating pumps will do the same work for 0.24 cent per barrel, for the electric power costs.

CONSIDERABLE interest is usually shown by executives of oil-pipe-line companies in the operating costs of an electric-motor-driven pumping station when they are considering the installation of new pumping stations, but authentic data and facts are always hard to obtain, even from a company's own records, to show what the costs actually amount to, for the reason that conditions at particular pumping stations may be different from those which are under consideration.

Some of these conditions are as follows: Electric-motor-driven pumps may operate in parallel with oil engines or steam engines; load factors may be very poor; pipe-line capacity may be too small, causing excessive pressures; or the stations are all oil engine driven, with no electric data available. Consequently, it is necessary to rely on theoretical data, which are not very acceptable.

The purpose of this paper is to present definite electric energy consumption, actual facts, for both centrifugal and reciprocating pumps. The data have been obtained from pipe-line companies, "economy log records."

At the present time there are only a few pipe-line companies which have stations operating at a good capacity factor combined with good electrical load factor, and completely electric motor driven, to provide data for a comprehensive report.

Fortunately, the author has been able to obtain data on fourteen motor-driven centrifugal-pumping stations operating at desirable conditions on a 10-in. pipe line, spaced about 34.5 miles apart. The data cover the average operating results for a year. Likewise the author is able to present corresponding data for four motor-driven reciprocating-pumping stations, operating at desirable conditions on an 8-in. pipe line and spaced about 16.24 miles apart.

CENTRIFUGAL PUMP STATION DATA

The centrifugal pumps operated at approximately constant pressure throughout the year, with varying volume. The pumps were throttled during the colder months in order to maintain same pressures. The characteristics of the crude oil pumped are as follows:

Temperature of oil, deg. fahr.	46	50	55	63	70	80
Viscosity, Saybolt Universal, seconds	150	130	110	90	78	70

The lowest average temperature of crude oil pumped was 53 deg. fahr. in February, whereas the highest average temperature was 80 deg. fahr. in August. These readings were actually observed temperatures.

Table 1 shows the compiled average data assembled for each station for the different months in the year. The pressures at the manifold of each station approximated 700 lb. per sq. in.

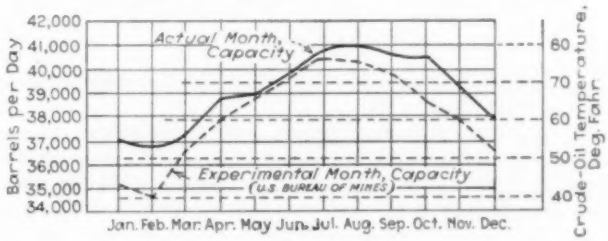

FIG. 1

The pumping units in each station consisted of 400-hp. 1750-r.p.m. induction motors, direct-connected to centrifugal four-stage pumps, each pump unit capable of delivering total volume pumped against 350 lb. per sq. in. Two pump units are connected in series.

TABLE 1

(Constant pressure maintained at the pipe-line manifold, or approximately 20 lb. per sq. in. per mile)

Month	Average barrels pumped per day	Average kw-hr. consumed per 1000 bbl.
January	37,000	338
February	36,700	332
March	37,300	334
April	38,700	340
May	38,900	340
June	39,800	332
July	40,700	317
August	41,000	332
September	40,600	332
October	40,500	325
November	39,200	339
December	37,800	352
Totals for year	14,259,313 bbl.	4,778,437 kw-hr.

From these data the graph shown in Fig. 1 was prepared, with the months of year plotted against barrels per day pumped, as taken from Table 1; also, barrels per day pumped are plotted

against average temperature of the crude oil pumped. It is to be noted how the volume pumped from actual data conforms with the theoretical capacity expected for the temperature of the oil for the given month.

It is interesting to note in Fig. 1 that the actual capacities obtained on this pipe line for different temperatures of the crude oil approximated the theoretical capacities computed with the Bureau of Mines experimental temperature curve for pipe lines buried 2 ft. in the ground in Oklahoma as a basis for the viscosity determination throughout the year.

In order to further check the data given in Table 1 and the data in Fig. 1, where the months of year are plotted against oil temperatures, the curves of the chart shown in Fig. 2 are plotted to indicate that there is a great deal of merit to the observed readings.

The curves are plotted with Universal Saybolt seconds against pounds per square inch per mile pressure drop for given volumes

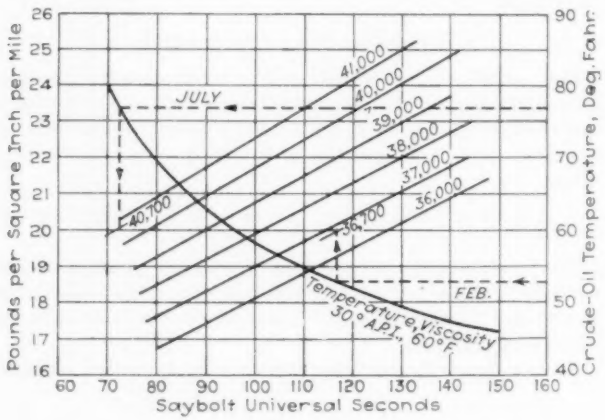

FIG. 2

of oil pumped through a 10-in. pipe line based on approximately 30 deg. A.P.I. gravity oil.

In Fig. 2 the Universal Saybolt seconds are plotted against degrees temperature of oil pumped. It is noted for the month of February, with the average crude temperature of 53 deg. fahr., that the viscosity is 117 Universal Saybolt seconds and that to maintain a constant pressure of 20 lb. per sq. in. per mile the volume pumped will be 36,700 bbl. per day. Correspondingly, the average temperature of the oil pumped in July is approximately 77 deg. fahr., with a viscosity of 72 Universal Saybolt seconds, and the chart indicates further that in order to maintain 20 lb. per sq. in. per mile the volume pumped would be 40,700 bbl. per day. Table 1 and Figs. 1 and 2 show that the theoretical and actual values agree closely.

It is assumed that the foregoing data are approximately correct in all details, since it is known from pressure charts observed at the various stations and also from the characteristics of centrifugal pumps that in order to operate efficiently the pressure maintained by the pump should remain constant throughout the year, which in this case is approximately 700 lb. per sq. in.

Reference to Table 1 shows that the average kilowatt-hour consumed per 1000 bbl. pumped approximates 335, which in terms of electrical input based on pumping an average of 39,000 bbl. per day will represent an average demand of 544 kw. From this electrical input of 544 kw., and assuming electric motor efficiency of 93 per cent, the mechanical efficiency of the pumps is approximately 70 per cent, and is apparently maintained throughout the year.

Reciprocating-Pump-Station Data

Table 2, showing summarized averages, is taken from the "economy log reports" of the individual pumping stations. The data shown in Table 2 are taken from annual records of pump stations containing 500-hp. synchronous motors, 514 r.p.m., geared through reducing gears to 46.25 r.p.m. reciprocating double-acting pumps, triplex, $6^1/_2$ in. by 24 in.

TABLE 2

Station	Days operated	Consumed energy, kw-hr.	Average demand, kw.	Amount actually pumped, bbl.	Average manifold pressure, lb. per sq. in.	Kw-hr. per 1000 bbl.
A.....	301	2,086,500	288.6	9,461,866	643	221
B.....	303	1,962,300	270.0	9,601,356	588	204
C.....	306	2,097,200	285.0	9,580,173	640	219
D.....	294	1,999,960	284.0	9,458,865	605	212

It is noted from the data in Table 2 that the items of electric energy consumption per 1000 bbl. pumped are all proportional to manifold pressures; also, from the demands in kilowatts and average energy consumed and work performed by the pumps, that the average pump mechanical efficiency is approximately 92 per cent.

Conclusions

Since there have been obtained yearly data from both types of pumping units available, and they have been found in keeping with expectancy of line capacities for such operations, and using a cost of 1 cent per kilowatt-hour, it may be said that centrifugal pumps will pump oil at 700 lb. per sq. in. for 0.335 cent per barrel, and that reciprocating pumps will pump oil at 700 lb. per sq. in. for 0.24 cent per barrel for electric power costs only.

Discussion

John M. McGregor.[2] The author shows that the cost for electric power for pumping a barrel of crude oil against a line pressure of 700 lb. per sq. in., using an electrical-centrifugal unit, is 0.335 cent, whereas while using an electrical-reciprocating unit, under the same conditions, the cost of power is 0.24 cent. He gives the approximate mechanical efficiency of the reciprocating pump at 92 per cent and the efficiency of the centrifugal pump at 70 per cent. Little improvement has been made toward attaining nearer perfection in the reciprocating pump during the last four or five years, but strides have been made in increasing the efficiency of the centrifugal pump. The centrifugal pumps cited in the paper are probably three or four years old, and at the time they were purchased, 70 per cent was accepted as being very good. However, recently, percentages of 80 and over are not uncommon. In view of this, the cost per barrel pumped for power would not be 0.335 cent per barrel, but would be 0.285 cent per barrel, or, in other words, modern efficiencies of centrifugal pumps being what they are, the difference in power costs between the reciprocating and centrifugal pump is very much less than shown by the author.

There are some men who, on glancing through the paper in question and seeing these cost figures standing out, would be likely to condemn the centrifugal pump. Although the paper dealt with operating data for Diesel-motor-driven reciprocating and centrifugal oil-pipe-line pumps, it is the writer's feeling that, in fairness to the centrifugal pump, mention might have been made of the purchase price, cost of building, and installation charges, also the time taken to install the different types of units.

It is not the writer's wish to detract in any way from the paper, but merely a desire to bring the questions of efficiencies and overall costs up so that a true comparison might be made.

Author's Closure

It is true the author shows considerable discrepancy between

[2] Byron Jackson Company, Tulsa, Okla. Assoc-Mem. A.S.M.E.

the power cost per barrel pumped of the reciprocating and centrifugal oil-pipe-line pumps.

It is a well-known fact that at this time there are no definite conclusions reached as to the type of equipment to install for main trunk-line stations, and further that some engineers recommend reciprocating pumps and others recommend centrifugal pumps.

The discussor apparently takes the author to task for not setting up the difference in installation costs of the two types of stations. This was taken for granted, as any engineer fully realizes that there is a discrepancy in installation costs, in that the reciprocating stations cost installed perhaps 50 to 75 per cent more than a similar capacity centrifugal station, and that therefore the fixed charges on the increased investment of the reciprocating station would overcome, to a great extent, its lower power costs. Conclusions reached by a great many engineers leave the annual charges for the operation of either type of station an open question, on the assumption that they are approximately equal, and therefore the choice of equipment is entirely up to the likes or dislikes of the engineer in making his design of stations.

The matter of higher efficiencies obtained from centrifugal pumps, mentioned by the discussor, was not available at the time this paper was written, and centrifugal pumps with 80 per cent efficiency, handling crude oil, have been on the market only perhaps for three or four months. The efficiency mentioned, of 80 per cent was obtained on a test conducted for a period of only one day. The original paper deals with average efficiencies obtained over a period of one year.

This higher efficiency of the centrifugal pump as now obtains, namely, 75 to 80 per cent, it is true, will tend to lower the power costs for such an operation; however, the total annual operating charges—after taking into account the fixed charges and maintenance on equipment, and the possibility of decreased efficiencies being obtained over a period of one year, due to sand and other coarse material cutting the impeller, and thereby lowering its efficiency—may again bring such annual operating charges approximately equal to or a stand-off with reciprocating pumps.

PET-52-7

Effect of Hydrogen Sulphide on Wire Rope

By LESLIE W. VOLLMER[1] and BLAINE B. WESCOTT,[2] PITTSBURGH, PA.

Drilling operations in West Texas called attention to the brittleness induced in steel by contact with hydrogen sulphide. This paper is concerned with the investigation of this action on cable tool drilling lines. A sensitive test and the apparatus developed for determining embrittlement in wire are described. The effect of hydrogen sulphide on cold-drawn and annealed plain carbon steels of varying carbon content was determined, and the influence of carbon content and amount of cold work was evaluated. The probable mechanism of the action is explained. The values of several protective metallic coatings were also found.

LESLIE W. VOLLMER

BLAINE B. WESCOTT

ONE of the most interesting of the many new problems which have arisen during the past few years from the rapid expansion in the production of petroleum has to do with the effect of hydrogen sulphide upon the physical properties of steel. The Petrolia pool in Ontario, developed in 1868, was among the first of the sulphide fields. This was followed by others, among which were Trenton, Spindle Top, El Dorado, Kansas, and the Panhandle. It was soon recognized that corrosion of well equipment, gathering lines, and tanks was more rapid in these fields than in the non-sulphide fields, and that failures of parts subjected to repeated stresses while in contact with the gas and oil were somewhat more numerous than usual.

However, it was not until the extensive development of West Texas in 1926, with its gas containing up to 15 per cent by volume of hydrogen sulphide, that its effect on steel was fully recognized. It was manifested by premature failures of apparently sound cable tool drilling lines after but a few hours' service in the pay horizon. The lines became exceedingly brittle; so much so that very often the individual wires could not be bent through an angle of 90 deg. without breaking. Nearly all of these embrittled fractures had a characteristic jagged appearance without any necking, as contrasted to the relatively smooth break of unembrittled, fatigued wire or the smooth diagonal appearance of worn or abraded failures. The type of fracture caused by embrittlement of drilling cable is illustrated in Fig. 1.

It was soon noticed that an embrittled line recovered at least a portion of its original ductility when allowed to remain in the open air for a day or more. This behavior is very similar to that of wire pickled in acid solutions, commonly termed acid or hydrogen brittleness.

The fact has been successfully demonstrated[3] that molecular hydrogen cannot induce brittleness in steel. Atomic or nascent hydrogen, however, rapidly causes brittleness in steel, and it has been generally supposed that the degree of embrittlement was at least roughly proportional to the carbon content.[4] Nascent hydrogen may be generated from the interaction between hydrogen sulphide and steel according to the equation,

$$H_2S + FE \longrightarrow FeS + 2H$$

Occlusion of this freshly generated hydrogen by the wire lines results in embrittlement analogous to that produced in pickling operations, the only difference in the two phenomena being in the method of hydrogen generation. The extreme rapidity with which brittleness can be induced, coupled with the observations that the tensile strength is practically unaffected while ductility is decreased and hardness slightly increased, indicates that the effect is largely a surface reaction. The crystalline character of failures resulting from brittleness justifies the opinion that the atomic hydrogen is absorbed by the intercrystalline material, where it combines to form molecular hydrogen with a change in volume which produces severe boundary strains within the metal.

Embrittlement Testing

Because the maximum effect of hydrogen brittleness is at the surface, the most suitable method for its measurement is by a test in which the greatest stress is at the surface, as for instance, a bend test of some nature. The apparatus devised for the purpose was patterned somewhat after a method previously used[3] to study the effect of caustic on boiler plates. The machine, shown in Fig. 2, consisted of a chuck mounted on a horizontal shaft, motor driven through a single-reduction-gear unit, and connected to a counter at the end of the shaft opposite the chuck. A 3-in. length of the wire to be tested was fastened in the chuck, while the other end passed through a case-hardened bushing mounted in vertical support whose height and distance from the face of the chuck could be accurately measured and varied at will. Throughout this study wire of 0.064 in. diameter was used. The distance from the face of the chuck to the face of the bushing was 1.25 in., and the vertical displacement was 0.25 in. The motor current was controlled by a relay which was actuated by battery current passing through the sample to be tested. Failure of the sample caused the motor to stop.

The number of revolutions to cause failure under these arbitrary conditions was termed rotary endurance, and the ratio of the difference between the rotary endurances of wire exposed to the action of hydrogen sulphide and unexposed wire was called the

degree of embrittlement. Thus, embrittlement was measured as the per cent decrease in the number of revolutions caused by the exposure to hydrogen sulphide. In all cases, the results reported were the averages of at least five determinations.

The wire samples were treated with hydrogen sulphide, generated from iron sulphide and hydrochloric acid, in flasks interposed between two bubbling flasks containing water in order to assure an excess of hydrogen sulphide at all times. All wires were cleaned

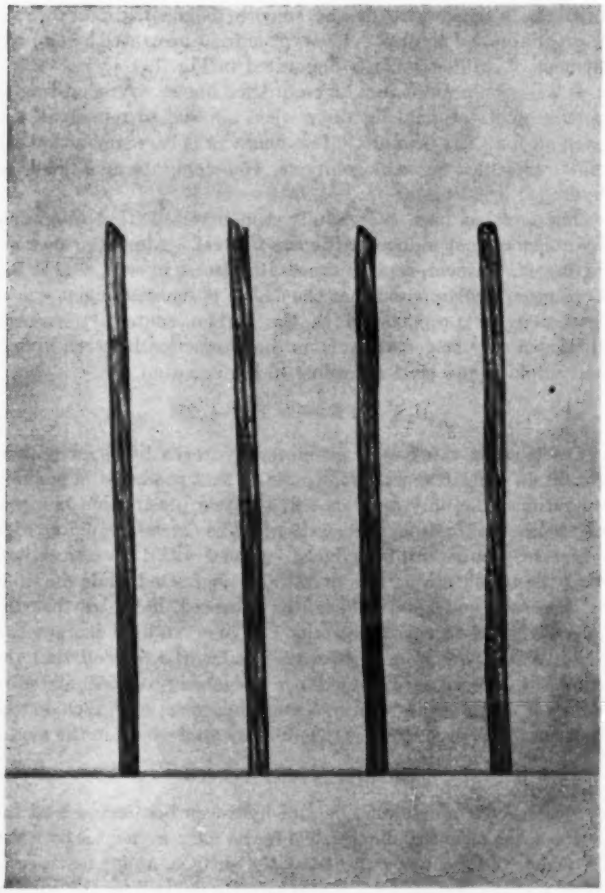

FIG. 1 SERVICE FAILURES OF EMBRITTLED WIRE OF A DRILLING CABLE

in a cold 20 per cent solution of ammonium citrate, washed in cold water, and dried before use.

The effects of hydrogen sulphide were determined for both cold-drawn and annealed wires of varying carbon contents and for

metallic-coated wires. It was found that wire treated with perfectly dry hydrogen sulphide or immersed in water-free crude oil saturated with the gas did not become embrittled. On the other hand, wire treated with gas moistened by bubbling through water or immersed in well brine saturated with hydrogen sulphide rapidly became brittle.

Table 1 gives the analyses and physical properties of the uncoated wires investigated.

EMBRITTLEMENT OF COLD-DRAWN WIRE

Table 2 gives the results of embrittlement tests made on cold-drawn plain carbon steel wires of varying carbon contents. In

most cases, the figures in the table represent the averages of at least three separate experiments under the stated conditions. The variations shown were due to two causes: (1) The rotary endurance test is extremely sensitive to any inhomogeneities in surface conditions or internal composition, and (2) there are greater relative variations in the size and the physical make-up of small wire than in specimens of greater cross-sectional area.

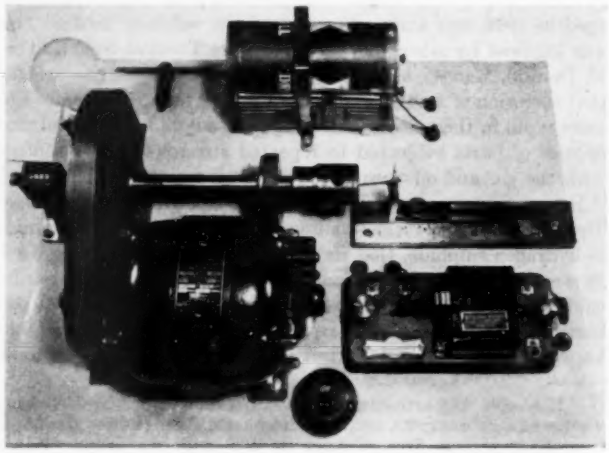

FIG. 2 WIRE-EMBRITTLEMENT-TESTING MACHINE

In addition, practically all of the wire used in this investigation was made in small lots especially for this purpose, thus introducing greater differences in uniformity than commonly occur in commercial wire.

The rates of embrittlement were somewhat slower in the samples immersed in brine, although the maxima were practically the same. With each grade of wire a maximum was reached after which the embrittlement decreased. This action was similar to that found with caustic and boiler plate.[3] It may be explained in this instance by the fact that the formation of atomic hydrogen was dependent upon the hydrogen sulphide coming into contact with the steel. As the reaction progressed, a coating of iron sul-

phide was formed upon the surface of the steel, and the rate of diffusion of hydrogen sulphide into the surface constantly decreased. Finally, this rate of diffusion became less than that of the occluded gas from the steel, and the embrittlement consequently decreased.

The similarity between failures from embrittlement in service and in this investigation is illustrated by a comparison of Figs. 1 and 3. The same angular type of fracture occurred in nearly every instance. The cause of this type of break will be made clear later. The 0.034 per cent carbon wire (ingot iron) behaved in a very irregular manner throughout. If this material is disregarded, there is a qualitative relation between the carbon content and degree of embrittlement—the latter increased as the former. It will be shown later that this was not a true relation. The wires containing more than 0.75 per cent carbon ruptured spontaneously after three hours' exposure to hydrogen sulphide.

Wires ruptured in this manner are shown in Fig. 4. In some cases the 0.75 per cent carbon wire also split. The cracks started in a direction nearly perpendicular to the surface of the wire, and after penetrating for about one-third of the diameter, proceeded in a longitudinal direction. The intercrystalline character of the cracks is evident from Figs. 5 and 6.

It was quite certain from this that the action of the sulphide gas caused rupture by intensifying previously existent internal stresses—quite logically, the stresses engendered by the cold-drawing operations of manufacture. The angular character of the embrittled failures was caused by the tendency to follow these longitudinal lines of internal stress.

Furthermore, it seemed probable that there was no direct relationship between carbon content and degree of embrittlement. The draft or reduction of cross-sectional area in cold drawing of wire is very nearly the same for steel of all carbon contents when

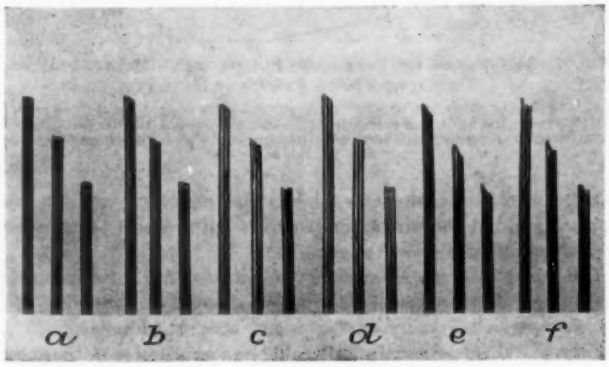

FIG. 3 FRACTURES OF EMBRITTLED COLD-DRAWN CARBON-STEEL WIRES

(*a*, 0.034 per cent carbon; *b*, 0.386 per cent carbon; *c*, 0.453 per cent carbon; *d*, 0.645 per cent carbon; *e*, 0.688 per cent carbon; *f*, 0.745 per cent carbon.)

maximum strength is sought. High-carbon steels are less ductile than the lower-carbon steels, and when subjected to the same amount of cold work, the internal stresses resulting are much greater.

The apparant relation between carbon content and degree of embrittlement was then primarily a relation between internal stress or cold work and degree of embrittlement.

The speed with which hydrogen sulphide can cause embrittlement affords a very interesting line of investigation. This was determined for the 0.688 per cent carbon steel, which was a commercial grade of improved plow steel for drilling lines. The embrittlement increased steadily from 20.4 per cent in 15 min. to a maximum of 69.8 per cent in 3 hr. It no longer seems strange that failures occur after a short time in lines exposed to hydrogen sulphide while subjected to severe repeated stresses.

Samples of the same wire were treated to produce maximum brittleness, and were then allowed to stand in the open air for 24 hr. The original degree of embrittlement decreased from 70.0 per cent to 12.8 per cent. At the end of seven days the embrittlement had dropped to 6.4 per cent, representing a recovery of 90.9 per cent of the ductility lost. Similar results can be effected in shorter times by heating. Systematic periods of rest or recovery would materially increase the life of uncoated steel drilling lines in sulphide fields.

The recovery is quite simply explained by the formation of molecular hydrogen and its diffusion from the steel.

EMBRITTLEMENT OF ANNEALED WIRE

In order to verify the foregoing reasoning with direct evidence, brittleness tests were carried out on samples of the same wires after dead-soft annealing. These results are given in Table 3.

The elimination of internal stresses was forcefully reflected by the type of fractures obtained. It is clear from Fig. 7 that

the angular breaks were obtained only from cold-drawn wire. As predicted, with the exception of the ingot-iron wire, the maximum embrittlement of the annealed samples was much less than that found with cold-drawn wires. There was an inverse relation between carbon content and degree of embrittlement, the higher carbon wires embrittling less than the lower. From this

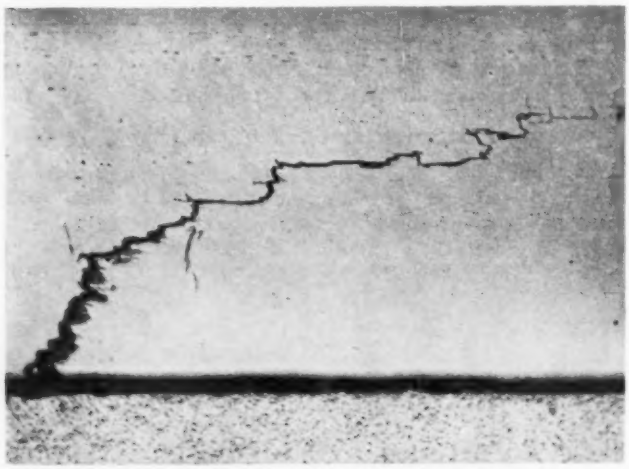

FIG. 5 INTERCRYSTALLINE CRACK IN 0.745 PER CENT CARBON-STEEL WIRE RESULTING FROM EXPOSURE TO MOIST HYDROGEN SULPHIDE
(Unetched; magnification, 75 times.)

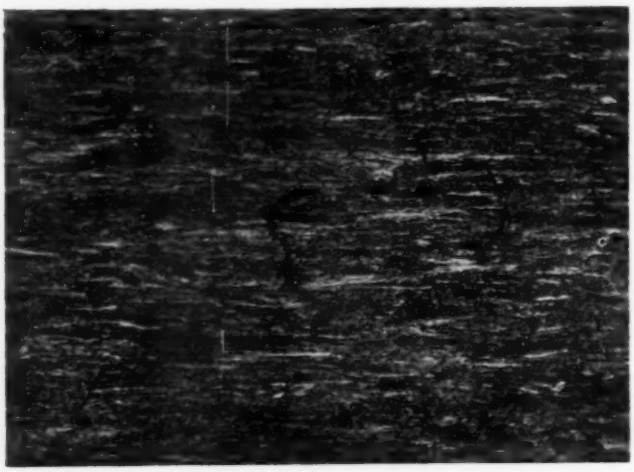

FIG. 6 INTERCRYSTALLINE CRACK FOLLOWING FERRITE GRAIN BOUNDARIES IN 0.745 PER CENT CARBON-STEEL WIRE RESULTING FROM EXPOSURE TO MOIST HYDROGEN SULPHIDE
(Etched; magnification, 460 times.)

it was concluded that the occlusion or absorption of atomic hydrogen increases as the purity of the iron, or, strictly speaking, the ferrite increases. The ingot iron, being nearly carbon free, is essentially pure ferrite, while in the steels containing carbon, the intergranular material, being the last to solidify, has a higher melting point, and is therefore ferrite of greater purity.

These conclusions explain the angular fractures of the cold-drawn carbon-steel wires and their absence in the case of the ingot iron.

[1] Ordinary galvanized drilling wire.
[2] Special galvanized drilling wire with very thin coating.

PREVENTION OF EMBRITTLEMENT

The most obvious method of combating embrittlement is by the use of protective coatings to prevent contact between the hydrogen sulphide and the steel.

The values of several common metals for the purpose were determined, with the results given in Table 4.

In consideration of these results it should be pointed out that the tests were of short duration and none of the coatings was tested to destruction, excepting the tin and the zinc B. The tin afforded practically no protection; zinc B gave partial protection for three days. Zinc A and lead furnished excellent protection

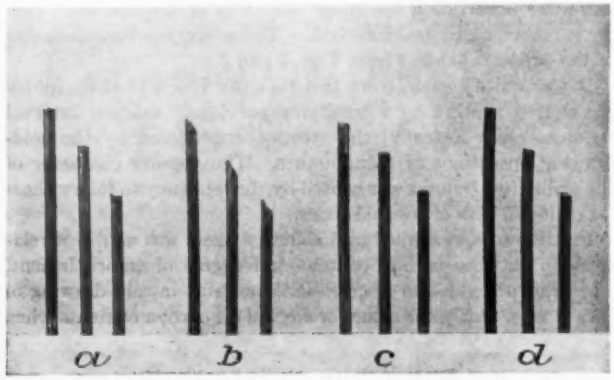

FIG. 7 FRACTURES OF IMPROVED PLOW-STEEL DRILLING WIRE, CONTAINING 0.688 PER CENT CARBON
(*a*, cold-drawn wire not exposed to hydrogen sulphide; *b*, cold-drawn wire exposed to moist hydrogen sulphide for 24 hours; *c*, annealed wire not exposed to hydrogen sulphide; *d*, annealed wire exposed to moist hydrogen sulphide for 24 hours.)

for the total time of the tests, while copper not only gave complete protection, but the wire actually gained with respect to its initial rotary endurance strength.

The results given by ordinary galvanized drilling wire agree with field experience. In the early days of drilling in West Texas it was customary to start a new black steel line at the top of the pay. If possible the well would be completed with the same line and another started. Usual service averaged less than one well per line. It is now general practice to use galvanized lines for drilling in all wells. Uncoated lines are used to top the pay.

Galvanized lines so used average five or more wells before it becomes necessary to discard them. They are unsuited to ordinary drilling, however, because of their lower strength and resistance to abrasion. Very substantial economies in both time and expense have resulted from their use in the manner outlined. A test of a copper-clad drilling line in this area would be of considerable interest.

Further tests on wire coated with a light grease have given much less embrittlement, indicating that frequent lubrication of drilling lines would lessen their susceptibility to embrittlement. Any chemical treatment of the lubricating oil which would keep the steel preferentially wet with oil rather than water would be of real value also.

Additional experiments are now in progress on other coatings, alloy steels, and the effects of hydrogen sulphide on other physical properties of steels.

Conclusions

1 A sensitive method has been developed for determining the degree of embrittlement in steel wire.

2 Plain carbon steels become rapidly embrittled when subjected to the action of moist hydrogen sulphide.

3 The embrittlement is caused by the absorption of atomic hydrogen formed from the reaction between hydrogen sulphide and iron.

4 In cold-worked plain carbon steels the degree of embrittlement is proportional to the amount of cold work and has no relation to the carbon content.

5 In dead-soft annealed plain carbon steels the degree of embrittlement is inversely proportional to the carbon content.

6 Absorption of atomic hydrogen occurs mainly in the purest ferrite—i.e., intercrystalline material of carbon steels and more or less uniformly throughout pure iron.

7 Steel wire embrittled by hydrogen sulphide recovers nearly all of its original ductility after standing for a time or by a gentle baking for a few hours.

8 The life of uncoated steel drilling lines in sulphide fields may be substantially increased by systematic periods of rest or by heating to 400 deg. fahr. for three hours.

9 Embrittlement may be prevented by various protective metallic coatings or other materials which prevent hydrogen sulphide from coming into contact with the steel.

10 Galvanizing has been shown to form an excellent protective coating, both in the laboratory and in actual drilling service.

11 Lead and copper coatings appear to possess protective ability against sulphide embrittlement, but tin is worthless.

Acknowledgments

The authors wish to express their appreciation to the Williamsport Wire Rope Company, the Hazard Wire Rope Company, and the Broderick & Bascom Rope Company for samples used in this investigation.

Also they acknowledge the aid of Mr. F. J. Reed and Mr. S. J. Edge, of the Gulf Laboratories, in the experimental work carried out.

Discussion

Dudley R. Dale.[5] This discussion will be confined to the conclusions reached and their application to sucker-rod failures. The writer did not feel justified in discussing wire lines as his entire interest is in the manufacture and use of sucker rods. However, the conditions under which both sucker rods and drilling lines work and fail are similar.

Three thoughts occur. First, hydrogen-sulphide embrittlement of steel oil-field equipment is not a new problem, but rather a relatively unknown one, comparatively recently discovered. Second, there is a similarity of the duties of drilling lines and sucker rods, both being subjected to alternate and reciprocating repeated high stresses and operating in the presence of hydrogen sulphide gas. Third, there is little information available concerning this type of equipment failure.

The paper throws much light on this puzzling subject and gives the metallurgist and designer data which he can feel justified in safely using.

Sucker rods, unlike wire lines, are not manufactured of cold-worked material. The best present practice in the manufacture of sucker rods is to use hot-rolled steel, and after the necessary forging operations are completed, they are given a complete normalizing heat treatment. This is done to remove local heat demarcations, forging strains, and to refine and make uniform the micro-constituents. They are therefore initially in a condition of strain equilibrium. The results shown by Table 3 will therefore more aptly apply to sucker rods.

Sucker rods are usually made of straight carbon steel, the carbon varying from 0.30 to 0.55 or 0.60 per cent, with the manganese varying from 0.50 to 2 per cent, the phosphorus and sulphur being 0.04 per cent maximum.

For many years rod manufacturers and producers were puzzled by premature failures, which could not be explained by an analysis of the pumping loads and their relation to the physical properties of the steel of which they were made, notwithstanding that this analysis showed a somewhat high factor of safety. Nor did a study of crooked holes, tight or sanded working barrels, inertia loads, etc., explain some of the failures which it is now known were caused by hydrogen-sulphide embrittlement. One example of this condition remains fixed in mind. In a certain West Texas well, new rods of one make started to break at the end of four days after installation. Other makes started to break in from 10 days to two weeks after installation. Pumping loads, speed, size of tubing, and depth of pump were studied, and the rods had a factor of safety in physical properties which should have given reasonable performance. Analysis of the fluid, however, showed a high content by volume of hydrogen-sulphide gas.

Rods taken from this well showed the typical progressive fatigue fracture invariably found on most rod failures, these fractures being smooth and silky for approximately half of the cross-section and somewhat coarse and crystalline for the remainder. All of these fractures are approximately at right-angles with the axis of rod.

Some of these rods, immediately upon being pulled from the well, were given a bend test by bending them around the derrick leg, and much to one's surprise did not bend more than 40 to 50 deg., breaking with a brittle snap and showing a crystalline fracture. New rods could be cold bent 180 deg. without fracture.

Samples of these prematurely failed rods were then sent to the laboratory for examination. Chemical analysis was up to standard and did not reveal a possible cause of the trouble. Physical tests also showed the material to be up to standard, the Brinell test showing only a slight increase in hardness. Microscopic study was also made. After laboratory examination failed to reveal any satisfactory answer to the problem or to show any fault with the material, some of the broken rods, which in the meantime had laid on the ground for about ten days, were again given the same bend test, with results pleasingly satisfactory. The steel had now almost recovered its former ductility.

The conclusion then was reached that the steel was absorbing something which had an embrittling effect as long as it was in contact with the fluid in the well, but which was self-purged if given a period of rest or other natural treatment. As examination of the fluid revealed a high content of hydrogen-sulphide gas, and as it was well known that steel was embrittled by hydrogen, it was justly concluded that the answer to the problem had been found. It also was revealed why laboratory tests did not give the answer, as the samples had opportunity to purge themselves of the hydrogen during the time they were going to the laboratory and awaiting testing.

Some manufacturers and producers in the past have advocated a rest treatment for rods, some even going so far as to recommend an annealing treatment, the thought being that the rods were in a highly strained condition due to the work they performed. They were thought to be in a condition similar to what is known as Stead's brittleness. As is well known, Stead's brittleness occurs only in steel of low carbon content (under 0.15 per cent) where they have been subjected to temperatures of 900 to 1400 deg. fahr. for long periods of time, and which action resulted in an enlarged grain growth. Sucker rods, being made of 0.30

[5] S. M. Jones Co., Toledo, Ohio.

to 0.60 carbon steel and not being subjected to any such temperature, could not of course be in that condition.

It is also the opinion that many sucker-rod failures can be attributed to varying degrees of sulphide embrittlement, the time of the commencement of such failures depending upon the degree of gas present.

The conclusion therefore has been reached that, where premature failure of sucker rods occurs due to hydrogen-sulphide embrittlement, the steel will recover nearly its original ductility if allowed to rest in the open air and sunlight for comparatively short periods of time, and as the authors have stated, this can be made more complete by a gentle heat treatment.

There is danger, however, in giving sucker rods an oil-field heat treatment; improper equipment and supervision might result in unequal heating. Under proper conditions of heating and supervision it should be beneficial.

Where rods have been in service long enough to start fatigue fractures no heat treatment (exclusive of welding) or rest will repair the damage. The rest cure, only, is advocated to remove hydrogen, the cause of embrittlement.

The writer agrees with the authors that embrittlement in annealed or normalized steels is inversely proportional to the carbon content, and is caused by the absorption of atomic hydrogen formed from the reaction between iron and hydrogen sulphide. The mechanism of the embrittling action is, first, the reduction of oxide by the hydrogen forming water which causes a swelling at the grain boundaries. This increase in volume, in turn, creates a stress, which, added to the pumping stress, causes the rupture.

The authors have constructed a testing machine which in theory and in practice should give results that can be relied upon. A bend test is first a test of the surface of the material, where the maximum effect of the embrittlement is encountered. The combined rotating and bending of the test specimen reacts on all points of the circumference where bending is concentrated.

While the authors have been able to test individual wires of the complete wire line, this procedure is not followed in the testing of sucker rods. Small test samples, made to fit the standard Moore rotating fatigue machine, are used instead.

In conclusion it is desired to state that physical, chemical, and microscopic tests do not reveal hydrogen embrittleness. Immediate bend tests upon pulling the rods from wells, and comparison with later tests after rods have been rested or treated, are very often conclusive.

In regard to protective coatings, it has been found that certain paints have resulted in improved performance rods, but the effect can be considered as only temporary and probably not worth the expense.

Zinc galvanizing seems to slightly improve performance, but is not an ideal coating, as it has a tendency to flake, especially if the rods are stressed beyond the elastic limit of the steel.

It is also the opinion of some operators who have extensively used galvanized rods that the extra cost did not compensate them for the slight increase in service given over black or ungalvanized rods and that it is a temporary cure at the most.

Leadized rods are now being tested, and from the conclusion of the authors, should show good performance.

While this discussion on hydrogen-sulphide embrittlement of sucker rods is rather apart from the paper, the results obtained and the conclusions reached by them were so clearly applicable to sucker rods that it was felt that the paper is doubly valuable.

H. W. Fletcher.[6] The authors have attacked a problem which is of increasing importance to the oil industry, particularly the producing departments, and to the manufacturer of drilling and production equipment. Broadly the action of hydrogen sulphide on steel is in effect an "etch" of the surface producing a weak brittle coating of iron sulphide and liberating nascent hydrogen. This being absorbed into the structure of the metal combines to form a molecular gas, thus building up high internal pressures, adding to the stresses already present, and causing local failure where critical values are exceeded. The deleterious effect of such flaws, acting as they do to produce stress concentration out of all proportion to the actual reduction in coherent cross-section, can hardly be overemphasized.

It should be noted that two separate and distinct results follow the exposure of steel to a moist hydrogen-sulphide atmosphere. The original surface is destroyed, and the action is preferential due to chemical inhomogeneity, thus roughening the surface. That this in itself results in lower fatigue resistance is indicated by experience with fatigue specimens where the degree of mechanical finish influences largely the fatigue limit, the rougher specimens showing the lower values. On the other hand, whereas surface roughness does not within reasonable limits affect static strength, exposure to moist hydrogen sulphide will cause spontaneous rupture of steel parts where internal (static) stress exists due to previous cold working. As surface finish is not in this case of prime importance, increase of stress due to absorption of hydrogen is the logical explanation of failure.

That hydrogen penetration progresses most rapidly along grain boundaries is fairly certain. At least, the fact that the cracks develop there indicates that the resultant pressures exist mainly at grain boundaries; and experience with other gases such as carbon monoxide and oxygen has demonstrated a more rapid penetration along grain boundaries. It does not seem, however, that the evidence presented offers sufficient grounds for the conclusion stated in the paper that "The intergranular material, being the last to solidify, has a higher melting point, and is therefore ferrite of greater purity."

Relatively pure ferrite, to be sure, has the higher melting point, but because of this fact is the first to solidify from a melt, and the last material to freeze is of higher carbon concentration. The resulting structure consisting of austenitic grains undergoes a secondary crystallization as the temperature falls, resulting, where cooling is slow, in the formation of an aggregate of ferrite and pearlite grains, jointed by an intercrystalline material of undetermined composition. Since the intergranular material is mainly a product of secondary crystallization, it seems unlikely that its composition is a function of melting point in view of the fact that the grain boundaries existing after secondary crystallization are not in general those boundaries formed in the freezing of the melt.

It is true that the lower the carbon the more nearly continuous is the network of ferrite grains and the more completely this network encloses the pearlite grains, from which it might be argued that the hydrogen is absorbed principally by the ferrite grains in mass. On the other hand, there is reason for concluding from results with other gases that penetration is mainly along grain boundaries rather than the body of the grain.

Any explanation of the relation of degree of corrosion embrittlement to carbon content must necessarily depend in its conclusions to a degree at least on the reaction assumed to take place after the atomic hydrogen has entered the metal. Suppose for instance that only part of the atomic hydrogen reverts to the molecular form and the balance combines with carbon drawn from the carbides present, forming perhaps hydrocarbons of the methane series. With a given amount of hydrogen taken in, it might with reason be argued that the resultant pressure maximum might be lower than where all the hydrogen reverted to the molecular form. On the other hand, this would require

[6] Chief Engineer, Hughes Tool Company, Houston, Texas. Mem. A.S.M.E.

that the rate of diffusion of the hydrogen-hydrocarbon mixture be not too much lower than that of molecular hydrogen alone, since the pressure maximum must obviously be the result of the difference between rate of input and rate of loss. Should this be the case it would be reasonable to expect that in the annealed state high-carbon steels would show less damage than low-carbon steels because of the greater proportion of hydrogen going to form hydrocarbons, resulting in lower gas pressures, whereas in the cold-worked condition the residual stress increase with higher carbon might be great enough to overbalance the reduction in maximum gas pressure attained, such a relation explaining the results of the authors' experiments. In this connection it might be mentioned that it has been demonstrated that high-

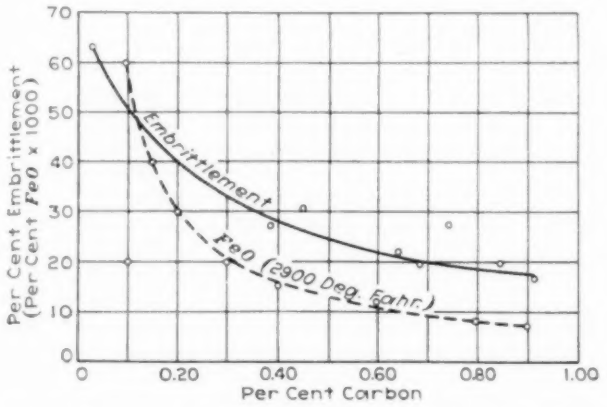

FIG. 8 RELATION OF HYDROGEN-SULPHIDE EMBRITTLEMENT TO DISSOLVED OXIDE CONTENT IN ANNEALED WIRE

(Note: Per cent of embrittlement values are averages of authors' figures for all tests of a given carbon content in annealed samples.)

carbon steel heated in a hydrogen atmosphere loses its carbon (presumably as hydrocarbons), but the assumed reaction between atomic hydrogen and iron carbide at room temperature (but possibly at higher pressure and in the presence of catalysts) is so far without experimental verification. Acceptance of such a theory would avoid the necessity of postulating an intergranular material composed of pure or nearly pure ferrite.

Still another possible explanation of the phenomenon has been suggested by R. W. Schlumpf, metallurgist for the Hughes Tool Company. If the authors' values for decrease in fatigue resistance and C. H. Herty's values for oxygen concentration in steel are plotted on the same sheet against carbon content as abscissa, two curves result similar in form and for some distance closely parallel. (See Fig. 8.) This suggests the correspondence of degree of corrosion damage with the amount of oxides in solid solution in the metal rather than an inverse relation to the carbon. If we assume that part of the atomic hydrogen combines with oxygen to form water, we might expect high pressures to develop due to the inability of the water molecule to diffuse from the structure. A reaction of this nature is encountered when copper is heated in a hydrogen atmosphere, resulting in the production of internal flaws presumably from the reaction of hydrogen with the oxide content of the metal. Recovery is perhaps more difficult to explain on this theory, but might be due to diffusion of that part of the hydrogen not combined as water, in which case recovery should probably be less complete with the lower carbon material.

Several years ago the writer observed some phenomena that are of interest in connection with the subject of this paper. Samples of boiler plate were boiled for three hours in 40 per cent hydrochloric acid, and were then sealed in a nickel container and baked for 50 hours at 1850 deg. fahr., after which they were cooled and removed from the container. The surface of the samples initially rough polished was found after baking to be distinctly matte in finish and at 40 diameters magnification resembled coarse pumice stone, while an initially pure nickel target placed about $^1/_8$ in. from the plate analyzed, after baking, 10 per cent iron. There was clear evidence to show that minute bubbles of gas burst through the surface of the specimen, driving off particles, some of which impinged on and alloyed with the target. Small pimples were found on the specimen where bubbles of gas were about to break through when heating was discontinued. Samples baked without previous boiling in acid showed no apparent surface change except that due to the small amount of oxidation attendant upon the process of baking. It was noted that samples polished after the acid treatment and baked for a shorter time showed a clear development of the grain boundaries, indicating that the gas traveled mainly along the boundaries, but also to some extent through the structure of the grains themselves.

The authors' work on protective metallic coatings is most interesting, particularly in respect to the failure of tin and the marked success with copper. The latter has long since proved its usefulness in a similar situation, but at elevated temperatures, where it is desired to prevent carburizing of certain portions of pack-hardened work which are plated before packing, the copper "sealing the pores" and preventing the entrance of the carburizing agent, probably chiefly carbon monoxide. The results of commercial applications of protective coatings in service as recounted by the authors are most encouraging, and it is perhaps not too much to hope that means may be discovered to incorporate the protecting elements into the surface layers of the steel, as for instance in the calorizing of steel with aluminum, thereby extending this protection to such products as are exposed to abrasive wear too severe for surface coatings.

AUTHORS' CLOSURE

The authors are greatly appreciative of the interest expressed in this problem by Messrs. Dale, Fletcher, and Schlumpf. The mechanism of hydrogen occlusion and the resultant embrittlement of steel, whether it be caused by acid pickling or exposure to hydrogen sulphide, is undoubtedly identical and has been the subject of several hypothetical suppositions. The explanation offered that the embrittlement is caused by the formation of water from the reaction of hydrogen with occluded oxygen or metallic oxides should be capable of demonstration by the use of steels containing determined amounts of both gaseous oxygen and metallic oxides. If the formation of water is the determining factor, then steels poor in oxygen content should be less susceptible than those containing larger amounts. The similarity of the curves pointed out by Mr. Schlumpf is interesting and suggests a very promising line of investigation. However, higher-carbon steels might generally be expected to contain less oxygen than low-carbon steels or iron. In either case the damage resulting from the formation of water might probably be of a more or less permanent nature, making it difficult to explain the almost complete recovery.

The postulation of the formation of hydrocarbons seems to agree more fully with the recovery effects noted. The rapidity with which embrittlement can be caused by pickling indicates a high rate of reaction seemingly more consistent with the formation of molecular hydrogen than with a chemical reaction involving the formation of hydrocarbons from the decomposition of metallic carbides. The effect may be the resultant of all three theories offered. It is the expressed hope of the authors that subsequent experimentation will indicate the true mechanism of the phenomenon. It is suggested that an X-ray study of embrittled steel might go far in the solution of the problem.

PET-52-8

Economic Design of Oil-Pipe-Line Transportation Systems

By OSCAR WOLF,[1] HOUSTON, TEX.

Carriers of energy and transportation systems for gas or oil should be so designed that the sum of their total yearly charges (fixed charges plus all operating expenses) is a minimum. This paper presents the basic cost data entering into the design of an oil-pipe-line system as a function of the known quantites, usually given in the form of:

(1) The permissible maximum working fiber stress of the steel in pipe
(2) The physical characteristics of the oil to be transported
(3) The length of the prospective line
(4) Elevation of initial and terminal points of the system
(5) Daily capacity for which the system is to be designed
(6) Period of years during which all non-salvageable investments are to be retired by a proper depreciation reserve
(7) Interest, depreciation, and tax, and insurance rates.

It is possible to express the total pressure heads to be overcome, and consequently the power requirements of such a system, as a function of these given terms. The resulting equation, representing the sum of the fixed charges and operating expenses Y + X, can then be differentiated, and by making the first differential coefficient equal to zero, the most economical pipe diameter, pipe-wall thickness, and station spacing can be determined.

It will be found that a system designed according to these principles, but without regard for the requirements of mechanical strength of the pipe, will result in a layout calling for pipe diameter, pipe-wall thickness, and station working pressure considerably at variance with established practicability. It is therefore necessary to base such computations not merely upon hydraulic considerations, but the question of sufficient wall thickness to insure mechanical strength must be introduced in a manner so as to reflect requirements which, in the past, have been found satisfactory in fulfilling these conditions.

Illustration by means of an actual example reveals the very striking fact that a difference of one commercial size in the pipe diameter of such a system may affect the total yearly cost by sums of such magnitude that the carrying out of such basic calculations is amply justified.

IN ITS initial conception, the oil-pipe-line design problem is usually stated in the form of providing transportation of a given quantity Q barrels from point A to destination B. When confronted with this problem, it has long been the endeavor of pipe-line engineers to solve the fundamental question as to whether the proposed system should be laid out on the basis of relatively small diameter pipe calling for the installation of many relay stations employing high working pressure or whether the system should be designed with larger pipe and thus reduce the number of pumpings. It is of course easily seen that, if the first plan can be followed, the total investment in the system is likely to be much less than if larger diameter pipe and fewer stations had been chosen. But it also follows that operating charges, such as successive pumping costs, will have the tendency to offset the saving created by the lowered fixed or capital charges of the lower-priced small-diameter pipe.

As in many other engineering problems, there is a middle ground where fixed or capital charges, which are a function of the magnitude of the investment, bear such a relationship to the operating expenses as to make the total yearly cost of the entire plant (i.e., the sum of all capital charges and operating expenses) a minimum.

How serious the results of disregarding these fundamental tenets of sound engineering design may become is clearly demonstrated by the experiences of one company which was confronted by electric power bills representing 20 per cent of its line operating revenue. When face to face with such a fact, checking over of equipment efficiencies is of little avail, for the causes lie much deeper. There is naturally an economic limit to the rate of operation for a line of given diameter, and if these boundaries are disregarded, the effect will make itself felt by inordinately high operating costs. On the other hand, a line diameter so large as to be out of all proportion to the quantity of oil to be transported gives rise to fixed or capital charges which will be severely felt on the balance sheet. The numerical solution of this problem should therefore be of greatest interest to the oil-pipe-line transportation industry.

With carriers of energy in its various forms, be they electric-transmission lines or pipe-line systems handling gas, water, or crude petroleum, the annual cost to be charged against the system may be classified under two headings:

(1) Fixed, or capital, charges proportional to the investment
(2) Operating costs, depending on number and size of pump stations.

If we designate the fixed, or capital, charges by Y and the operating expenses by X, it has already been indicated that a

[1] Assistant Chief Engineer, Texas Pipe Line Company. Mr. Wolf was graduated from the Grossherzogliche Oberrealschule, Pforzheim, Baden; Bucknell University, Lewisburg, Pa., 1912. From 1912 to 1922 he was engineer of the southern group of pipe lines, Texas Pipe Line Co.; 1922 to 1928, Superintendent of Stations; 1928 to date, in his present position.

Presented at the National Petroleum Meeting, Tulsa, Okla., October 6 to 8, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

change in one of these quantities will affect the other in opposite direction. The most elementary reasoning leads one to expect high operating costs on a pipe-line system of comparatively small diameter and many relay stations which are operating at excessive working pressures. Since the greatest part of the investment of a pipe-line transportation system is represented by the pipe in the ground, such a system as the one just mentioned would naturally have lower fixed charges than one laid out on the basis of larger diameter pipe and fewer stations.

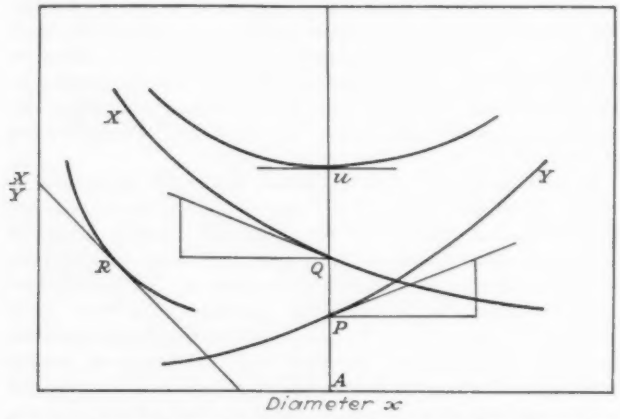

FIG. 1 CURVES SHOWING EFFECT OF CHANGE OF PIPE DIAMETER ON FIXED CHARGES Y AND OPERATING EXPENSES X

If we denote the total yearly cost of the system by u, it follows from the foregoing that[2]

$$u = X + Y \quad \ldots\ldots [1]$$

and it is the nature of our present problem to determine the conditions under which u will be a minimum. Designating the inside diameter of the pipe by x, and differentiating Equation [1], we obtain

$$\frac{du}{dx} = \frac{dX}{dx} + \frac{dY}{dx} \quad \ldots\ldots [2]$$

From the differential calculus we know this expression to be a minimum if $\frac{du}{dx} = 0$, and $\frac{d^2u}{dx^2}$ is positive in sign.

Hence

$$\frac{dX}{dx} = -\frac{dY}{dx} \quad \ldots\ldots [3]$$

and a maximum or minimum value of u will be found for the value of x, for which the slopes of X and Y are numerically the same, but opposite in direction. This condition will be fulfilled at some point A in the diagram shown as Fig. 1. This point A may be determined by plotting X and Y and locating the minimum point for u by trial and error. This point must fulfil the conditions of Equation [3] for the tangents at P and Q.

It also follows from Equation [3] that

$$\frac{dY}{dX} = -1 \quad \ldots\ldots [4]$$

which means that if we plot Y against X, the values of X and Y which will produce a minimum for u will be at point R, where the slope of the tangent is 135 deg., or where it is 45 deg. with the horizontal.[3]

[2] W. F. Durand, "Hydraulics of Pipe Lines," pp. 226–267.
[3] W. F. Durand, "Hydraulics of Pipe Lines."

In the equation $u = X + Y$

X = line maintenance plus station operation (fuel, lubrication, labor, maintenance, and supplies)
Y = annual amount of interest plus depreciation and taxes on all items of investment.

The application of these general equations to a definite pipe-line design problem makes it necessary that all terms entering into them be expressed as functions of the known quantities, such as length of line, permissible unit stress on steel in pipe, amount to be transported, physical characteristics of the oil, and the initial and terminal elevations of the line in question.

Most pipe-line systems of more than ordinary length require the operation of a number of pump stations in series. The following analysis is based on the assumption, easily carried out in practice, that the total power requirement of the entire system is equally divided among the several stations (Fig. 2). The pipe line is also assumed to have the uniform inside diameter of x inches throughout the entire length of the system.

Denoting:

L = length of line (miles)
Q = quantity to be pumped (bbl. per hr.)
η = kinematic viscosity of oil (c.g.s.)
s = specific gravity of oil

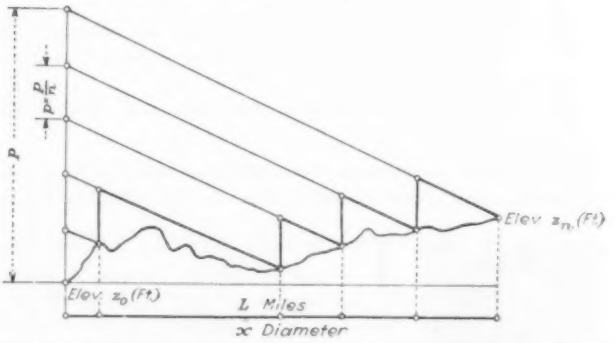

FIG. 2 PUMP-STATION SPACING ON PIPE LINE FOR EQUAL LOADS

S = permissible unit stress on steel in pipe (lb. per sq. in.)
n = number of stations on system
p = station gage pressure (lb. per sq. in.)
P = total pressure head (lb. per sq. in.)
t = thickness of pipe wall (in.)
x = inside diameter of pipe (in.)
N = operating life of system (years)
R = interest rate
T = rate of taxes and insurance
Δ = depreciation rate
σ = salvage value of system (decimal fraction).

SECTION I

FIXED CHARGES Y

The annual fixed charges of the system are equal to:

$$Y = [\text{first cost of line} + \text{first cost of stations}][(1 - \sigma)\Delta + R + T] + \text{value of oil in line } [R + T]$$

The depreciation rate Δ is based on the theory that the investor is entitled to the return of his capital during the operating life of the property. If the depreciation reserve is productively invested from year to year at the interest rate R and compounded annually, the depreciation rate

$$\Delta = \frac{R}{(1+R)^N - 1}^{4} \quad \ldots\ldots\ldots\ldots\ldots [5]$$

$$N = \frac{\log\left(\frac{R}{\Delta} + 1\right)}{\log\,(1+R)} \quad \ldots\ldots\ldots\ldots\ldots [6]$$

when applied to the total investment, will insure the return of the first cost of line and stations, less salvage, at the end of the operating period N.

The following salvage values are tentatively suggested for the line and stations:

SALVAGE VALUE, PER CENT OF FIRST COST[5]

Operating period	Line	Stations
5 years	25 per cent	25 per cent
10 years	15 per cent	15 per cent
15 years	10 per cent	10 per cent
20 years	.....	.....
30 years	.....	.....

According to the Barlow formula, the wall thickness of this pipe may be expressed by the following equation:

$$t = \frac{(x + 2t)p}{2S}$$

which reduces to

$$t = \frac{xp}{2(S-p)} \quad \ldots\ldots\ldots\ldots\ldots [7]$$

and the sectional area of the pipe wall

$$\text{Area} = (x + t)\,t\pi$$

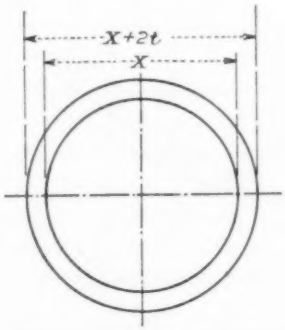

FIG. 3 PIPE-WALL SECTION

which reduces to

$$\text{Area} = \frac{x^2 p\pi}{2(S-p)}\left(1 + \frac{p}{2(S-p)}\right) \text{(square inches)}$$

If we assume the weight of steel at 0.2833 lb. per cu. in., the weight per mile of pipe may be written as follows:

$$\text{Weight per mile of pipe} = \frac{x^2 p\pi}{2(S-p)}\left(1 + \frac{p}{2(S-p)}\right) \times \frac{5280 \times 12 \times 0.2833}{2000} \text{(tons)} = \frac{14.1x^2 p}{S-p}\left(1 + \frac{p}{2(S-p)}\right) \text{(tons)}$$

which can be transformed into:

$$\text{Weight per mile of pipe} = 7.05x^2\left(\frac{S^2}{(S-p^2)} - 1\right) \text{(tons)} \quad [8]$$

Multiplying Equation [8] by the cost per ton of steel, we obtain

$$\text{Cost per mile of pipe} = 7.05x^2\left(\frac{S^2}{(S-p)^2} - 1\right) \times \text{cost per ton of steel}$$

$$\text{Cost per mile of pipe} = 7.05x^2\left(\frac{S^2}{\left(S - \frac{P}{n}\right)^2} - 1\right) \times \text{cost per ton of steel} \quad \ldots\ldots [9]$$

The average cost of finished steel pipe, delivered at Texas common points, on the basis of cost per ton, is shown in the diagram Fig. 4. When expressed as a function of the pipe diameter x, the cost per ton of fabricated pipe is given by the equation:

$$\text{Cost per ton of steel pipe} = \frac{100}{x^{0.133}} \text{(dollars)}$$

This value must of course be multiplied by a proper coefficient allowing for difference in freight rates between average Texas

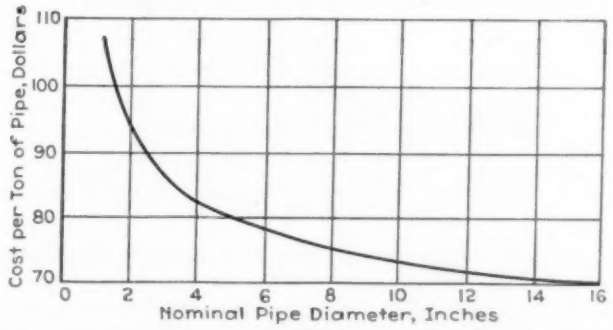

FIG. 4 AVERAGE PRICE PER TON OF STEEL PIPE AS A FUNCTION OF THE DIAMETER (TEXAS COMMON POINTS)

common-point shipments and those in force for the prospective location of the system under analysis. Abnormal basic costs of steel should also be incorporated in this coefficient.

Introducing this value in Equation [9], we obtain for the cost of steel in pipe, delivered, for a system of length L:

$$\text{Cost of pipe} = 705x^2\left(\frac{S^2}{\left(S - \frac{P}{n}\right)^2} - 1\right)\frac{L}{x^{0.133}} \text{(dollars)}$$

which may be written in the form:

$$\text{Cost of pipe} = 705x^{1.867}\left(\frac{S^2}{(S-p)^2} - 1\right) L \text{ (dollars)} \quad \ldots [10]$$

This expression establishes the relation between the cost of fabricated pipe and the strength of the steel for a given working pressure p. If the pipe is made of high-carbon steel containing 0.2 to 0.3 per cent carbon and electrically welded in the longitudinal seam, maximum unit fiber stresses S = 15,000 to 16,000 lb. per sq. in. and 100 per cent longitudinal joint efficiency may safely be employed. If, on the other hand, the skelp is made of 0.08 to 0.15 per cent carbon steel and the pipe is of lap-welded fabrication, the value of S should be reduced to the

[4] Goldman, "Financial Engineering."

[5] These percentages are to be applied to the whole investment. They are purposely kept low, since a certain portion of the investment is nonsalvageable. For pump stations this nonsalvageable portion in the investment is approximately 35 per cent and for pipe lines from 40 to 50 per cent of the whole investment.

neighborhood of from 10,000 to 12,000 lb. per sq. in., with corresponding deductions for the longitudinal joint efficiency. This formula therefore furnishes a ready means for comparing the cost of pipe when based on steels of different working stresses, assuming of course that the working pressure remains constant.

In the diagram, Fig. 5, it will be noticed that the actual costs per mile indicated for the various pipe sizes fall considerably above the curves for the smaller pipe diameters. This is accounted for by the reason that for the smaller sizes of pipe the wall thicknesses of standard "line pipe" are much greater than considerations based entirely on hydraulic pressure would warrant. This extra thickness is provided to insure the necessary mechanical strength for the pipe. Again, the working pressure rating for the pipe sizes below 6 in. is somewhat higher than the 750 lb. forming the basis for the set of curves shown in Fig. 5.

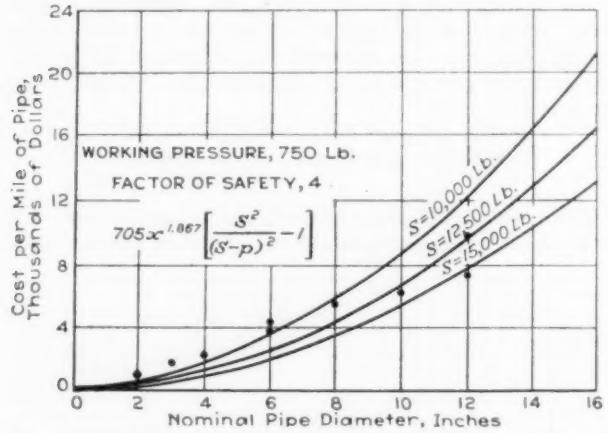

FIG. 5 COST PER MILE OF STEEL PIPE AS A FUNCTION OF THE PERMISSIBLE FIBER STRESS

The cost of laying the line varies, of course, with the physical characteristics and topography of the terrain traversed by the line. Wide variation in the construction costs for a given size of line are to be expected, as they are a function not only of the factors mentioned above, but also of the efficiency of the construction organization and of the type of construction, i.e., whether gas-, electrically welded, or screw-connected. The following formula gives results representing fair average results. It can, however, be so modified as to represent such special conditions as may, in the judgment of the engineer, be warranted. It is naturally supposed that the general features of the terrain traversed by a pipe-line project under analysis are sufficiently known to permit an intelligent application of such information as may be obtained from past construction cost records.

$$\left.\begin{array}{l}\text{Pipe-line construction:}\\ \text{Cost per mile of line}\\ \text{(includes cost of right-}\\ \text{of-way .....}\end{array}\right\} = \left\{\begin{array}{c}120x + 44.5x^2 \text{ (high)}\\ 100x + 36x^2 \text{ (average)}\\ 50x + 32.5x^2 \text{ (low)}\end{array}\right\}$$

(dollars).....[11]

The total line investment can now be expressed by the following equation:

$$\text{Total cost of line} = \left\{705x^{1.867}\left[\frac{S^2}{(S-p)^2}-1\right] + 100x + 36x^2\right\} L \text{ (dollars)}.....[12]$$

It follows from the preceding discussion that the amount of steel in the line is regarded as a direct function of the unit maximum fiber stress permissible on the steel under consideration. An economic design study based on this assumption will be found to produce results calling for such thin pipe-wall sections that an application of this formula without qualifying limitations is impossible. It is of course obvious that the pipe must have sufficient wall thickness to satisfy all requirements for mechanical strength, aside from the stresses brought to bear upon it by the internal fluid pressure.

The factors influencing the choice of a minimum wall thickness for a given size of pipe are enumerated by Professor Durand in his "Hydraulics of Pipe Lines," and according to his statement the pipe-wall thickness must be sufficient to take care of:

1 The maximum static or steady-condition pressure to which the pipe is likely to be subjected in operation
2 Any excess pressure due to shock or water hammer to which the pipe may be exposed
3 Collapsing pressure due to a reduction of pressure on the inside to less than atmospheric pressure
4 Stiffness, rigidity, and strength to meet such bending stresses as may be set up due to the action of the pipe as a beam
5 Any reasonable special stresses to which the pipe may be subjected as a result of expansion and contraction under temperature changes

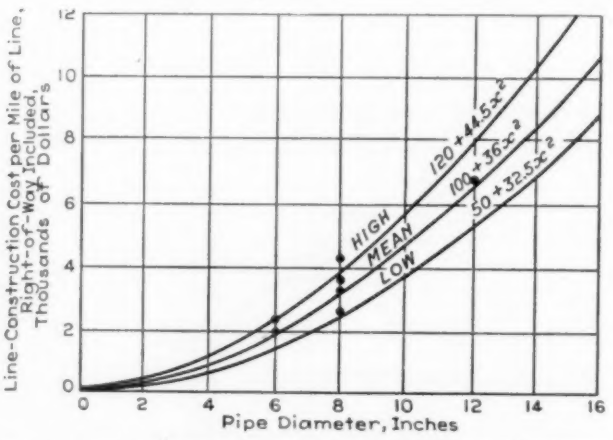

FIG. 6 LINE-CONSTRUCTION COST AS A FUNCTION OF THE DIAMETER

6 Special stress due to distortion of the cross-section of pipe from true circular form, or failure to realize this form as in lap-riveted pipe
7 The usual variations to be expected in the strength of the plates resulting from the accidents of manufacture
8 Corrosion and wear, in order that the pipe may have a lifetime of reasonable length and without too rapid decline of the factor of safety.

This minimum pipe-wall thickness is, naturally, a function of the pipe diameter, based largely upon previous satisfactory experience for the fulfilment of all the conditions mentioned. The years of experience with pipe lines of such diameters as come within the scope of oil-pipe-line systems suggest a minimum wall thickness expressed by the following equation:

$$\text{Minimum pipe-wall thickness} = t' = 0.17 + \frac{x}{100} \text{ (inches)}. [13]$$

Denoting:

t' = minimum pipe-wall thickness
p' = safe working pressure for unit stress S

we have, according to Equation [7]:

$$t' = \frac{p'x}{2(S - p')}$$

and substituting Equation [13], we obtain:

$$p' = \frac{S(17 + x)}{51x + 17} \text{ (Pounds per square inch)} \ldots\ldots [14]$$

which represents the safe working pressure for the pipe as based on fiber stress S and minimum wall thickness t'. The pipe-section area has previously been shown to be

$$\frac{p'x^2\pi}{2(S - p')}\left[1 + \frac{p'}{2(S - p')}\right]$$

and substituting the expression for p' in this equation, we obtain:

$$\text{Minimum pipe-section area} = \frac{(101x^2 + 1734x + 289)\pi}{10{,}000} \text{ (Square inches)} \ldots\ldots [15]$$

and in the following discussion the value of the working pressure p must be so chosen as to fulfil the conditions:

$$p \geqq p' = \frac{S(17 + x)}{51x + 17}$$

and

$$\frac{px^2\pi}{2(S - p)}\left[1 + \frac{p}{2(S - p)}\right] \geqq \frac{(101x^2 + 1734x + 289)\pi}{10{,}000} \text{ (Square inches)} \ldots [16]$$

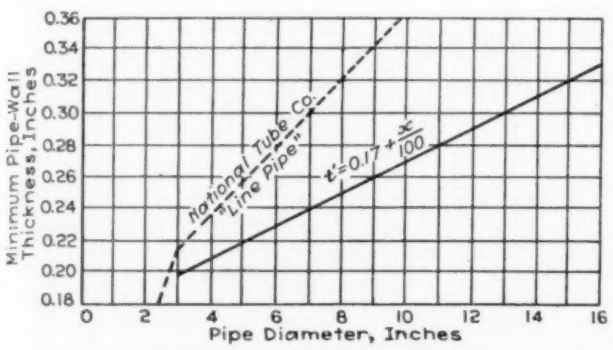

FIG. 7 MINIMUM PIPE-WALL THICKNESS

For a given size line the minimum cost of the pipe should therefore be not less than

$$\frac{L(101x^2 + 1734x + 289)\pi \times 5280 \times 12 \times 0.2833}{10{,}000 \times 2000} \times \text{cost per ton of steel}$$

$$\text{Minimum cost of pipe} = \frac{0.282L(101x^2 + 1734x + 289)}{x^{0.133}} \text{ (dollars)} \ldots [17]$$

and the total minimum line investment is represented by

$$\text{Minimum line investment} = \left[\frac{0.282(101x^2 + 1734x + 289)}{x^{0.133}} + 100x + 36x^2\right] L \text{ (dollars)} \ldots [18]$$

WORKING PRESSURES FOR MINIMUM SECTION AREA STEEL PIPE

Nominal diameter, in.	x	$\frac{17 + x}{51x + 17}$	S = 10,000 lb. (lb.)	S = 12,500 lb. (lb.)	S = 15,000 lb. (lb.)

$$p' = \frac{S(17 + x)}{51x + 17}$$

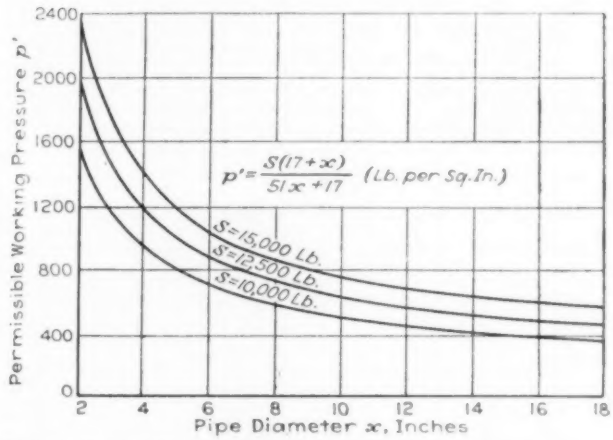

FIG. 8 PERMISSIBLE WORKING PRESSURE FOR MINIMUM WALL-THICKNESS PIPE

The equation for the fixed charges on the line investment may now be written:

$$\text{Fixed charges on line investment} = \left[705x^{1.667}\left(\frac{S^2}{(S - p)^2} - 1\right) + 100x + 36x^2\right]\left[(1 - \sigma)\Delta + R + T\right] L \text{ (dollars)} \ldots [19]$$

in which σ is the salvage value of the line corresponding to the operating life N under consideration. σ is expressed as a decimal fraction. The value of Equation [19] should never be less than

$$\left[\frac{0.282\,L\,(101x^2 + 1734x + 289)}{x^{0.133}} + (100x + 36x^2)\,L\right]\left[(1 - \sigma)\Delta + R + T\right] \text{ (dollars)} \ldots [20]$$

which represents the cost of the line as based on the minimum pipe-wall section which is required to satisfy the conditions enumerated.

OIL-PIPE-LINE DESIGN

The expression $P/n = p$ represents the station working pressure (see Fig. 2), which can be derived as a function of the line diameter x, the length of the system L, and the physical characteristics of the oil η and s. Inasmuch as practically all pipe-line systems handling oils of ordinary viscosities are operating under conditions of turbulent flow, i.e., $Q/x\eta < 93$, only that regime of flow will be considered in the following analysis. Exceptions are the lines handling highly viscous California and Mexican crudes which require heating before being pumped into the line.

The friction head, in pounds per square inch, is given by:

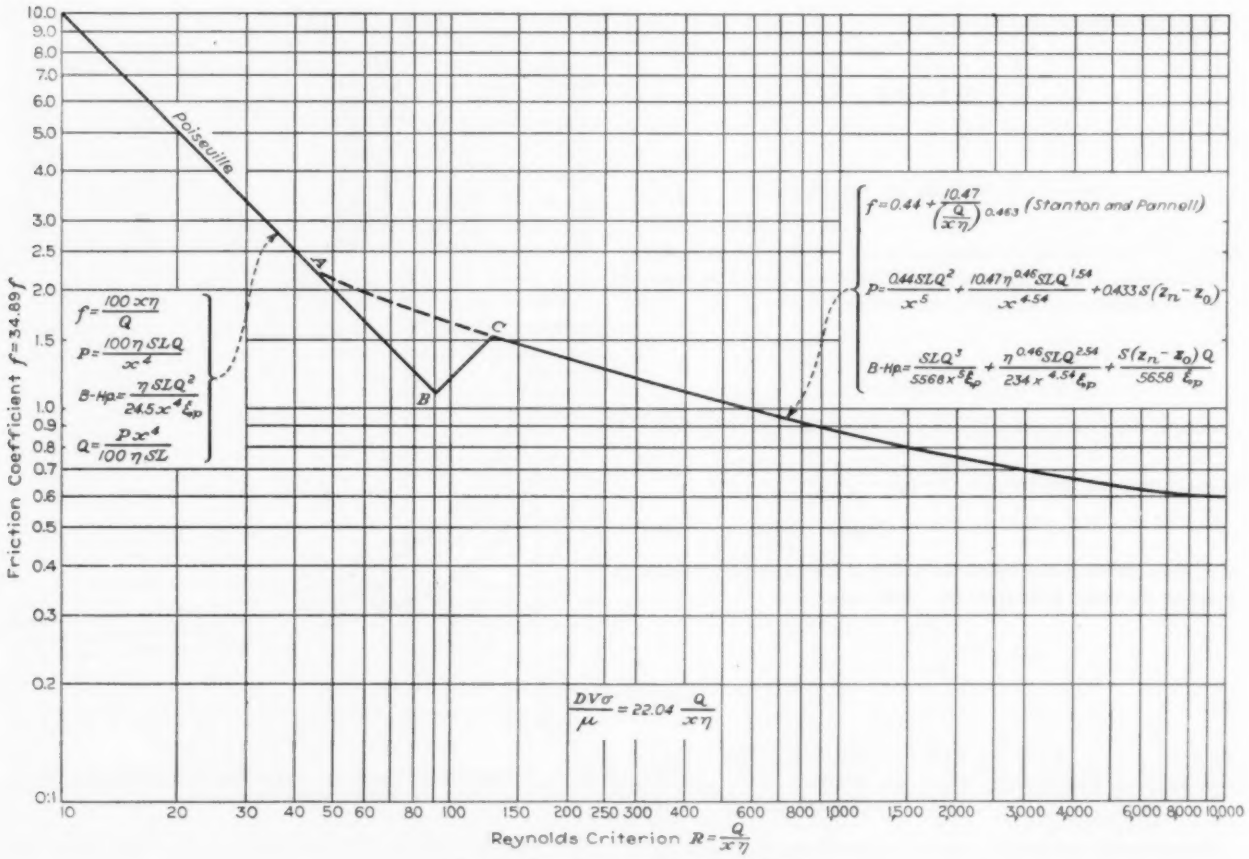

FIG. 9 STANTON AND PANNELL CURVE

$$P = \frac{fsLQ^2}{x^5} \quad \ldots\ldots [21]$$

in which

P = friction head (lb. per sq. in.)
s = specific gravity of the oil
L = length of line (miles)
Q = rate of flow (bbl. per hour)
x = inside diameter of pipe (in.)
f = friction coefficient.

The friction coefficent f has been found to be a function of

$$f = \Phi\left(\frac{Q}{x\eta}\right) = \Phi\left(\frac{sQ}{x\mu}\right) \quad \ldots\ldots [22]$$

μ = absolute viscosity (poises)
η = kinematic viscosity = μ/s

This function was evaluated by Stanton and Pannell at the National Physical Laboratory, London.[6]

The turbulent-flow region of the curve in Fig. 9 may be expressed by the equation:

$$f = 0.44 + \frac{10.47}{\left(\frac{Q}{x\eta}\right)^{0.463}} \quad \ldots\ldots [23]$$

and by substituting in the formula for P, we obtain:

$$P = \frac{0.44sLQ^2}{x^5} + \frac{10.47\nu^{0.46}sLQ^{1.54}}{x^{4.54}} + 0.433s(z_n - z_o)$$

(lb. per sq. in.) .... [24]

[6] Stanton and Pannell, Philosophical Transactions of the Royal Society, A, vol. 213.

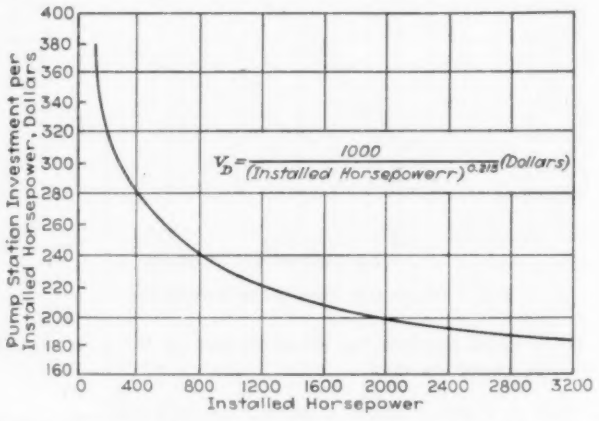

FIG. 10 STATION INVESTMENT PER INSTALLED HORSEPOWER (DOLLARS)

in which

z_n = elevation of terminal point of the pipe line (feet)
z_o = elevation of initial point of the pipe line (feet)

and $0.433s(z_n - z_o)$ represents the static head on the system, expressed in pounds per square inch.

The hydraulic horsepower of a pump may be shown to be:

$$\text{Hydraulic horsepower} = PQ/2450$$

and if the pump efficiency is given by E_p, the brake horsepower necessary for the operation of the pump is:

$$\text{Brake horsepower} = PQ/2450E_p$$

Introducing Equation [24] in this expression, we get

$$\text{Brake horsepower} = \frac{sLQ^3}{5568x^5E_p} + \frac{\eta^{0.46}sLQ^{2.54}}{234x^{4.54}\,E_p} + \frac{s(z_n - z_o)Q}{5658E_p} \quad \ldots\ldots [25]$$

It is to be noted that this represents the total horsepower required for pumping the quantity Q through the entire length of the system, and if the line is so designed that each station will carry an equal portion of the total load, the horsepower per station will be:

$$\text{Brake horsepower per station} = \frac{s}{nE_p}\left(\frac{LQ^3}{5568x^5} + \frac{\eta^{0.46}LQ^{2.54}}{234x^{4.54}} + \frac{(z_n - z_o)Q}{5658}\right) \ldots [26]$$

It is considered good practice to install a certain amount of extra pumping capacity for standby purposes, and if we assume this additional installation at 25 per cent of the required horsepower, the total installed capacity of the plant will be:

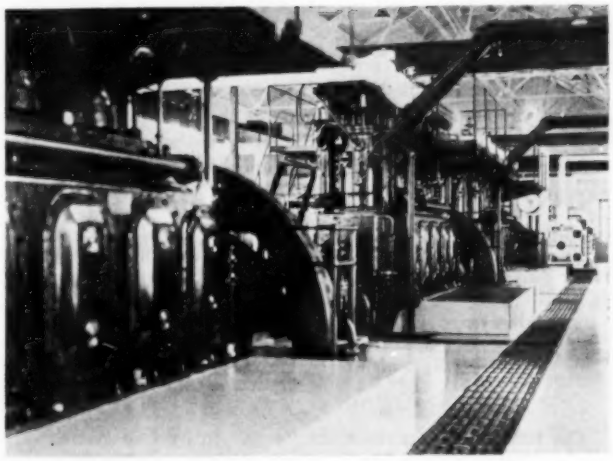

FIG. 13 WEST DALLAS DIESEL PUMP STATION

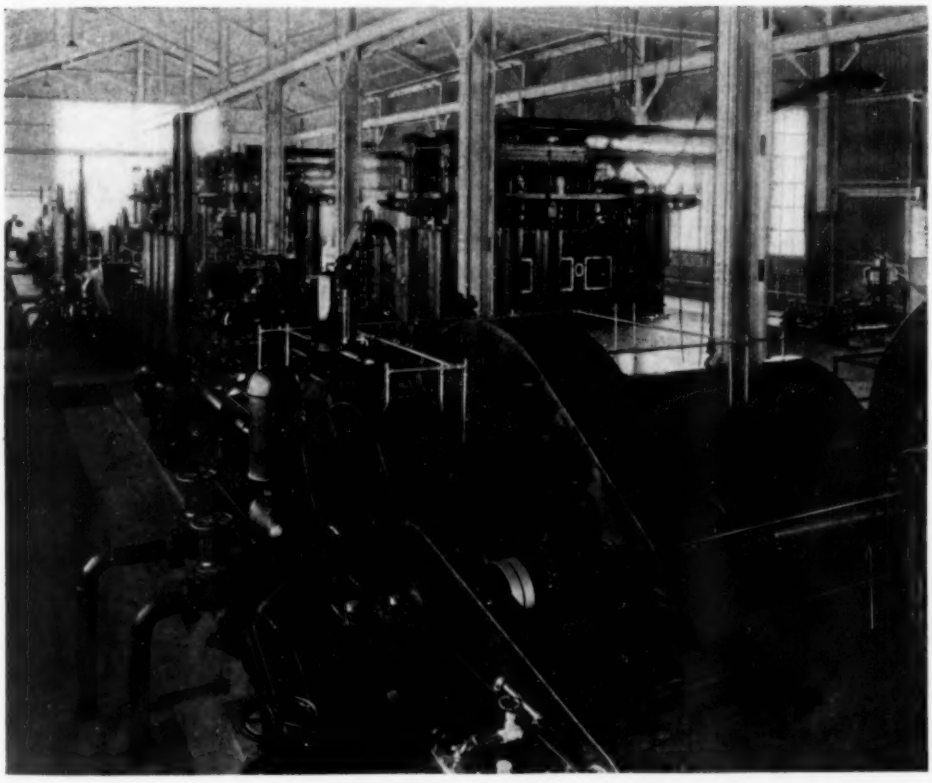

FIG. 12 JUNCTION DIESEL PUMP STATION

FIG. 11 EXTERIOR VIEW OF ROSANKY DIESEL PUMP STATION

$$\text{Installed horsepower per station} = \frac{1.25s}{nE_p}\left(\frac{LQ^3}{5568x^5} + \frac{\eta^{0.46}LQ^{2.54}}{234x^{4.54}} + \frac{(z_n - z_o)Q}{5658}\right) \ldots [27]$$

and if

V = cost per installed horsepower (dollars)

the total station investment for the entire system (n stations) will be:

$$\text{Cost of } n \text{ pump stations} = \frac{1.25sV}{E_p}\left(\frac{LQ^3}{5568x^5} + \frac{\eta^{0.46}LQ^{2.54}}{234x^{4.54}} + \frac{(z_n - z_o)Q}{5658}\right) \text{(dollars)} \ldots 28]$$

The unit cost V per installed horsepower depends upon the type of station; i.e., whether Diesel-driven, motor-operated reciprocating pumps, or centrifugal units. It is of course also a function of the general quality of the plant, the elaborateness of the design, and the efficiency of the construction organization. Wide fluctuations of unit cost are naturally to be expected under these conditions, and the following data are representative of average conditions only, to be multiplied by such coefficients as will allow for such deviation from the average as may, in the judgment of the designing engineer, be warranted. An increase or decrease of 15 per cent from the following data shown should be sufficient to delineate the range normally encountered. The unit cost per installed horsepower may be assumed as follows:

1 *Diesel Stations.* The following unit-cost figures cited include all of the main pumping equipment, auxiliaries, piping, cooling systems, and buildings. Inasmuch as the amount of working tankage provided for each station varies somewhat

with the policies of the different companies, this item will be considered separately. The general features of construction may be seen from the views in Figs. 11, 12, and 13. The cost per horsepower installed varies with the size of the installation, and may be expressed as a function of the installed horsepower. It is assumed, however, that the sizes of the individual units making up the installation are commensurate with the general capacity of the plant.

$$\text{Cost per installed horsepower} = V_D = \frac{1000}{\left(\text{Installed horsepower per station}\right)^{0.215}}$$

$$\text{(dollars)} = \frac{1000}{\left[\frac{1.25s}{nE_p}\left(\frac{LQ^2}{5568x^5} + \frac{\eta^{0.46}L^2Q^{2.54}}{234x^{4.54}} + \frac{(z_n - z_o)Q}{5658}\right)\right]^{0.215}} \text{ (dollars)} \quad [29]$$

The total station investment for the entire line system of n stations is therefore given by:

$$\text{Total station investment } n \text{ stations} = 1000n^{0.215}\left[\frac{1.25s}{E_p}\left(\frac{LQ^2}{5568x^5} + \frac{\eta^{0.46}LQ^{2.54}}{234x^{4.54}} + \frac{(z_n - z_o)Q}{5658}\right)\right]^{0.785} \text{(dollars)} \quad [30]$$

2 *Motor-Driven Reciprocating Station.* For motor-driven reciprocating stations the investment per installed horsepower is approximately one-half of that required for Diesel stations. Hence:

$$V_{MR} = \frac{500}{(\text{installed horsepower})^{0.215}} \text{ (dollars)}$$

and the total station investment for the entire line system of n stations is therefore given by:

$$\text{Total pump station investment } n \text{ stations} = 500n^{0.215}\left[\frac{1.25s}{E_p}\left(\frac{LQ^2}{5568x^5} + \frac{\eta^{0.46}LQ^{2.54}}{234x^{4.54}} + \frac{(z_n - z_o)Q}{5658}\right)\right]^{0.785} \text{(dollars)} \quad [31]$$

3 *Motor-Driven Centrifugal Station.* For motor-driven centrifugal stations the investment per installed horsepower is approximately one-fourth of that required for Diesel stations. Hence:

$$V_C = \frac{250}{(\text{installed horsepower})^{0.215}} \text{ (dollars)}$$

and the total station investment for the entire line system of n stations is therefore given by:

$$\text{Total station investment } n \text{ stations} = 250n^{0.215}\left[\frac{1.25s}{E_p}\left(\frac{LQ^2}{5568x^5} + \frac{\eta^{0.46}LQ^{2.54}}{234x^{4.54}} + \frac{(z_n - z_o)\,Q}{5658}\right)\right]^{0.785} \text{(dollars)} \quad [32]$$

Tankage. On long pipe-line systems made up of a number of pump stations operating in series, it is sufficient to provide the stations with single tanks only which "float" on the line, and thus absorb any difference in the rate of pumping which may exist between successive stations. "Check" stations are provided at certain intervals for an accurate gage on the oil stream passing through the system, and these stations are equipped with two or more tanks. The "floating" tankage erected at each station varies from 50 to 100 per cent of the daily oil movement passing through the system. If elasticity of operation and security against interruptions of service are of vital concern, the amount of tankage thus provided should be as large as possible. Naturally this is governed more or less by the general policies of the company making the installation. If we designate the size of each tank as a decimal fraction K of the daily line capacity, we obtain:

$$\text{Size of tank} = 24\,KQ \quad [33]$$

and

$$\text{Cost per tank} = 24\,KQ \times C \quad [34]$$

in which C = unit cost per barrel of capacity $24\,KQ$, and if we decide to install a total of $n + v$ tanks on the system, the total cost for tankage will be:

$$\text{Cost of working tankage} = 24\,KQ(n + v) \times \text{cost per bbl. of capacity} \quad [35]$$

Fixed Charges on Pump Station Investment (n Stations)

The equation for the fixed charges on the station investment may now be written.

1 *Diesel Station:*

$$\left\{1000n^{0.215}\left[\frac{1.25s}{E_p}\left(\frac{LQ^2}{5568x^5} + \frac{\eta^{0.46}LQ^{2.54}}{234x^{4.54}} + \frac{(z_n - z_o)Q}{5658}\right)\right]^{0.785} + 24KQ\,(n + v)C\right\}\left[(1 - \sigma)\Delta + R + T\right] \text{ (dollars)} \quad [36]$$

2 *Motor-Driven Reciprocating Station:*

$$\left\{500n^{0.215}\left[\frac{1.25s}{E_p}\left(\frac{LQ^2}{5568x^5} + \frac{\eta^{0.46}LQ^{2.54}}{234x^{4.54}} + \frac{(z_n - z_o)Q}{5658}\right)\right]^{0.785} + 24\,KQ(n + v)C\right\}\left[(1 - \sigma)\Delta + R + T\right] \text{ (dollars)} \quad [37]$$

3 *Motor-Driven Centrifugal Station:*

$$\left\{250n^{0.215}\left[\frac{1.25s}{E_p}\left(\frac{LQ^2}{5568x^5} + \frac{\eta^{0.46}LQ^{2.54}}{234x^{4.54}} + \frac{(z_n - z_o)Q}{5658}\right)\right]^{0.785} + 24KQ(n + v)C\right\}\left[(1 - \sigma)\Delta + R + T\right] \text{ (dollars)} \quad [38]$$

For any given problem the following terms are constant, and denoting:

$$a = 0.44sLQ^2$$

$$b = 10.47\eta^{.046}sLQ^{1.54}$$

$$c = 0.433s(z_n - z_o)$$

$$\alpha = \frac{sLQ^2}{5568E_p}$$

$$\beta = \frac{\eta^{0.46}sLQ^{2.54}}{234E_p}$$

$$\gamma = \frac{s(z_n - z_o)Q}{5658E_p}$$

the Equations [36], [37], and [38] may be written in simpler form, and the total annual fixed charge for the line and pump station investment of the system is given by:

$$\left[\left\{705x^{1.867}\left[\frac{S^2}{(S - p)^2} - 1\right] + 100x + 36x^2\right\}L + 1000n^{0.215}\left[1.25\left(\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right)\right]^{0.785} + 24KQ(n + v)C\right]\left[(1 - \sigma)\Delta + R + T\right] \text{ (dollars)} \quad [39]$$

in which

$$p = \frac{P}{n} = \frac{a}{nx^5} + \frac{b}{nx^{4.54}} + \frac{c}{n} \quad \ldots\ldots\ldots\ldots [40]$$

If the value of the crude oil in the line is assumed at φ dollars per barrel, the fixed charges representing interest and taxes on this investment are given by:

Fixed charges on oil in line $= 5.16\, x^2 \varphi L(R + T)$ (dollars). [41]

and the total fixed charges of the entire system:

$$Y = \left[\left\{705x^{1.867}\left[\frac{S^2}{\left(S - \frac{a}{nx^5} - \frac{b}{nx^{4.54}} - \frac{c}{n}\right)^2} - 1\right] + 100x + 36x^2\right\}L + 1000n^{0.215}\left[1.25\left(\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right)\right]^{0.785} + 24KQ(n + r)C\right]\left[(1 - \sigma)\Delta + R + T\right] + 5.16x^2\varphi L\,(R + T) \text{ (dollars)}$$

$\ldots\ldots\ldots [42]$

Equation [42] represents the total fixed charges on a system based on Diesel-pump station installations. If either motor-driven reciprocating or centrifugal stations are under consideration, Equations [37] or [38], as the case may be, must be inserted in Equation [42]. It should also be remembered in connection with Equation [42] that its component representing the line investment should never be less than:

$$\frac{0.282L(101x^2 + 1734x + 289)}{x^{0.132}} + (100x + 36x^2)L \text{ (dollars)}. [18]$$

for the reasons mentioned.

SECTION II

Operating Expenses X

The operating expenses of a pipe-line system may be divided into:

(1) *Line Maintenance and Repairs*, which may be expressed by:

Annual cost of line maintenance and repair $= (50 + 1.5x)L$ (dollars)$\ldots\ldots\ldots [43]$

(2) *Station Operation*, i.e., (*a*) labor, (*b*) fuel, (*c*) lubrication, (*d*) maintenance and supplies, and in the case of motor-operated stations electrical energy.

(*a*) *Labor.* As to Diesel stations: The station attendance cost is naturally a function of the size of the station. It is further dependent upon the size of the individual units making up the total installation. A 1000-hp. station made up of ten 100-hp. units requires more operating labor than a station of the same size made up of two 500-hp. units. The following data are therefore based on the assumption that the individual unit capacities are commensurate with the total capacity of the station. If we express the attendance cost as a function of the installed horsepower, we obtain for a Diesel station:

Attendance cost per installed horsepower per year (Diesel engines), one station only $= \dfrac{2062}{(\text{installed horsepower})^{0.725}}$ (dollars)

$$= \frac{2062}{\left[\frac{1.25}{n}\left(\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right)\right]^{0.725}} \text{ (dollars)}\ldots\ldots [44]$$

Hence the total attendance cost for n pump stations of the system is given by:

Total annual attendance cost n Diesel stations

$$= 1470n^{0.725}\left(\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right)^{0.275} \text{ (dollars)}\ldots\ldots [45]$$

In the course of this analysis it will be assumed that the station attendance cost will remain the same whether the system is operated at 100 per cent "use factor" or not. This may not be strictly true when the system is operated at very low "use" or "load" factors, but it will not change the result of the analysis to any noticeable degree. It is further assumed that all of the pumping equipment will be operated at full load at all times, and that reductions in the average daily capacity of the system are brought about through reduction of the hours of pumping. In actual pipe-line operation practice this procedure is not always followed, it being more often the custom to reduce the load on the system through reduction of the working pressure

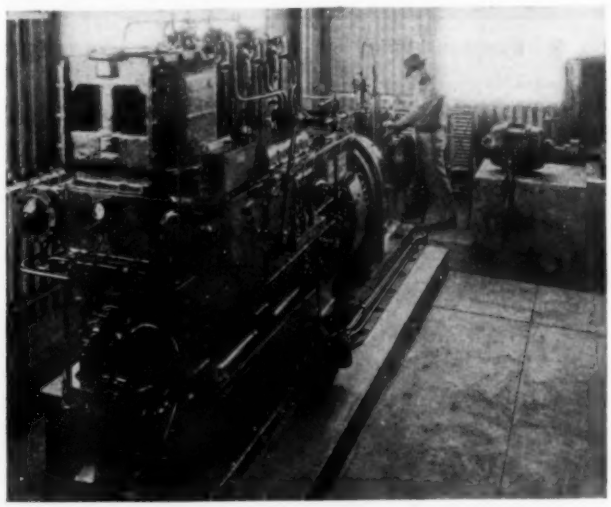

Fig. 14 Auxiliary Engine Room at Junction Diesel Pump Station

Fig. 15 Pump-Station Manifold at Heyworth Station

and, consequently, the average hourly rate of flow. Under some conditions it may even be found advantageous to "bypass" some of the stations altogether and thus obtain the reduction

FIG. 16 EXTERIOR VIEW OF FREDERICKSBURG CENTRIFUGAL PUMP STATION

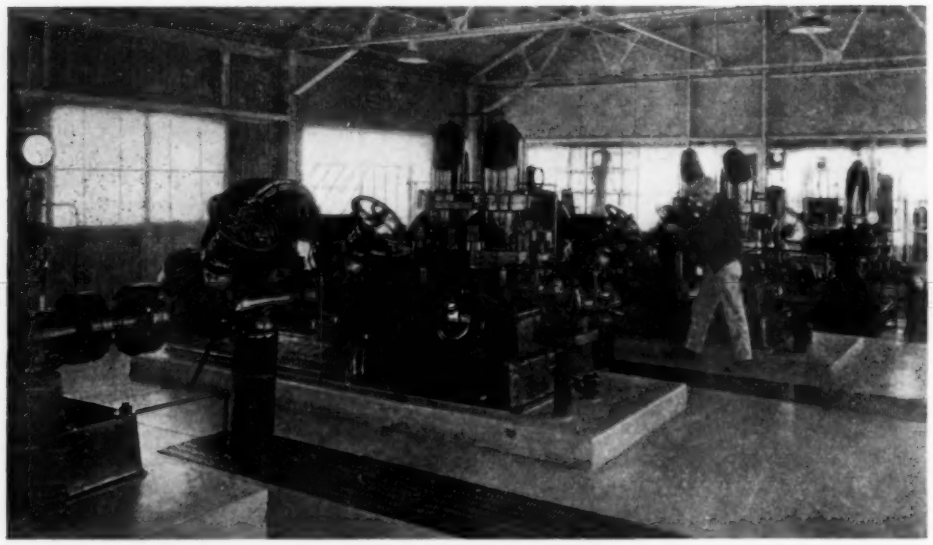

FIG. 17 CRANE CENTRIFUGAL PUMP STATION

in flow through lengthening the pumping distance between stations. In an investigation of this sort it is of course impossible to introduce all of these contingencies in a single mathematical equation, and the previously made assumption will therefore be used as the basis for operating costs at use factors less than 100 per cent.

As to motor-driven reciprocating stations: The attendance cost of a motor-operated reciprocating pump station is somewhat less than that required for a Diesel station of like capacity. If expressed on the basis of installed horsepower, the yearly labor cost per horsepower is given by the following equation:

Yearly attendance cost per installed horsepower (one station)

$$= \frac{4445}{(\text{installed horsepower})^{0.935}} \text{ (dollars)}$$

$$= \frac{4445}{\left[\frac{1.25}{n}\left(\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right)\right]^{0.935}} \text{ (dollars)} \quad \ldots [46]$$

and the total attendance cost for the n stations of the system is:

Yearly total attendance cost n motor-reciprocating stations

$$= 4510n^{0.935}\left(\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right)^{0.065} \text{ (dollars)} \quad \ldots [47]$$

As to motor-driven centrifugal pumps: The chief argument advanced in favor of the centrifugal-pump installation lies in its low first cost and small labor expense. When coupled with an advantageous power rate, the effect of its slightly lower efficiency may be offset so as to represent a very desirable installation from an economic point of view. As a function of the installed horsepower, the labor cost per horsepower per year is given by the equation:

Yearly attendance cost per installed horsepower (one station)

$$= \frac{6000}{(\text{installed horsepower})} \text{ (dollars)}$$

$$= \frac{6000}{\frac{1.25}{n}\left(\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right)} \text{ (dollars)} \quad \ldots [48]$$

Hence the total attendance cost for the system of n pump stations is equal to:

Total yearly attendance cost (n centrifugal stations)

$$= 6000\ n \text{ (dollars)} \quad \ldots [49]$$

(*b*) *Fuel* (*Electrical Energy*). As to Diesel Stations:

Denoting:

- φ = cost per barrel of fuel (dollars)
- h = number of hours per year engines are in operation
- e = specific fuel consumption of engines per brake horsepower hour (may be assumed at 0.45 lb. for Diesel engines of good make)
- s' = specific gravity of fuel.

The total annual fuel cost for operating the n stations of the system is equal to:

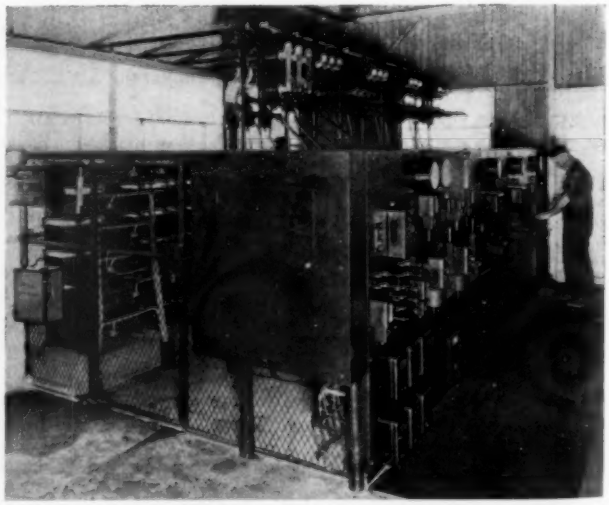

FIG. 18 SWITCHBOARD AT BROOKSHIRE CENTRIFUGAL PUMP STATION

$$\text{Annual cost of fuel} = \left(\frac{\alpha}{x^{\delta}} + \frac{\beta}{x^{4.54}} + \gamma\right)\frac{h\varphi e}{350\,s'} \text{ (dollars)} \quad [50]$$

As to motor-driven stations (centrifugal or reciprocating): Denoting:

φ'' = average energy cost per kw-hr. at load factor (per cent) $\frac{100\,h}{8760}$ (dollars).

The total annual cost of electrical energy for operating the n stations of the system is:

$$\text{Annual cost of electrical energy} = \left(\frac{\alpha}{x^{\delta}} + \frac{\beta}{x^{4.54}} + \gamma\right) \times 0.746\,h\varphi''$$

It is of course to be remembered that the pump efficiency E_p must be chosen in accordance with the type of station under consideration. For centrifugal stations of good design E_p ranges between 70 and 80 per cent, depending upon the size of the individual units. Values between 85 and 89 per cent may be assumed for reciprocating power pumps. Taking, for instance, an assumed energy rate of 1 per cent per kw-hr. at 100 per cent use factor, it will be obvious that the average cost per kilowatt-hour will be greater than 1 cent at use factors lower than 100 per cent. There is, unfortunately, no uniformity

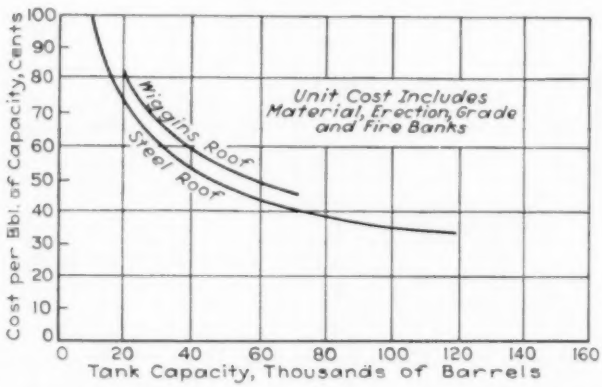

FIG. 19 COST OF STEEL TANKAGE PER BARREL OF CAPACITY

of form nor rate at which electrical energy is being offered by the various power companies. However, the following curve will serve as a typical example for the average cost per kilowatt-hour at different use factors, where the 100 per cent average is 1 cent per kw-hr. It is also appreciated that this rate will vary somewhat with the "demand" put upon the power company, and the following data are therefore offered for illustrative purposes only.

For a load or use factor range between 30 and 100 per cent, such a representative rate may be expressed by the following equation:

$$\varphi'' = \text{average cost per kw-hr.} = \frac{0.048}{(\text{use factor})^{0.34}} \text{ (dollars)}$$

in which the use factor is equal to $100h/8760$; hence

$$\varphi'' = \text{average cost per kw-hr.} = \frac{0.22}{h^{0.34}} \text{ (dollars)} \quad [51]$$

and the total annual energy cost for the system of n stations is:

$$\text{Total annual energy cost } (n \text{ stations}) = 0.164h^{0.66}\left[\frac{\alpha}{x^{\delta}} + \frac{\beta}{x^{4.54}} + \gamma\right] \text{ (dollars)} \quad [52]$$

Equation [52] is of course true only for this particular energy rate and for use factors between 30 and 100 per cent.

If the power rate is materially different from that cited, the actual values of φ'' must be used in accordance with the contract offered.

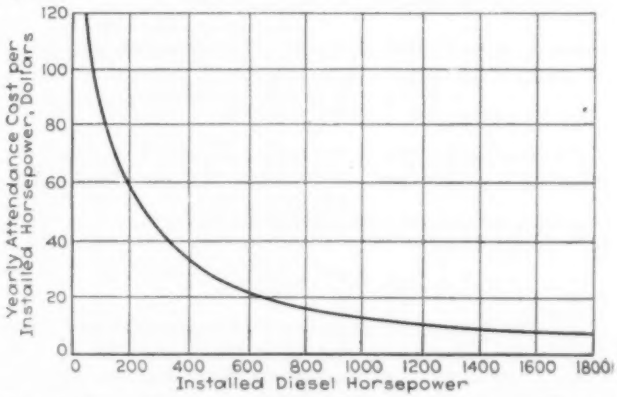

FIG. 20 PUMP STATION ATTENDANCE COST PER INSTALLED HORSEPOWER PER YEAR

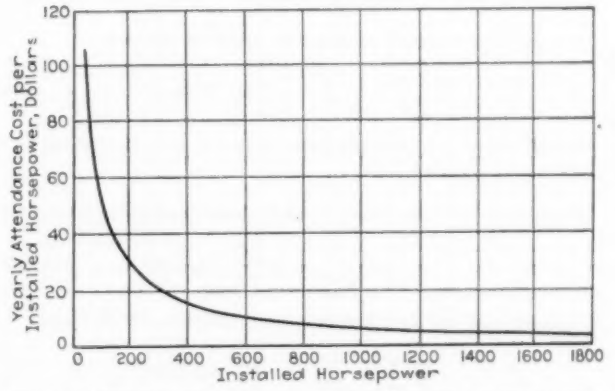

FIG. 21 ATTENDANCE COST OF MOTOR-DRIVEN RECIPROCATING PUMPS

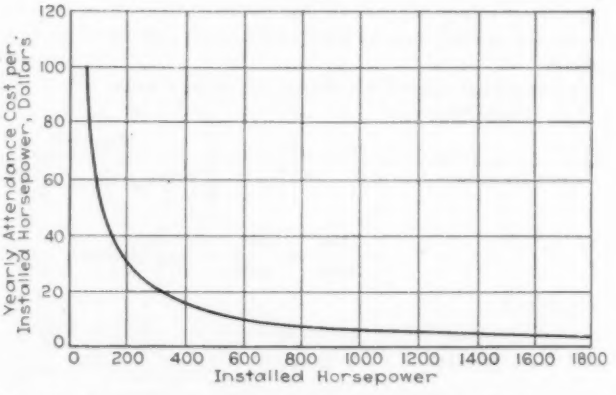

FIG. 22 ATTENDANCE COST OF MOTOR-DRIVEN CENTRIFUGAL PUMPS

(c) *Lubrication.* For Diesel-powered pump stations the lubricating-oil consumption may be assumed at 2000 hp-hr. per gallon of oil. If we designate

m = cost per gallon of lubricating oil (dollars)

the total yearly cost of lubrication for the n stations of the system may be written as follows:

Annual cost of lubrication (Diesel stations)

$$= \left(\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right)\frac{hm}{2000} \text{ (dollars)} \ldots [53]$$

For motor-driven reciprocating pumps, the cost of lubrication may be taken as one-fourth of Equation [53].

Annual cost of lubrication (motor-reciprocating station)

$$= \left(\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right)\frac{hm}{8000} \text{ (dollars)} \ldots [54]$$

For centrifugal stations, the lubricating cost is nominal, and assuming it at one-tenth of Equation [53], we obtain:

Annual cost of lubrication (centrifugal stations)

$$= \left(\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right)\frac{hm}{20{,}000} \text{ (dollars)} \ldots [55]$$

(*d*) *Maintenance, Supplies, and Miscellaneous Station Upkeep.* The yearly maintenance cost of a Diesel installation varies between one and two dollars per installed horsepower per year. If we include supplies and miscellaneous station upkeep expenses in this item, a charge of $g = 0.0005$ dollars per horsepower-hour should give representative results. Hence, for n stations:

Annual cost of maintenance and supplies (Diesel)

$$= \left[\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right] hg \text{ (dollars)} \ldots [56]$$

For motor-reciprocating stations this cost may be divided by 4 and for centrifugals by 10.

Annual cost of maintenance and supplies (motor-reciprocating)

$$= \left[\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right]\frac{gh}{4} \text{ (dollars)} \ldots [57]$$

Annual cost of maintenance and supplies (centrifugal)

$$= \left[\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right]\frac{gh}{10} \text{ (dollars)} \ldots [58]$$

We are now in position to write the equation for the total annual operating expense of the entire system of n stations. Summing up the various component costs just developed, we obtain:

Total annual operating cost for the entire system =

(*a*) *Diesel Stations:*

$$X = (50 + 1.5x)L + \left[\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right]\left[\frac{2194n^{0.725}}{\left[\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right]^{0.725}}\right. + \left.\frac{h\varphi e}{350s'} + \frac{hm}{2000} + hg\right] \text{(dollars)} \ldots [59]$$

in which

$$\alpha = \frac{sLQ^3}{5568E_p},\quad \beta = \frac{\eta^{0.46}\, sLQ^{2.54}}{234E_p},\text{ and } \gamma = \frac{s(z_n - z_o)Q}{5658}$$

(*b*) *Motor-Driven Reciprocating Stations:*

$$X = (50 + 1.5x)L + \left[\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right]\left[\frac{4510n^{0.975}}{\left[\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right]^{0.975}}\right. + 0.164h^{0.66} + \left.\frac{hm}{8000} + \frac{hg}{4}\right] \text{(dollars)} \ldots [60]$$

Based on power cost of 1 cent per kw-hr. at 100 per cent use factor, i.e., $h = 8760$. For $h < 8760$ the cost per kilowatt-hour is assumed according to Equation [51].

(*c*) *Centrifugal Pump Stations:*

$$X = (50 + 1.5x)L + 6000n + \left[\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right]\left[0.164h^{0.66} + \frac{hm}{20{,}000} + \frac{hg}{10}\right] \text{(dollars)} \ldots [61]$$

It must be remembered that E_p in α and β must be based on centrifugal-pump performance in this case.

SECTION III

According to Equation [3] the total annual charges against the system, i.e., the sum of the fixed charges and operating expenses $u = X + Y$ is a minimum when $\frac{dX}{dx} + \frac{dY}{dx} = 0$, and d^2u/dx^2 is positive in sign.

Substituting the equations developed in Sections I and II in (1), and making the differential coefficient equal to zero, we obtain:

(*a*) *Diesel Station System:*

$$\frac{dY}{dx} + \frac{dX}{dx} = \left\{\frac{x^{0.867}LS^2}{\left(S - \frac{a}{nx^5} - \frac{b}{nx^{4.54}} - \frac{c}{n}\right)^2}\right.$$

$$\left[1316 - \frac{1410\left(\frac{5a}{nx^5} + \frac{4.54b}{nx^{4.54}}\right)}{S - \frac{a}{nx^5} - \frac{b}{nx^{4.54}} - \frac{c}{n}}\right] - 1316x^{0.867}L + 100L + 72xL$$

$$\left. - \frac{935\left(\frac{5\alpha}{x^6} + \frac{4.54\beta}{x^{5.54}}\right)n^{0.215}}{\left(\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right)^{0.215}}\right\}[(1 - \sigma)\Delta + R + T] + 10.32$$

$$x\,\varphi L(R + T) + 1.5L - \left(\frac{5x}{x^6} + \frac{4.54\beta}{x^{5.54}}\right)\left[\frac{600n^{0.725}}{\left(\frac{\alpha}{x^5} + \frac{\beta}{x^{4.54}} + \gamma\right)^{0.725}}\right. + \left.\frac{h\varphi e}{350s'} + \frac{hm}{2000} + hg\right] = 0. \quad [62]$$

In connection with this equation it must not be forgotten that the line investment should not become less than indicated in Equation [18]. In other words, the pipe-wall thickness and its diameter should be such that $p' \geq \frac{S(17 + x)}{51x + 17.}$

This will be shown more in detail in the example below.

(*b*) *Motor-Driven Reciprocating Station System:*

For a pipe-line system depending upon motor-driven reciprocating stations, the equation representing the minimum may be written as follows:

$$\frac{dY}{dx} + \frac{dX}{dx} = \left\{\frac{x^{0.867}LS^2}{\left(S - \frac{a}{nx^5} - \frac{b}{nx^{4.54}} - \frac{c}{n}\right)^2}\right.$$

$$\left[1316 - \frac{1410\left(\frac{5a}{nx^5} + \frac{4.54b}{nx^{4.54}}\right)}{S - \frac{a}{nx^5} - \frac{b}{nx^{4.54}} - \frac{c}{n}}\right] - 1316^{0.867}L + 100L + 72xL$$

$$-\left\{\frac{467n^{0.215}\left(\frac{5\alpha}{x^5}+\frac{4.54\beta}{x^{5.45}}\right)}{\left(\frac{\alpha}{x^5}+\frac{\beta}{x^{4.54}}+\gamma\right)^{0.215}}\right\}[(1-\sigma)\Delta+R+T]+1.5L$$

$$-\left(\frac{\alpha}{x^5}+\frac{4.54\beta}{x^{5.54}}\right)\left[\frac{290n^{0.935}}{\left(\frac{\alpha}{x^5}+\frac{\beta}{x^{4.54}}+\gamma\right)^{0.935}}+0.164h^{0.66}+\frac{hm}{8000}+\frac{hg}{4}\right]+10.32x\varphi L(R+T)=0\ldots[63]$$

(c) *Centrifugal Pump System:*

It must be remembered that the efficiency of centrifugal pumps is somewhat lower than that obtainable with reciprocating pumps. Calling this efficiency E'_p, and the corresponding constants α' and β', we can write the following equation:

$$\frac{dY}{dx}+\frac{dX}{dx}=\left\{\frac{x^{0.867}LS^2}{\left(S-\frac{a}{nx^5}-\frac{b}{nx^{4.54}}-\frac{c}{n}\right)^2}\right.$$

$$\left[1316-\frac{1410\left(\frac{5a}{nx^5}+\frac{4.54b}{nx^{4.54}}\right)}{S-\frac{a}{nx^5}-\frac{b}{nx^{4.54}}-\frac{c}{n}}\right]-1316x^{0.867}L+100L+72xL$$

$$\left.-\frac{234n^{0.215}\left(\frac{5\alpha'}{x^5}+\frac{4.54\beta'}{x^{5.54}}\right)}{\left(\frac{\alpha'}{x^5}+\frac{\beta'}{x^{4.54}}+\gamma\right)^{0.215}}\right\}[(1-\sigma)\Delta+R+T]$$

$$+10.32x\varphi L(R+T)+1.5L-\left(\frac{5\alpha'}{x^5}+\frac{4.54\beta'}{x^{5.54}}\right)\left(0.164h^{0.66}+\frac{hm}{20{,}000}+\frac{hg}{10}\right)=0\ldots\ldots[64]$$

Numerical Example

To demonstrate the application of these equations, let it be required that a pipe-line system is to be designed for the transportation of 50,000 bbl. of crude oil per day, $Q = 2080$ bbl. per hour. The total length of the system is $L = 537$ miles, the elevation of the initial station $z_o = 880$ ft., and the terminal 790 ft. The oil to be pumped has a viscosity of 50 S. U. S., i.e., $\eta = 0.072$, and a specific gravity $s = 0.83$. The line is to be designed for best over-all financial efficiency, and preliminary comparisons have resulted in a choice of Diesel-powered stations in preference to purchased electrical power. The expected load or "use" factor of the line is assumed at 7000/8760, i.e., it will be on full-capacity operation for $h = 7000$ hr. per year. The Diesel engines will be operated on pipe line crude for fuel, $s' = 0.83$, costing $\varphi = \$1.25$ per bbl., and the specific fuel consumption of the engines is $e = 0.45$ lb. per b.hp-hr. The mechanical efficiency of the reciprocating pumps $E_p = 0.85$, and the cost of lubrication is $m = \$0.5$ per gal. All maintenance and supplies for the station are assumed at $g = 0.0005$ dollars per hp-hr.

It has also been decided to construct the line of high-carbon steel pipe of a permissible working stress $S = 15{,}800$ lb. per sq. in. The initial and terminal stations on the system are to be equipped with two Wiggins roof working tanks each, $K = 0.8$, and all other intermediate stations with one "floating" Wiggins roof tank.

A general appraisal of the future of this system has developed the desirability of assuming a 10-year depreciation period, hence $\Delta = 6.90$ per cent. Expected taxes are 2 per cent, and money is considered worth 8 per cent to the company. Salvage value at the end of the 10 years is assumed at 25 per cent, or $\sigma = 0.25$.

What is the most economic layout for such a transportation system that will make the sum of the total yearly charges, both fixed and operating, a minimum?

For a pipe-line system based on Diesel-driven pump stations the most economical pipe diameter is given by the following Equation [62]:

$$\left\{\frac{x^{0.867}LS^2}{\left(S-\frac{a}{nx^5}-\frac{b}{nx^{4.54}}-\frac{c}{n}\right)^2}\right.\left[1316-\frac{1410\left(\frac{5a}{nx^5}-\frac{4.54b}{nx^{4.54}}\right)}{S-\frac{a}{nx^5}-\frac{b}{nx^{4.54}}-\frac{c}{n}}\right]$$

$$\left.-1316x^{0.867}L+100\,l+72xL-\frac{935\left(\frac{5\alpha}{x^5}+\frac{4.54\beta}{x^{5.54}}\right)n^{0.215}}{\left(\frac{\alpha}{x^5}+\frac{\beta}{x^{4.54}}+\gamma\right)^{0.215}}\right\}$$

$$\left[(1-\sigma)\Delta+R+T\right]+10.32x\varphi L(R+T)+1.5L$$

$$-\left(\frac{5\alpha}{x^5}+\frac{4.54\beta}{x^{5.54}}\right)\left[\frac{600n^{0.725}}{\left(\frac{\alpha}{x^5}+\frac{\beta}{x^{4.54}}+\gamma\right)^{0.725}}+\frac{h\varphi e}{350s'}+\frac{hm}{2000}+hg\right]=0$$

This equation can be solved only by trial and error. It will also be necessary to determine the minima for a number of values of n, plot the resulting "total yearly costs" of the system on coordinate paper, and choose the most economical combination from the derived curve.

To assist in the solution of this equation, the exponential functions of the pipe diameter x are given in the following tabulation for a number of values of x:

x	x^5	$x^{5.54}$	x^5	$x^{4.54}$	$x^{1.867}$	$x^{0.867}$
4....	4,096	2,165	1,024	541	13.3	3.3
8....	262,200	100,750	32,770	12,592	48.5	6.1
12....	2,987,000	952,400	248,900	79,360	103.3	8.6
16....	16,773,000	4,685,000	1,048,200	292,800	177.0	11.1
20....	63,980,000	16,125,000	3,199,000	806,300	268.6	13.4
24....	191,080,000	44,290,000	7,962,000	1,888,500	377.5	15.7

The constants for this particular problem are:

$S = 15{,}800$ lb. per sq. in.

$E_p = 0.85$

$F = \dfrac{h\varphi e}{350s'}+\dfrac{hm}{2000}+hg = 18.85$

$h = 7000$ hr.

$\eta^{0.45} = 0.2981$

$Q^{1.54} = 128{,}800$

$Q^{2.54} = 134{,}670{,}000$

$a = 0.44sLQ^2 = 850{,}000{,}000$

$b = 10.47\eta^{0.45}sLQ^{1.54} = 179{,}200{,}000$

$c = 0.433s(z_n - z_o) = -32.3$

$\alpha = \dfrac{sLQ^2}{5568E_p} = 848{,}500{,}000$

$\beta = \dfrac{\eta^{0.45}sLQ^{2.54}}{234E} = 90{,}000{,}000$

$\gamma = \dfrac{s(z_n - z_o)Q}{5658\,E_p} = -32.3$

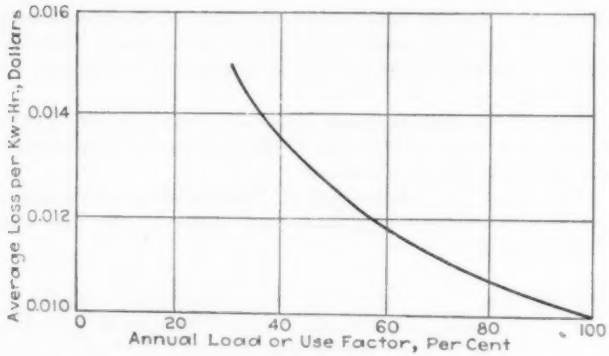

FIG. 23 REPRESENTATIVE ELECTRICAL ENERGY COST

and the evaluation of Equation [62] gives the most economical pipe diameters as a function of the station spacing (Fig. 24).

The working pressures corresponding to the various station spacings are found by means of Equation [21]:

$$\text{Friction head } P = \frac{fsLQ^2}{x^5} \quad [21]$$

or

$$p = \frac{fsLQ^2}{nx^5} \quad [21]$$

and the required pipe wall thickness:

$$t = \frac{xp}{2(S - p)} \quad [7]$$

Substituting the proper values in these equations, and taking account of the slight negative static head of —32.3 lb., we obtain:

n	x	Friction head (lb.)	Friction head —32.3 lb. (lb.)	p (lb.)	t (in.)	B.hp. required, each station
4	16.0	1798	1766	442	0.232	442
8	14.5	2770	2738	342	0.173	342
12	13.65	3715	3683	307	0.136	307
16	13.15	4400	4368	274	0.116	274
20	12.9	4790	4758	238	0.099	238
24	12.75	5078	5046	212	0.084	212

and if we assume each station to be equipped with 25 per cent extra capacity for standby purposes to insure continuity of operation, the installed horsepower will be as follows:

n	x	Installed horsepower, each station
4	16.0	556
8	14.5	431
12	13.65	386
16	13.15	343
20	12.9	300
24	12.75	253

If these values are inserted in Equations [42] and [59], we find the total yearly cost of the systems based on the station spacings as listed. If the resulting "total annual costs" ($X + Y$) are plotted on coordinate paper, the minimum value representing the most economical design may easily be determined by inspection.

The fixed charges and operating expenses for the various station spacings are given in the following tabulations:

FIXED CHARGES (DOLLARS)

n	x	Line investment	Pump-station investment	Station tankage	Total investment	Fixed charges (15.17%)	Interest and taxes oil in line (10%)	Total fixed charges
4	16.0	9,640,000	578,000	144,000	10,362,000	1,575,000	88,600	1,663,600
8	14.5	7,445,000	950,000	264,000	8,659,000	1,314,000	72,800	1,386,800
12	13.65	6,278,000	1,305,000	384,000	7,967,000	1,209,000	69,600	1,278,600
16	13.15	5,702,000	1,600,000	480,000	7,782,000	1,180,000	60,000	1,240,000
20	12.9	5,291,000	1,760,000	600,000	7,651,000	1,161,000	57,600	1,218,600
24	12.75	5,001,000	1,885,000	696,000	7,582,000	1,150,000	56,300	1,206,300

OPERATING EXPENSES (DOLLARS)

n	x	Line maintenance	Station labor	Fuel cost	Lubricating cost	Maintenance and supplies	Total operating cost
4	16.0	39,750	73,500	24,200	3,125	6,250	146,825
8	14.5	38,500	100,000	37,400	4,825	9,660	190,385
12	13.65	37,850	153,000	50,200	6,480	12,960	260,490
16	13.15	37,400	203,000	59,500	7,680	15,360	322,940
20	12.9	37,200	258,000	64,900	8,380	16,760	385,240
24	12.75	37,100	303,000	68,700	8,870	17,750	435,420

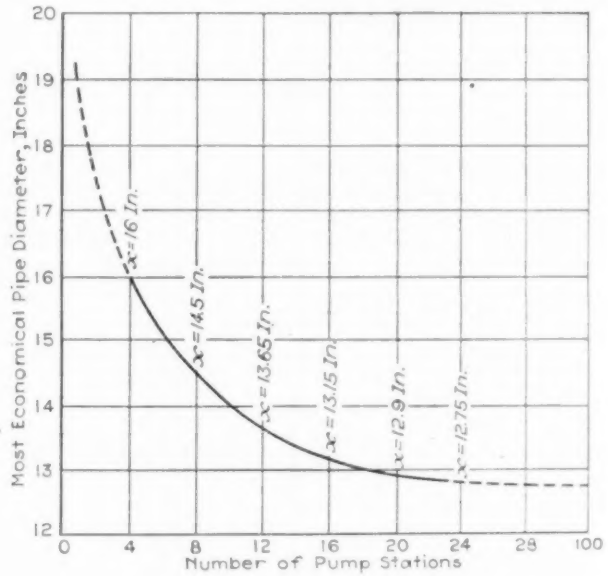

FIG. 24 MOST ECONOMIC PIPE DIAMETERS

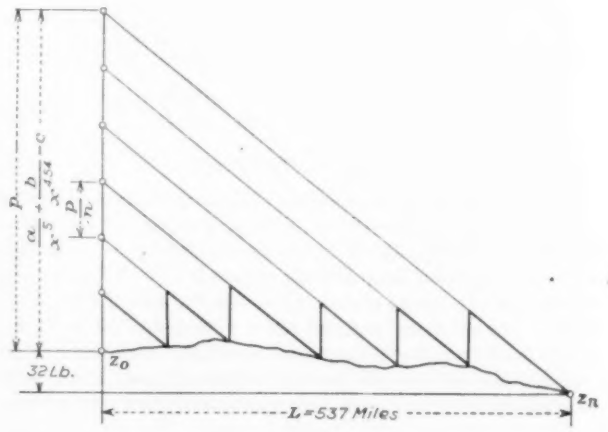

FIG. 26

TOTAL YEARLY COST ($X + Y$) (DOLLARS)

n	Yearly cost	x (in.)	Cost per bbl. pumped
4	1,810,375	16.00	0.1260
8	1,577,185	14.50	0.108
12	1,539,090	13.65	0.1052
16	1,562,940	13.15	0.1070
20	1,603,840	12.90	0.1100
24	1,641,720	12.75	0.1123

From the curve in Fig. 25 we find the most economical system to consist of 13.65 in. inside diameter pipe of a wall thickness of 0.136 in. and twelve pump stations operating at the normal gage pressure of 309 lb. per sq. in. The station spacing must of course be adapted to the profile of the line in such a manner as to equalize the load on

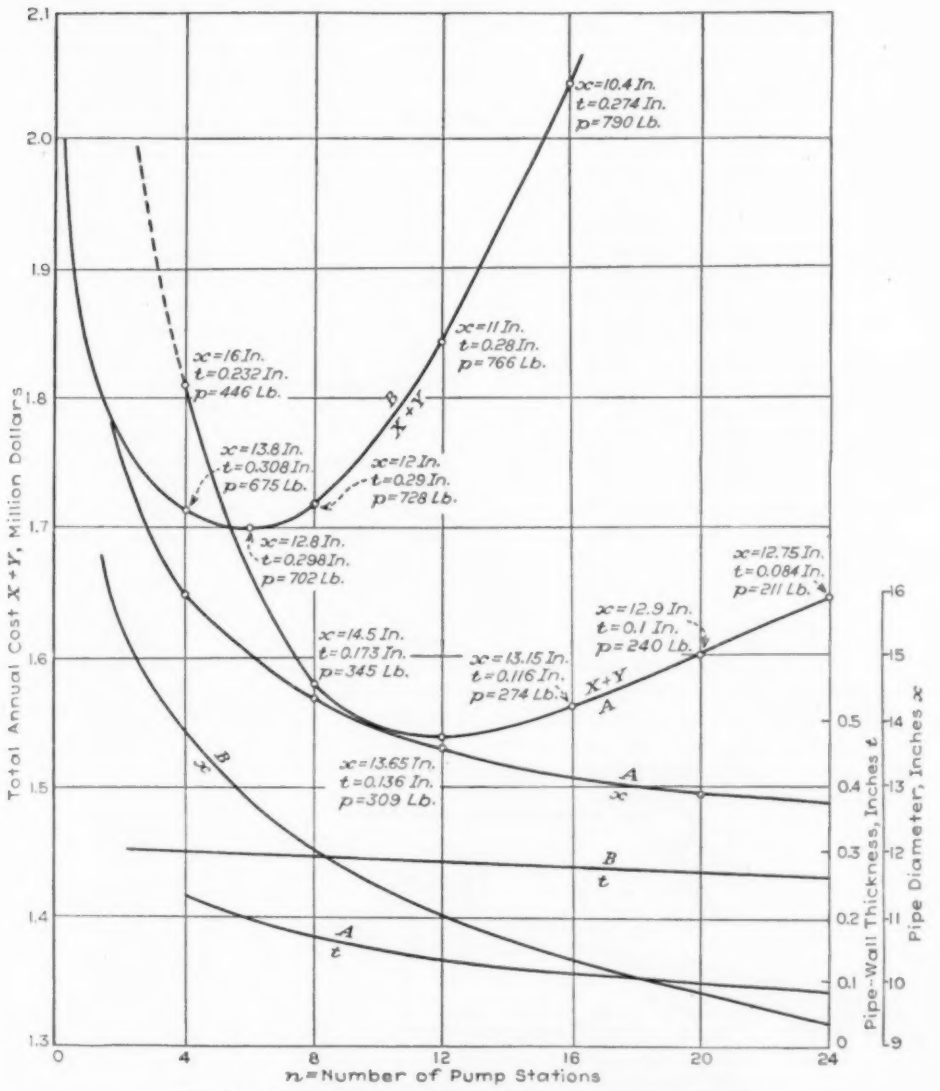

FIG. 25 CURVES INDICATING THE MOST ECONOMICAL SYSTEM

(Capacity of system, 50,000 bbl. per day; length of line, 537 miles; viscosity of oil, $\nu = 0.07 = 50$ S.U.S.; specific gravity, $S = 0.83$; depreciation period, 10 years; depreciation rate, 6.9%; interest rate, 8%; taxes and insurance, 2%; load factor, 7000/8760.)

each pump station to 309 lb. per sq. in., or 309 b.hp. This can easily be accomplished by using the graphical method suggested by Fig. 2.

It is at once apparent that this thin-walled pipe, while strong enough for the internal fluid pressure, does not satisfy the conditions of mechanical strength, and the problem must therefore be recomputed on the basis of a minimum wall-thickness.

$$t' = 0.17 + \frac{x}{100} \quad \ldots\ldots\ldots\ldots\ldots\ldots [13]$$

and the consequent minimum line investment:

$$\frac{0.282L(101x^2 + 1734x + 289)}{x^{0.133}} + (100x + 36x^2)L \text{ (dollars)}. \quad [18]$$

SECTION IV

According to Equation [14] $p = \dfrac{S(17 + x)}{51x + 17}$, and if the working pressure of the stations is chosen to stress the steel in the pipe to its greatest permissible value, we obtain:

$$\frac{nS(17 + x)}{51x + 17} = \frac{a}{x^5} + \frac{b}{x^{4.54}} + c \quad \ldots\ldots\ldots\ldots [65]$$

Solving for x, and inserting the given quantities, we obtain the following values of the different station spacings:

n	x (in.)	t (in.)	p (lb.)	B.hp. per station	Installed hp. per station
4.....	13.8	0.308	675	675	894
8.....	12.0	0.29	728	728	910
12.....	11.0	0.28	766	766	958
16.....	10.4	0.274	790	790	988
20.....	9.8	0.268	820	820	1025
24.....	9.3	0.263	846	846	1057

The permissible unit stress on steel in pipe $S = 15{,}800$ lb.

With the linear dimensions of the pipe, working pressure, and required horsepower installation per station thus given, we can, by using the unit costs for investment and operation given in the previous sections, prepare the following estimates

of fixed charges and operating expenses for the various station spacings:

FIXED CHARGES (DOLLARS)

n	x	Line investment	Pump station investment	Station tankage	Total investment	Fixed charges (15.17%)	Interest and taxes oil in line (10%)	Total fixed charges
4	13.8	8,975,000	840,000	144,000	9,959,000	1,510,000	66,000	1,576,000
8	12.0	7,375,000	1,710,000	264,000	9,349,000	1,418,000	49,800	1,467,800
12	11.0	6,415,000	2,660,000	384,000	9,459,000	1,432,000	41,900	1,473,900
16	10.4	5,920,000	3,630,000	480,000	10,030,000	1,520,000	37,400	1,557,400
20	9.8	5,460,000	4,675,000	600,000	10,735,000	1,620,000	33,300	1,653,300
24	9.3	5,080,000	5,715,000	696,000	11,491,000	1,740,000	30,000	1,770,000

OPERATING EXPENSES (DOLLARS)

n	x	Line maintenance	Station labor	Fuel cost	Lupricating cost	Maintenance and supplies	Total operating cost
4	13.8	37,900	49,000	38,000	4,725	9,460	139,085
8	12.0	36,500	102,000	81,800	10,190	20,800	251,290
12	11.0	35,700	155,000	129,000	16,100	32,200	368,000
16	10.4	35,200	205,000	177,500	22,100	44,300	484,100
20	9.8	34,700	256,000	230,600	28,700	57,400	607,400
24	9.3	34,300	305,000	285,000	35,500	71,000	666,900

TOTAL YEARLY COST ($X + Y$) (DOLLARS)

n	x	$X + Y$	Cost per bbl. pumped
4	13.8	1,715,000	0.1176
8	12.0	1,719,000	0.1178
12	11.0	1,841,000	0.1260
16	10.4	2,041,000	0.1400
20	9.8	2,260,000	0.1550
24	9.3	2,437,000	0.1670

Plotting the total costs $X + Y$ against n, the number of stations, we find from curve B in Fig. 25 the most economical system to consist of 12.8-in. inside diameter pipe of a wall thickness of $t = 0.298$ in. The six stations are all expected to operate on a gage pressure of 702 lb. per sq. in., which produces a maximum fiber stress in the pipe of 15,800 lb. at the high-pressure ends of the line. A similar computation based on the assumption that the steel be stressed to less than the permissible maximum would naturally require larger diameter pipe for a given station spacing, and it will be found that the total yearly costs representing such a system will be above those shown by curve B in Fig. 25.

In conclusion, it must be reiterated that the data on unit costs, both for investment and operating expenses, represent the author's viewpoint only, and that such modifications as appear necessary in the light of preliminary study of a given problem must be made so as to reflect actual conditions encountered as nearly as possible.

It is a very significant fact that a slight decrease in the pipe diameter, say to 10.4 in., i.e., the difference of approximately one commercial pipe size, would increase the yearly cost of the system by over $300,000, or $3,000,000 for an operating period of ten years. Such results should be conclusive evidence that proper economic studies for a proposed oil-pipe-line transportation system may produce far-reaching results. It is only too true that many pipe-line systems built during the past were designed on the hit-and-miss system and by rule of thumb without much regard for their financial efficiencies. Alert managements of the present day are ever on their guard, and if the pipe-line-designing engineer can produce basic calculations having such a striking influence upon the net earnings of his company, he will do much to dispel the suspicion of being a tolerated necessary evil, and thereby justify his existence.

Progress in the Petroleum Industry

Contributed by the Petroleum Division

Executive Committee: W. G. Heltzel, *Chairman*, J. W. Hays, *Secretary*, P. L. Guarin, C. F. Braun, H. R. Pierce, and Walter Samans

IN PREPARING its Progress Report for the year 1929, the Petroleum Division has confined its attention to two fields: namely, pipe-line transportation and refining. These have been reported on by engineers especially acquainted with their respective subjects, and their findings appear below.

PROGRESS IN PIPE-LINE TRANSPORTATION[1]

The last three years have marked a transitional period in the pipe-line industry from old and traditional methods to new and better ones. This change has come about in the industry largely through the cooperative efforts of the engineers both in the petroleum industries and those allied with it in the manufacturing of the products and commodities which it uses. The mechanical engineer has been recognized in the petroleum industry by the executives of the various companies, and much of the progress that has occurred during the last three years can be attributed to the efforts of the engineer to adopt new methods. It is the purpose of this report to summarize some of the outstanding developments during the year 1929 in the oil-pipe-line industry.

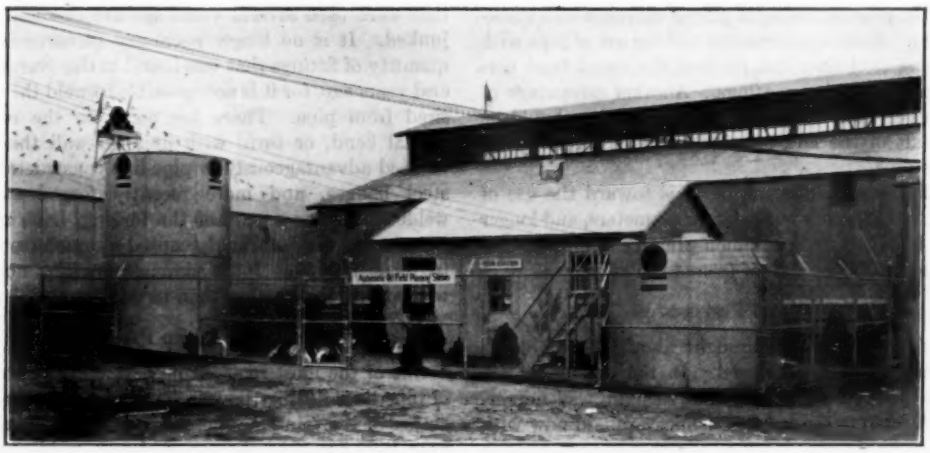

FIG. 1 EXTERIOR VIEW OF EXPERIMENTAL AUTOMATIC PIPE-LINE PUMPING STATION FOR GATHERING SYSTEMS AS EXHIBITED AT TULSA, OKLA., OCT. 5–12, 1929

LINE PIPE

One of the outstanding changes that has occurred in pipe-line equipment has been in line pipe. Three years ago the industry was following the same practice that it had been using for years: lap-welded pipe made of low-carbon steel with a tensile strength of about 48,000 lb. was used almost exclusively. At that time the screwed coupling was used for joining the pipe together. About two years ago seamless line pipe made of steel with a tensile strength of about 48,000 lb. was used in some welded lines which were then being laid. Immediately following the laying of these lines some seamless line pipe with a higher percentage of carbon and with a tensile strength of about 64,000 lb. was used in a long welded line. Since that time seamless line pipe has been used extensively for welded pipe lines. The merit of this class of pipe has been proved by the lack of failures either in tests or in the use since that time. A welded line 200 miles in length was tested without a failure, and no failures have occurred during its two years of service either in the pipe or in the oxy-acetylene welds joining the pipe. During the last year a large amount of autogenous electrically welded pipe has been used in trunk lines in diameter up to 12 in. This class of pipe is lighter in weight than the standard lap-welded or seamless pipe. The autogenous-welded pipe is made of steel with a carbon percentage of from 0.25 to 0.35 and a tensile strength of 64,000 to 72,000 lb. The wall thickness of the pipe is about $^1/_4$ in. The recent tests on a long line in which autogenous-welded pipe was used have proved it satisfactory.

It is understood that one of the steel companies will soon be ready to put on the market a pipe which will be welded by an electrical flash method. The last two years have marked the passing of lap-welded pipe for high-pressure trunk lines. There will be some lap-welded pipe used when the seamless and the autogenous pipe are not available, but less than formerly.

Although the seamless pipe has cost a little more than the lap-welded pipe, it is believed that its merits justify the small increase in cost. A distinct advantage of the seamless pipe is that it does not have welded longitudinal joints and consequently will be considerably less subject to failure than welded pipe. Other advantages in the use of seamless pipe are that it can be worked at higher pressures on account of the efficiency of the joint over lap-welded pipe, and it can be made in higher-carbon steels with higher tensile strength. The use of seamless pipe will permit much higher working pressures than could be obtained with low-carbon lap-welded pipe, which cannot be made in the higher-carbon steel. It will be seen, then, that with higher permissible working pressures the pumping stations can be spaced farther apart and consequently a smaller number of them required than on the standard lap-welded line. The use of this pipe, then, will permit either greater distances between stations or greater capacity between

[1] Prepared by William G. Heltzel.

stations as they are spaced on present lap-welded lines. The use of this seamless pipe should mean a lower overall investment and a considerably reduced operating cost. It is believed that when designing new lines, the higher-carbon steel, of a tensile strength of 64,000 lb. minimum, should be used at least on the high-pressure ends of pipe lines in order to take advantage of the higher permissible operating pressure, and in case it is desired to operate a line at a lower pressure, the "reserve strength" in the pipe would be available in the future if additional capacities were required. A design using the higher-tensile-strength pipe on the high-pressure end would permit additional capacity in the future, when it was needed, making it unnecessary to build loops to give that additional capacity.

The electrically welded pipe has proved its merit in service and it is believed that the joint will prove reliable. This reference pertains to the longitudinal weld along the pipe as well as to the circumferential weld made in the field to join the lengths of pipe together. What has been said as to the merit of high-tensile seamless pipe pertains to the autogenous-welded high-tensile-strength pipe also. The advantage of the autogenous-welded pipe is that it is lighter in weight per foot and consequently the freight cost is less, the stringing and laying cost is less, and the overall investment is smaller. The one question about the autogenous-welded pipe of $^1/_4$ in. thickness is that of corrosion. Engineers are asking themselves, "Will the pipe of $^1/_4$-in. wall thickness have the same life as the standard pipe with heavier walls?" It is realized that soil corrosion will cause failures in both classes of pipe, but what the relative life is for pipe of different wall thicknesses is not known. Some engineers are making use of pipe with lighter walls, hoping that they can prevent the metal from corroding by applying protective coatings. Another advantage of the pipe with thinner walls is that a greater capacity should be obtained on account of the larger inside diameter for the same normal size of the pipe.

In the design of new pipe lines the trend is toward the use of higher tensile strength, thinner walls, larger diameters, and longer lengths of pipe. It is becoming common practice in oil-pipe-line construction to use pipe in lengths of from 40 to 45 ft.

Pipe Joints and Fittings

The welding of pipe lines has brought about a remarkable change also in the type of joints used. In the pipe lines laid previous to about three years ago the screwed joint was universally used. However, few or no trunk lines are laid now with screwed joints, because the pipe is joined together either by gas or electric welding. The screwed joint has almost become obsolete for trunk-line work; however, it will continue to be used to some extent for temporary field gathering lines.

Until recent years the screwed joint was the best type of joint available for construction work, and consequently all of the old lines are joined by screwed couplings. The history of these old lines is filled with repeated failures in the couplings. The lines have pulled out of the joints and leakage has occurred through the screwed coupling when the line was expanding or contracting. The result has been that large losses of oil have occurred on account of the screwed joint. It has been learned recently also that the leakage of oil from the screwed coupling has resulted indirectly in severe corrosion of the lines where leaks have occurred. It is becoming common practice among pipe-line companies, when taking up old lines that are to be relaid, to cut out the coupling and threads and bevel the pipe for welding. And when old lines are uncovered and reconditioned it is the policy of some of the companies to put a light weld on each side of the coupling to prevent leakage and, indirectly, corrosion. The four methods used at present for joining welded pipe are:

a The butt joint with the ends of the pipe beveled at 45 deg. for gas welding. This type of joint is used in laying pipe with a standard wall thickness, and the joints usually are gas welded.

b The bell-and-spigot joint, with a special dam on the spigot end of each joint, is being used on the pipe of lighter walls for gas and electric welding.

c The plain bell-and-spigot joint without the special dam is being used also for gas and electric welding.

d A bell with expanded ends of the pipe butting together, beveled, and with a "back-up" ring on the inside fitting into the expanded ends. This type of joint is being used for gas and electric welding. It provides for good welding penetration and gives good strength.

It is understood that some development work has been done on another type of joint. This joint is made in the field by a hydraulic machine, which recesses a ring groove in the wall of the spigot end of a joint of pipe; the bell joint is then fitted over the spigot end and by hydraulic pressure a ring groove is recessed in the bell wall to fit into the corresponding recess in the wall of the spigot where they join, thereby providing strength in the joint against pulling apart. After the pieces of pipe are joined by the hydraulic recessing, the bell end is welded to the spigot end of the other joint of pipe.

A few years ago it was common practice to use heavy cast-iron fittings consisting of ells, tees, flanges, manifold barrels, valves, castings, etc. The use of welding has brought about a beneficial change in fittings for pipe-line work. The heavy cast-iron fittings that were used several years ago are obsolete and ready to be junked. It is no longer necessary to carry in stock the large quantity of fittings that was found in the average warehouse several years ago, for it is now possible to weld the type of fitting desired from pipe. There has come on the market recently a special bend, or turn, with uniform wall thicknesses that can be used advantageously in pipe-line construction work. Forged steel flanges, and more recently forged steel flanges with welded necks as a part of the forging, have replaced the cast-iron flanges which formerly caused so much trouble through their frequent failures. It is common practice now to use flanges welded into lines rather than to use screwed flanges.

Welded Pipe Lines

One of the most remarkable developments in the construction of pipe lines during the last three years has been the welding together of the joints. The most marked development during the year 1929 has been the use of electric welding for the joining of pipe together in the case of trunk lines. It is known now that the gas-welded line is reliable, and it is believed that the electrically welded line will prove likewise.

When the first gas-welded lines were laid, there was some question about the reliability of the welds and the possibility of "icicles" on the inside of the weld holding up the scrapers in their passage through the lines. In the construction of 200 miles of 8-in. line, not one failure occurred in the tests. After two years of operating no failure has occurred. A leak has not been reported on this line either on the test or in operation. In a line about 400 miles long about five failures occurred when the line was tested. These failures resulted from the pipe's being roughly handled when the pipe line was put into the ditch. However, no failures occurred on this line during the following year of operation.

Scrapers have been put through the entire length of this 600 miles of pipe line, and in no case has a scraper been held up on account of icicles at the welds. It is believed that the electrically welded line will give results equally reliable. Welding has eliminated the many leaks and the loss of oil that occurred in the lines with screwed joints. Welding should result in a much

smaller leakage cost, and certainly it will eliminate much of the corrosion caused by the many oil leaks from the couplings. As a result of the reliability of the welded pipe line, higher operating pressures can be carried and greater security of transportation is assured. It may be that the reliability of the welded line will pave the way to automatic pumping stations.

Pumping-Station Machinery

About 12 years ago the Diesel engine began to replace the steam engine for pipe-line pumping. The pipe lines built since that time have pumping stations equipped with only Diesel engines. However, on the old lines a few steam engines remain. The Diesel unit gave much higher efficiency and consequently it was exclusively used on new pipe lines up until about two years ago. The year 1928 marked the advent of electric-motor-driven pipe-line pumps for oil-trunk-line service. There has been considerable controversy over the economical use of electric motors for pipe-line pumping, and that question has not yet been settled. It is known, however, now that both motor-driven centrifugal and motor-driven reciprocating pumps have proved reliable in operation. If it can be proved that it is more economical, or equally economical, to use electric motors than oil engines for driving pipe-line pumps, then the trend will certainly be toward the electrification of pipe-line pumping stations for newly constructed lines. It will hardly be economical to convert the present oil-engine units in old pipe-line pumping stations to electrical units since the fixed charge is already established.

Where existing pipe-line systems are being increased in capacity, the trend is toward replacing smaller Diesel engines at the pumping stations with larger units. The early oil engines for pipe lines were built in capacities up to 250 and 300 hp., but the more recent installations are units of 750 to 800 hp. The smaller units in the pumping stations are being replaced when the capacity of the line is increased on account of the increased maintenance and labor cost on a number of smaller units. Just as the trend is toward large oil engines, so it is also toward the use of large reciprocating pumps. Some of the recent installations of reciprocating pumps have been units with capacities of 42,000 to 46,000 bbl. per 24 hr. The features of these pumps as compared with the earlier type of pipe-line pumps are sturdier frames, larger bearings, and better gearing.

Considerable trouble has been experienced in pipe-line pumping with the breakage of discharge lines between pipe-line manifolds and the discharge pumps, and of pump parts and other equipment. Some recent investigations have shown that this breakage has resulted from pressure surges in the pipe lines. It has been recommended that air chambers on the discharge side of the pump be used to eliminate this damage. Many of the pipe-line companies have accepted these recommendations, and much of the trouble has been eliminated.

The trend is toward the use of motor-driven pumps for field gathering stations, which have a comparatively short operating life as compared with trunk-line stations. It has been found that the station with a low investment cost is more desirable for field gathering stations on account of the fact that in the method used in the oil fields today a large amount of flush oil is produced within a comparatively short time. The production of a large amount of oil in a short interval of time means a larger gathering system and more stations than were used when fields were developed gradually. These pumping stations for gathering systems have a comparatively short life, and the investment cost must be kept low. Both motor-driven centrifugal and the reciprocating pumps are being used in these field stations. However, it has been found that the reciprocating unit is more desirable on account of its higher overall efficiency. It is probable that the future field gathering stations will have motor-driven reciprocating pumps with centrifugal pumps as spares or for emergency use.

Automatic Pipe-Line Pumping Stations

The use of the electric motor for pipe-line pumping stations has brought about the possible use of automatic control for these stations. It is believed now that automatic control can be used for smaller pipe-line gathering stations. It is believed, further, that after automatic-control equipment has been worked out for this class of station and more confidence is gained in it through reliability of operation, automatic control can be used for trunk-line work, especially where the motor-driven centrifugal pump is employed.

At the recent International Petroleum Exposition held in Tulsa, October 5 to 12, 1929, a full-sized experimental automatic oil-field pumping station was on exhibit. This exhibit was arranged through the Scientific and Technical Committee of the Exposition and was received favorably by pipe-line men, but it was pointed out that certain features had yet to be worked out to make the station fully automatic and foolproof. The exhibit, which is shown in Figs. 1 and 2, demonstrated the following features of automatic control:

a Starting up and shutting down motor-driven pump by a liquid-level instrument actuated by the pressure head exerted by the fluid in the tank.

b Automatically controlled and electrically operated gate valves on the discharge and filling lines.

c Automatic shutting down of motor-driven pump by high- and low-pressure protective gages. This automatic feature was used to demonstrate how the motor-driven pump could be shut down for an excessive increase of pressure in the line or a drop of pressure in the line as a result of a break.

d Automatic starting and shutting down of the motor at a definite time by a time clock.

The information gained from the operation of this experimental station showed that it will be necessary to add the following automatic features of the station to make it foolproof.

a Automatic control of the motor-driven pump by a flow meter, such as the venturi. Thus it is believed that the shutting down of the pump can be made foolproof for a break in the line by using a pressure-protective equipment and a flow meter combined; for a drop in pressure or an increased delivery of fluid usually means a broken line. With a centrifugal pump a break can occur in a line without any drop in pressure being indicated on the recording pressure chart; it is characteristic of a centrifugal pump to maintain its pressure with an increased delivery when a break occurs, provided the break is not too near the pump. Therefore it is believed necessary to adapt the flow meter to shut down a centrifugal pump when a break occurs in a line giving an increased delivery, even though a drop in the pressure does not occur.

b An automatically controlled and electrically operated bypass valve must be developed for use on the discharge pump in starting up so that the pressure is built up gradually with the closing of the bypass valve.

c The proper functioning of this control equipment will depend upon the elimination of the pressure surges on the discharge side of the reciprocating pump. Therefore it is believed necessary to develop an automatically charged air chamber to damper the pressure vibrations.

d It is believed that some work should be done on remote control of pipe-line pumping stations.

Construction of Pipe Lines

Although the use of welding in pipe-line work has resulted in more reliable lines, it is taking more time to lay welded lines than was required to lay screwed pipe, although more labor-saving machinery has been used for this construction work than was used four or five years ago. One reason for this delay is probably that the men who laid screwed lines are yielding their places to younger men who are learning the practice of laying welded lines instead. It will probably take a few years for these men to eliminate the time delays in this construction work. Another element that enters into the laying of welded pipe lines is the weather. When the screwed lines were laid the pipe-line crews were on the job in all kinds of weather. Each man was at his post in the morning at the start, and carried on even in the most severe weather. Each man had his part and kept active throughout the day, and in that way could keep warm when the weather was cold. Conditions are a little different now with the crews laying welded lines. Less physical energy is required on the part of the men, and it is a common sight along pipe lines that are being laid in the winter to find men standing around fires to keep warm. This fault is not so much in the men as it is in the fact that the crews that laid screwed lines were organized differently from those that lay welded lines. Something must and will be done to speed up the construction of welded lines. Already developments have taken place in the speeding up of the electric welding, and it is likely that the time required to lay welded lines will be materially lessened during the coming year. Each year marks the use of additional and more improved labor-saving machines in the construction of oil pipe lines.

Pipe-Line Tankage

The pipe lines built recently have been designed to make use of a smaller amount of tankage for storage at the pine-line stations located along the trunk lines. This condition is especially true on the lines that are using motor-driven centrifugal pumps. This policy of carrying the larger amounts of storage at strategic points and only a small amount of tankage at the relay pumping stations indicates the present trend in the use of pipe-line tanks.

As a means of conserving the light vapors in petroleum, pipe-line companies are making use of the floating roof, especially at the pumping stations where the amount of petroleum handled through the pipe-line system is checked for volume. It is believed that where the floating roof is used at the relay stations on working tanks it should be used only on a tank with a smaller capacity than that of the 55,000-bbl. tank. The use of a 10,000-bbl. working tank would probably result in a smaller maintenance cost, less evaporation, and less trouble from water that might get into the tank. The point might be made that where the oil is not delivered into a large tank, say, a 55,000-bbl. one with a steel roof, serving only as a surge tank on the line, no large amount of evaporation occurs on account of the liquid in the tank standing at an almost constant level; but it is to be remembered that a rather large vapor space exists in the tank and that breathing will result with a change of temperature. Where the floating roof is not used it is common practice now on almost all tankage, except in West Texas, where the oil vapors are very corrosive, to use welded steel roofs which are vapor tight and are equipped with flame-proof venting equipment. In West Texas where corrosive oils are being handled, the wooden roof with insulated top, equipped with lightning protective equipment, is being used.

Some experimental work is being carried out in West Texas on the use of all-aluminum and part-aluminum tanks in sizes up to 1000 bbl. to eliminate the corrosion caused by the vapors from the oil produced in that region. The results which have been observed from the use of these tanks are said to be satisfactory.

Aluminum paint has been used extensively for painting steel oil tanks to reduce evaporation losses that occur in the storage of petroleum. A recent development has been the use of aluminum foil to coat the roofs of the tanks. It is claimed that the tests indicate that a great amount of heat is reflected from the tank, resulting in a much lower temperature in the vapor space and at the surface of the petroleum, thereby reducing the evaporation through breathing losses.

Corrosion of Pipe Lines

One of the largest maintenance costs in the operation of oil pipe lines is the repairs made necessary by the corrosion of pipe. These pipe lines operate at pressures as high as 800 lb. per sq. in. and consequently the corrosion of the walls affects the operating efficiency of the system. The American Petroleum Institute has undertaken a study of the corrosion problem, and considerable has been learned during the last two years as to its extent and as to some of the faults in the methods used in protecting the lines against corrosion. During the last three years much reconditioning of pipe lines has been carried out, and protective coatings have been applied to these lines. During the last year considerable doubt has been expressed among pipe-line men as to the effectiveness of these coatings, and it has become the policy of some companies to delay the reconditioning of pipe lines until material and methods providing for an effective coating have been found. The practice now of some of the companies is to recondition the lines where corrosive conditions are known to exist. The use of accurate records as to the failures in pipe lines due to corrosion is assisting materially in locating the corrosive areas along the pipe line. In the meantime the corrosion committee of the American Petroleum Institute is obtaining some valuable information, which in time will be correlated and the question of protective coatings very much clarified. It is certain that if an effective protective coating can be found for the protection of pipe lines against soil corrosion, pipe with thinner walls and made of steel of high tensile strength will be used with confidence in the design of pipe lines, resulting in lower investment costs.

Economic Advantages of Joint Ownership in Constructing New Pipe Lines

About three years ago, two of the major oil companies built a long trunk pipe line under a provision of joint ownership. During the year 1929 two other major oil companies built a long trunk line under joint ownership. The advantages in such an arrangement are:

- *a* Risk reduced for each company.
- *b* Pipe line can be kept supplied with oil better than when owned by one company.
- *c* Use of one large line instead of two smaller lines with the same or smaller number of operating stations.
- *d* Materially reducing operating expenses by using one large-capacity system by two companies instead of two separate systems by two different companies.
- *e* Greater operating efficiencies can be obtained in one large system than in two smaller systems

From the engineering and economic viewpoint the joint ownership of newly constructed pipe lines has distinct advantages.

Pipe-Line Systems Affected by Economic Changes

An increasing amount of crude oil is being transported to the refineries on the Eastern Seaboard and Gulf Coast. The large amount of cheap oil that has been made available in Venezuela and in West Texas has resulted in the large amount transported by tanker. About five years ago most of the oil was being delivered from the Oklahoma and Kansas oil fields to the Eastern Seaboard refineries by pipe line. The development of the Vene-

zuelan and West Texas crude oils has affected the business of the pipe lines crossing the state of Pennsylvania, and some of these have been sold for gas lines. West Texas crude oil is being delivered to Gulf ports, transported by tanker to the Atlantic Seaboard, and pumped by pipe line west as far as Franklin, Pennsylvania.

An extension of oil trunk lines has been made necessary by the policy of the major companies providing for nationally distributed products. This policy has resulted in the building of refineries in the principal market zones and the extension of the trunk pipe-line systems to these refineries.

The hydrogenation process used in the refining of petroleum may affect pipe-line transportation of petroleum, in that the increasing demand for gasoline can be supplied through the use of this process rather than through an increased crude-oil delivery.

When the hydrogenation process can be used economically for converting heavy oil into gasoline, it is possible that the heavy oils that cannot be transported economically will be refined near the source of production and the gasoline transported by pipe lines.

Although gasoline has been transported through pipe lines for distances as great as 100 miles, a new development has been the converting of an 8-in. oil line that has been idle into a gasoline line to transport gasoline from the Atlantic Seaboard into and across the state of Pennsylvania and into the Ohio Valley. This development is significant, because it may mean the beginning of gasoline transportation by pipe lines at a much lower transportation rate than the present tank-car transportation cost.

PROGRESS IN OIL REFINING[2]

Crude oil is coming into refineries both by pipe lines and tankers, the preferred way depending upon location of refineries and source of crude. The Eastern Seaboard refineries obtain most of their oil by tanker, and there has been a strong tendency to provide centrifugal pumps on the ships, usually electric-motor-driven, each pump handling about 1000 gal. per min. at 125 lb. pressure, this maximum pressure being limited by the strength of the unloading hose and the possibility of leakage at its wharf connections.

If tanks into which crude is being pumped are too far from the wharf, or where the unloading rate is very high, it is customary to install booster pumps on shore, of the multi-stage centrifugal type, motor-driven.

In either case, safety semi-automatic controls are provided by means of which pumping is stopped from either ship or dock by an ordinary fire-alarm pull box. Hydraulic automatic shut-off valves are also provided in the pumping lines, closing off the pipe lines in case of a break.

Tanks and Tank Roofs

Tankage for receiving crude oil in refineries is being made larger as the capacity of tankers is increased, and also depending on the size of the refinery. Eighty thousand barrels is becoming a standard refinery size, and in many cases the same size is used for gasoline storage. These tanks are still made of riveted construction, although on some smaller tanks electric-arc welding has been applied experimentally on bottoms. The roofs of the tanks are almost entirely electric-arc welded where no fire hazard exists, and many are trying some type of floating roof or a roof of similar construction, the main purpose being to keep oil in contact with the steel surface to avoid loss of light ends in the vapor space, or to prevent breathing within certain temperature ranges by holding the vapor space at pressures varying from several ounces to one pound per square inch.

[2] Prepared by Walter Samans.

Refining Stills

The development of stills is so rapid in many types that only a few of the outstanding features can be mentioned.

Fractionating stills, made up of tube heaters in combination with fractionating towers, commonly termed "bubble towers," are being built for a capacity of 10,000 and 12,000 bbl. per day, and units of 16,000 bbl. capacity are being planned.

Similar stills are being considered for the making of asphalt from heavy crudes, and the fractionating is done in two stages, using vacuum on the second stage. The use of vacuum materially increases the tower diameters, thereby involving not only very complex construction and arrangement, but also bringing up questions of maximum shipping dimensions which materially affect final construction costs.

Vacuum distillation is being rapidly developed on account of close fractionation and the larger production of valuable lubricating products, due to less loss resulting from overheating, which is apt to occur in the so-called atmospheric pipe still. Practically every refiner is interested in this process, and many have made trial installations. The initial cost and the size of apparatus have been the main drawbacks to rapid development heretofore.

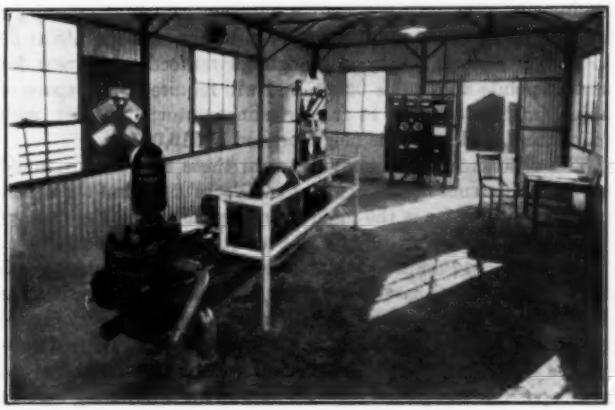

Fig. 2 Interior View of Experimental Automatic Pipe-Line Pumping Station Shown in Fig. 1

As regards cracking stills, vapor-phase processes are gaining headway, in spite of high initial costs and difficulties with fixed as and coke formation, due largely to the anti-knock properties of the gasoline produced. While similar properties in cracking-still distillates are sought after in so-called liquid-phase cracking stills, there is evidently real competition between different methods, and the development in each refinery will depend largely on the type of equipment already installed.

In cracking stills, the maximum temperature of 950 to 980 deg. fahr. in the outgoing oil, which may easily result in 1100 deg. on the hottest tubes, together with an outlet pressure of close to 1000 lb. has resulted in the application of chromium-nickel alloy tubes, at an initial cost many times that of the carbon-steel tubes, in all those portions of the tube heater subject to the higher temperatures.

Tube lengths of 30 ft. are quite common, and the established size of 4 in. O.D. $\times$ $^1/_2$ in. thick is being supplanted by even larger and heavier tubes, with possibilities of greater lengths as capacities are increased. At least one tube manufacturer is installing a drawbench for tubes 40 ft. long, the initial reason being that this length is required by the large-capacity fractionating stills where pressures may go only as high as 300 or 400 lb.

The object in all cracking stills is, of course, economical conversion of low-gravity fractions to a distillate that can be incorporated into a motor gasoline, and a satisfactory process re-

quires that the fixed gas and corresponding quantity of coke be kept to a minimum.

Hydrogenation of Petroleum. By the introduction of hydrogen under pressures from 1400 to 4200 lb. and in the presence of a catalyst, it is now possible to convert practically all of the original oil into gasoline and other products. Carbon formation is actually eliminated and the production of fixed gases reduced to a minimum. Two plants which will employ this process are now being constructed by the Standard Oil Company of New Jersey at Bayway, N. J., and Baton Rouge, La.

Pumps

Hot-Oil Charging Pumps. Charging pumps for stills, particularly cracking stills, are of interest to mechanical engineers from the viewpoint of high pressure and temperature and the need for corrosion-resisting metals. A reciprocating steam pump for a capacity of 6000 bbl. throughput of 600 deg. fahr. oil at 1400 to 1600 lb. discharge pressure, operating with crank and flywheel on the compound steam end, will use 20 lb. of steam per l. hp. with condensing operation, and cost in the neighborhood of $28,000, including foundation. Its floor space of 12 ft. × 32 ft. is its main drawback, particularly in the application to existing equipment. On the other hand, a ten-stage centrifugal pump for the same capacity, requiring a 400-hp. motor, will operate at 50 to 55 per cent efficiency, although guaranteed when new for several points above this figure, and will require a floor space of approximately 5 ft. × 14 ft., including motor; the cost, with foundation, will be in the neighborhood of $16,000.

The difference in economy between these two pumps would save the difference in cost in about two years' time, but the uncertain factor thus far is the maintenance expense and the damage that may be occasioned by small fires in the pump house.

Motor-Driven Pumps. Motor-driven reciprocating pumps with intermediate gears have been tried with satisfactory results, as they give very satisfactory operation, but must be of very rugged construction to avoid excessive wear on gears. The main objection to them, particularly the larger sizes, is that variable speed is not possible except with special motors for alternating-current or direct-current motors which may not be adapted to the current available, and in either case provide some additional fire hazard on account of sparks from the commutators.

Charging Multiple Stills. Charging pumps for cracking stills, as well as fractionating stills, have been applied to as many as twenty stills for one pump; however, it is then necessary to maintain the maximum pressure that any of the stills may require, this pressure being affected by friction losses due to carbon collecting in the tube heaters, in order to maintain flow control for each still. The centrifugal charging pump lends itself well to this service, particularly since the larger the pump the greater the efficiency, but this scheme has not been sufficiently used to lead to general adoption at this time.

Corrosion in Pumps. Corrosion in pumps is accelerated by reason of the high velocities through valve passages on reciprocating types and impellers on centrifugal types, requiring in the first instance stainless-steel plungers and valve parts, and in the second, chromium or nickel-chromium alloys. The initial cost and manufacturing losses on these materials add greatly to the final cost of the pump.

Automatic Control of Stills

Full automatic control on stills has not been possible, due to imperfections in the apparatus offered and the severe requirements for service conditions, oils containing both finely divided solids, mostly carbon, and corrosive elements which cannot be eliminated economically.

Of course the usual pressure, speed, and temperature controls used in large boiler plants are applied to oil stills, and there are but few installations which do not have flow meters to indicate in some measure the quantities of oil being handled in the important parts of the system.

Their successful application, however, is confined mostly to the larger refineries where the instruments can receive proper care and repairs by the plant force.

Refinery Processes Require Technically Trained Men

Just as in large boiler plants, it is found that technically trained men are required for the operation of important refinery processes, particularly still batteries, and for the proper supervision and maintenance of the equipment which is designed on high-grade technical principles. While chemical engineers are preferable in petroleum refining-process operations, the actual operating and maintenance work has been equally well handled by mechanical engineers.

Gasoline Recovery and Stabilization

In gasoline recovery and stabilization the maximum operating pressures are in the neighborhood of 300 lb. per sq. in., and while both compression and absorption plants, or a combination of these, are being used, depending upon local conditions, the greater initial cost of the absorption plant in connection with the recovery of gasoline from still gas is warranted by the greater percentage of recovery of the lighter hydrocarbons. There seems to be no limit to the minimum quantity of gasoline per 1000 cu. ft. which can be economically recovered, this varying from three to fifteen gallons, depending upon the time of year and the temperature of the cooling water available, and of course the composition of the still gas.

General Practice

Treating Cracking Distillates. In the treating of cracking distillates, the tendency is very marked toward obtaining the maximum recovery of anti-knock fractions, which means the supplanting of acid treatment with processes similar to the Gray vapor-phase treatment.

Processing Lubricating and Paraffin Products. In the processing of lubricating and paraffin products, centrifuge dewaxing is making rapid strides, as all the more important refineries have such an installation.

Contact filtration is being used to a greater extent, but is limited to conditions where less than the highest-quality product is wanted.

Refrigeration is being used to remove waxes from lubricating oils and make them suitable for low-temperature operation, the oil being chilled to as low as —40 deg. fahr.

Drying of Fullers' Earth. In the drying of filtering clays, usually fullers' earth, the wedge furnace or one of similar design, consisting of a number of floors of refractory material over which the clay is moved by rotating arms counter to the flow of hot gases from a separate combustion chamber, has practically supplanted the old-type rotary kilns and various types of gravity furnaces. The expense of installing furnaces of the wedge type, however, has not permitted their general adoption by small refineries.

Acid Recovery. For sulphuric acid recovery plants, the vacuum system seems to be preferred in locations where occasional fumes from other types are apt to cause public nuisances, although, of course, the combination of acid concentrators with electric precipitators is still in use and being installed.

Multiple Heat-Transfer Units. Heat-transfer equipment for the larger still units is being mostly made in multiple-shell designs, although there is a tendency to standardize for convenience of stock and maintenance.

Corrosion of Equipment. Corrosion and deposits on tube surfaces are the main elements affecting the mechanical design, but there is a strong tendency in favor of making designed pressures much greater than working pressures, and large allowances for corrosion. Corrosion, particularly in gasoline condensers and exchangers, is most noticeable on initial condensation of the distillates, and chemical treatment of the charge is still applied as heretofore.

Piping. The adoption of the new American Engineering Standards for piping is becoming general, and for hot oil and vapors, seamless steel pipe has been generally adopted in place of lap-welded pipe.

Welding of the Lines. Welding of plant piping is coming into use where the pressure is not over 150 lb., but it is not yet thought feasible for hot-oil and vapor lines on account of the need for taking down lines for cleaning and for inspecting them for corrosion.

Power-Plant Practice

Steam boiler plants for refineries are being built for as high as 535 lb. pressure, with the needed superheat for turbine generators which may exhaust at sufficient pressure for process-steam distribution sometimes by the use of bleeder-type turbines; but, where possible, the plant is designed to balance the power requirement with process steam.

Steam is further superheated for process work, varying from 800 deg. fahr. total temperature at 10 lb. pressure, to 500 deg. at 120 lb. pressure.

It is still the practice for each refinery to generate its own electric power on account of this need for process steam, but in some special cases power has been purchased on account of remoteness of power use, compared to the location of steam plant, or some particular advantage in the cost of purchased power.

In the application of power, the possibility of gaseous atmosphere around pumps handling petroleum and its products makes it customary to place a fire wall between the motor and pump, surrounding the shaft by a stuffing box.

In some cases, particularly on foamite and water pumps, dual drive is applied with a motor at one end and a steam turbine or gasoline engine at the other. These run in sizes from 150 to 300 hp.

While a brush-shifting-type motor has been used in a few instances for a variable speed on reciprocating power pumps supplied with reduction gears, usually of the herringbone type, they have not gained much favor, because of first cost and the possibility of sparking commutators' igniting gas, even though the motor be in a separate room.

Production Engineering in the Printing Plant, a Factor That Can Be Merchandised

By H. R. LEWIS,[1] HAMMOND, IND.

As a result of an analysis of plant, equipment, personnel, costs, and merchandising methods the company with which the author is connected specializes on the manufacture of hard-bound books. A straight line system of production was worked out which made it necessary to enlarge various departments. The author tells of the changes that were made and the result accomplished.

IN THE present era of keen competition in every industry and between industries, together with the attendant struggle for lower costs, there is a still greater responsibility being placed upon the engineering of production.

To no industry is this subject of more vital importance than to those who manufacture to contract. Many manufacturers in many different lines whose business requires that they manufacture to contract have developed their plan of production to the point where it may be said that they have proved beyond any doubt the efficacy of a well-engineered production plan.

In the author's comparatively short experience in the printing industry, he feels inclined toward the belief that this particular phase of manufacture has not been developed to as high a degree in the printing industry as it has been in many other industries. The short experience of our company along this line tends to verify this. Although all plans have not yet been developed to the point which is considered the ultimate goal, yet there is every reason to believe that such experiences as we have undergone and such facts as we have proved to ourselves will undoubtedly be of great interest.

It may be well to give a brief picture of the history of the W. B. Conkey Company as a basis of comparison between the conditions which formerly existed and those which exist in the plant today. As some of the changes contemplated have not been completed, it will be impossible to show diagrams and illustrations of the conditions existing before applying the principles of production engineering. The W. B. Conkey Company has been in existence for some fifty years. The plant now occupied was built about thirty-five years ago. It was so well planned and constructed that, at the time of its completion, it was considered to be far ahead of its day. This plant is of one-story construction, sawtooth roof design, and contains 300,000 feet of floor space.

Sensing the trend of business, it was decided that if the company was to maintain its position, certain changes would be necessary. A complete analysis of the plant, the equipment, personnel, costs, and merchandising methods was made, extending over a period of approximately a year. The findings indicated that certain changes would have to be made throughout the company, and a definite program was formulated and put into practice. As a consequence, three years of this program have now passed, and already some very definite accomplishments can be pointed out.

Throughout the life of the company it has been the policy to do a general printing business. The first tangible result of the analysis was the determination that with the type of plant, the character of equipment, and experience of the people, it was best qualified for the manufacture of hard-bound books that could be produced completely in the plant, from the composition to the finished product, with flatbed-press equipment. This was probably the most important decision, and the results so far have indicated the correctness of this decision.

While the decision to specialize on this particular type of work has caused the passing up of a considerable volume of business that might otherwise have been secured, yet this loss of business has been offset to a very desirable degree by the improvement in the service which it has been able to maintain and the costs which it has been able to reduce.

Therefore, this paper will deal primarily with the methods and equipment which it is believed must be employed for the specialized mass production of hard-bound books and catalogs.

Having reached the decision to specialize in the mass production of hard-bound books of all kinds, an analysis of the equipment and the location of equipment by each department was undertaken. Excessive material-handling costs due to backtracking of materials, improper storage, and absence of progressive assembly were disclosed.

After a careful study to determine the character of work best suited to the equipment, taking into consideration the most modern processes, the question of obsolescence of equipment, and the balance of equipment for the best coordination with the various departmental operations, a straight-line system of production was worked out which necessitated the enlargement of the various departments to bring about free movement of materials and the proper storage of work in process.

Engineers and architects were called in, and a plan of enlargement was worked out by the erection of two additional rooms and changing of partition walls which increased the floor space of each department. This resulted in a more efficient utilization of the original floor area.

The boiler-room equipment consisted of two 150-hp. and one 300-hp. boilers. Coal was the fuel employed and the boilers were hand-fired. Feeling that this department should receive first consideration, heating and power plant engineers were called in. Data were compiled on automatic coal-handling equipment, stokers, pulverizers, and oil burners.

After comparing the results of this analysis and the factors which were indicated to be advantageous or disadvantageous to various types of equipment, oil burners of the steam-turbine-driven type were finally selected. The principal factors in-

---

[1] General Manager, W. B. Conkey Company. Mr. Lewis has had experience in various phases of organizing, management, manufacturing, selling, and advertising. For five years he was associated with General Motors as an executive of its subsidiary, the Harrison Radiator Corporation. In 1920 he organized a selling company in Detroit to handle automobile equipment and after selling his interests in this joined the W. B. Conkey Company.

Presented at a meeting of the Metropolitan Section, A.S.M.E., New York, N. Y., April 4, 1930, sponsored by the Printing Industries Division.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

fluencing their selection were, first, the elimination of coal dust and soot which contributed to the spoilage losses in all departments, and, second, the availability of oil and low cost of delivery, due to our location near some of the world's largest refineries.

The result of this installation has already shown a reduction of 51 per cent in labor costs, an increase of 30 per cent in efficiency, with an increase of fuel cost of 15 per cent. The reduction in spoilage losses by the elimination of coal is an indeterminable factor.

The heating of the plant was also made the subject of an engineering study. The former method of heating by an indirect system, with open recirculation from a central heating plant, was changed to the use of unit heaters of the high-velocity type, because of the large open areas existing in the plant, which is of sawtooth roof construction and all on one floor.

The unit-heater system shows an increase in efficiency over the central heating plant of approximately 43 per cent. Figuring interest on the investment of unit heaters, depreciation, and maintenance, the change-over to the unit-heater method has resulted in a reduction of 21 per cent in heating costs.

After a careful study of the composing room, the metal-casting department was removed from the main composing room to a small foundry room built on an outside wall with special attention given to ventilation, in order to remove heat and undesirable fumes and to bring about a better arrangement of the composing-room equipment. Additional steel cabinets were purchased, together with several thousand new galleys. Two new Intertype machines were installed. Special departments were created within the composing room where the standing type and plates of certain large customers were consolidated in order further to facilitate the handling of the work of these customers. As a result of these changes, the realignment of equipment, etc., indirect labor in this department was reduced 27 per cent.

The pressroom next came in for attention. The first move was to call upon the master mechanic, the superintendent, and the pressroom foreman for a report upon the condition of each press. Men from the engineering and service departments of the various press manufacturers were called in, and the presses were put in condition to produce the highest quality of work.

A study of pressroom operations and production figures disclosed inefficiency due to improper scheduling, loss of time in make-ready, and excessive spoilage losses.

A system of schedule planning was worked out which gave the pressroom foreman advance information as to what jobs were to be run next and what presses were to be employed. This relieved the foreman of detail and responsibility and permitted him to watch production of quality work more closely.

It was found in this study that the principal loss of time in the pressroom was in the make-ready. This was due to the fact that the ordinary proofing press in use did not disclose minor imperfections in plates and type pages. These were invariably disclosed after the job was made ready for the press, which caused loss of time in returning the plates to the foundry for repair and for type repair on the presses.

To overcome these details and to eliminate this loss of time, a pre-make-ready system was established whereby all plates and type pages were tested on precision proof presses as well as through the use of testing gages, and all necessary readjustments were made before plates and type pages were delivered to the pressroom. In practice this pre-make-ready system worked out exactly as planned. The loss of time in make-ready was reduced to a minimum, spoilage losses were eliminated to a very great degree, production was materially increased, and a higher quality of work resulted.

Needless to say the subjects of ventilation, temperature, and humidity control in the pressroom also received attention with very gratifying results.

Following the changes which were made in the pressroom, reorganization of the bindery was undertaken.

For the benefit of some who may not be familiar with the conditions existing in the printing business, the fact should be pointed out that of all the departments in the modern printing plant, the bindery department probably shows the greatest fluctuation on the production chart. Therefore for this reason and because of the fact that there are so many different operations, the reorganization of the methods, equipment, and personnel employed in the bindery called for greater attention than practically any other department of the company. Because of all these factors a careful study of all the ramifications was made. There were the operations of folding, gathering, sewing, trimming, gluing, rounding and backing, forwarding, case-making, stamping and embossing, casing-in, etc., to be considered.

It might be said that a finished book is only as good as the folding. Therefore, the folding department is a very important department in the manufacture of books. Inaccuracies in the folding of otherwise perfectly printed sheets cause a high percentage of rejections in the final inspection. Because of this, the folding department came in for special consideration. All of the folding equipment was very carefully checked. Poor equipment was eliminated. Improper layout, lack of intelligent supervision, and careless inspection were entirely done away with. Consequently, the resulting high spoilage losses and the high percentage of rejections which were discovered after the books had passed through succeeding operations were very greatly reduced.

Equipment in this department was brought up to a high degree of efficiency by the repair and adjustment of certain pieces of equipment, the removal of old models, and their replacement by new folding machines.

A new system of scheduling was worked out which coordinated with the pressroom schedules to meet the requirements of particular conditions with respect to sizes of sheets handled by the presses and the imposition. In conjunction with the operation by schedules and the realignment of equipment, a system of inspection of the folded signatures was inaugurated, which reduced spoilage 37 per cent and substantially reduced the rejection of finished books for inaccuracies in folding in the final inspection.

The personnel of the engineering department was increased in order to give study to the development of mechanical means for the displacement of certain hand operations. As an illustration, an automatic head-banding device was developed and attached to a forwarding machine, which makes and attaches either linen or silk head bands with a remarkable degree of efficiency. This improvement made possible the elimination of two hand workers.

An automatic end-sheet marking device was perfected and attached to a gathering machine. This made it possible to eliminate two girls.

Special equipment was designed which increased the efficiency of the tipping machines approximately 30 per cent.

Mechanical improvements were developed by the engineers in the hook-up of stitching heads to gathering machines. This also resulted in a marked increase in the efficiency of the combination.

Belt conveyors were developed to eliminate trucking and the handling of material within certain departments of the bindery.

Rounding and backing machines which operated from a line-shaft at fixed speeds were brought into better alignment in the

production scheme and equipped with individual motors with speed controls. As a result the cost of power for operating these machines was reduced 10 per cent and the production increased 13 per cent.

As will be noted, the natural flow of finished material is from the bindery to the inspection department. This department was also analyzed, with the result that it was relocated to provide the most favorable natural light. Special artificial light was also added. The department was entirely reorganized. Tables of uniform height, length, and width were installed with wide aisles for the free movement of finished books.

The plan of inspection was improved. All of these changes resulted in better inspection with increased output and a reduction in the criticism of customers regarding imperfect books.

Inasmuch as it is a practice in the industry to produce a great number of books for a publisher and then hold these books in storage subject to the publisher's order, the question of book storage and the proper storage and shipping facilities is of vital importance. This company carries an enormous quantity of books on hand for its customers. Shipment of these books is subject to the customer's order, and the quantities range from a single book to a carload shipment.

Because of the fact that this department contained merchandise actually owned by the customer, it required intensive engineering study in order to eliminate losses due to improper handling of finished books.

Formerly these finished books were stored in four separate rooms, which resulted in excessive handling cost and poor supervision in storing and handling. In changing the general layout of various departments, a single commodious book storeroom was created, providing accurate direct supervision of the work of storing and handling these books and filling orders for them.

Wooden shelving was discarded for steel shelving of the latest type. Improvements in methods of storing and handling were worked out to insure protection of the books from dirt and moisture and from damage in handling. Books owned by the various customers were consolidated as to location on shelf and platform storage, and a perpetual inventory system was established, which gave the stock keeper the balances on hand and their location at a glance. These improvements resulted in a reduction of labor in this department, greater speed and accuracy in filling orders, and assured a perfect condition of the book stock at all times.

In conjunction with the reorganization and rearrangement of the book-stock department, similar changes were necessary in the shipping department. This department was gradually enlarged. Sidetracks to the plant were rearranged permitting the erection of longer and wider loading platforms, with both platforms and trucks brought under a roof, assuring complete protection from the elements to workers as well as to raw materials and finished products.

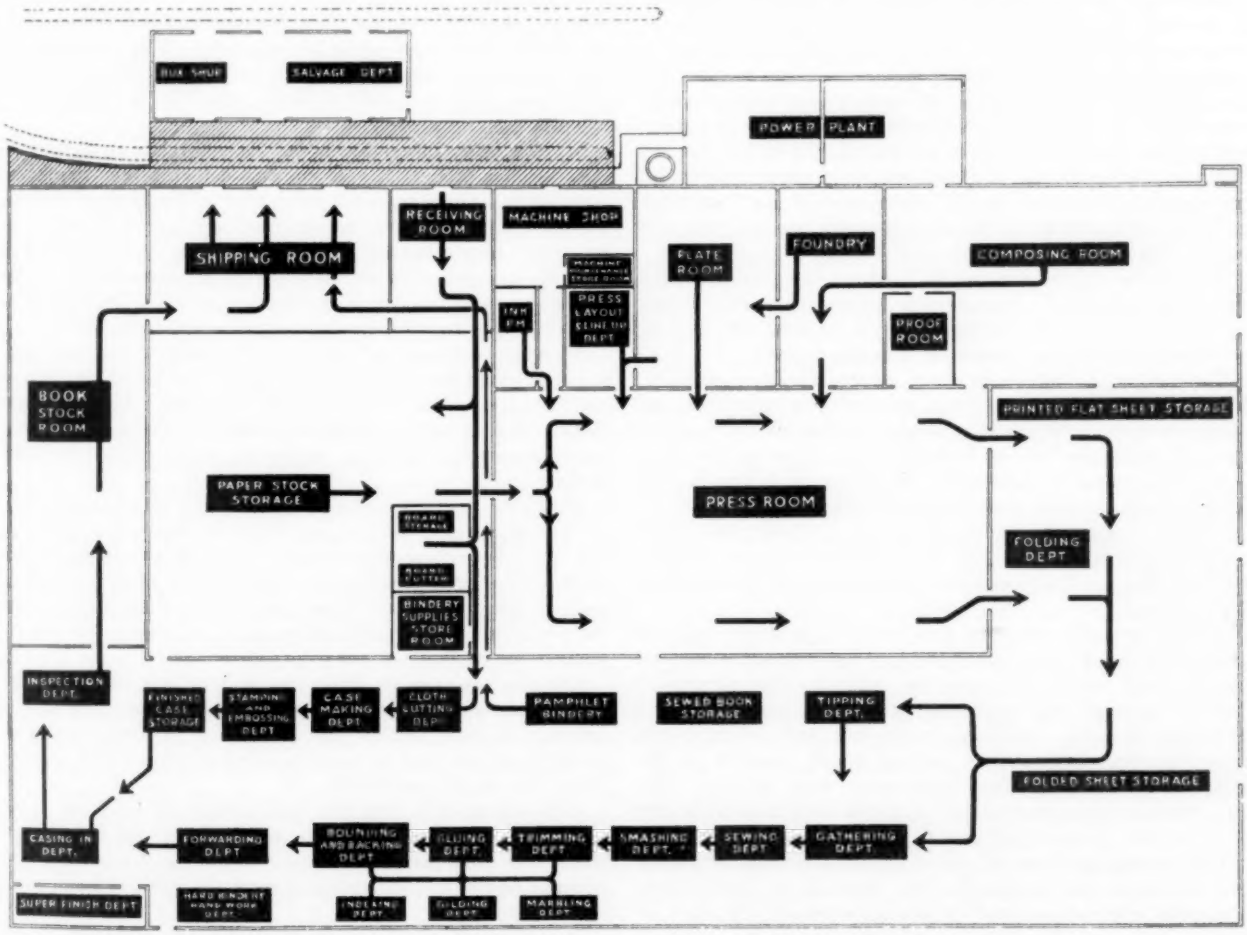

FIG. 1 PRODUCTION FLOW IN THE PLANT OF THE W. B. CONKEY COMPANY, HAMMOND, IND.

Additional material-handling equipment was provided, particularly lift trucks. Loading and unloading of freight cars was speeded up. Demurrage charges were eliminated. Spoilage losses caused by the elements were cut down. The time consumed in loading and unloading operations was materially reduced.

With the present methods employed, a carload of 40,000 lb. of paper on skids is now taken from the car and delivered to the floor of the paper stock room by two men in 24 minutes. This is a very substantial reduction in the time previously required for this operation.

Throughout the rearrangement of the plant and the changing of methods, the engineers were continually confronted with customers' problems which are peculiar to this business. For instance, many large contracts which involve type composition, electrotyping, presswork, and binding specify that only a portion of the total quantity be bound at a given time—the unbound portion to be held in storage to await further binding orders.

The former method of handling this problem was to store the flat sheets unfolded. This resulted in excessive spoilage losses in handling. A change was made in this method in the important respect that the entire quantity was folded, tied in bundles and stored in the production line between the folding department and the next operation. In the enlargement of the floor space and the rearrangement of the manufacturing, storage space for this purpose had previously been provided for.

This change in the method of handling the printed sheets resulted in a decided improvement in the quality of the finished books, better service to the customers, a material reduction in spoilage losses, and the consequent lowering of costs.

The storing of customers' plates involved another problem. It is a decided advantage for a printer after completing an edition to be able to retain possession of the necessary plates for that particular job, as it enables him to secure the next order with less sales resistance. These plates belong to the customer and naturally must be kept in good condition.

Prior to the rearrangement of the plant, these plates were stored in two rooms separated by a distance of approximately 400 ft. This resulted in excessive trucking, record keeping, and supervision.

After thoroughly studying this problem, a single room of ample area and of fireproof construction was located between the foundry and the layout room and adjoining the pressroom. The plate storage was consolidated in this room, which provided additional shelving, handling equipment, and an improved record-keeping system. The savings which resulted in the expense of operating this department were obvious. The importance of these savings can be gaged when it is considered that the cost of this department is purely a matter of overhead.

If a printing plant can be said to employ the use of perishable raw material, that perishable raw material is paper stock. Unprinted paper stock must be handled carefully. It must be stored carefully. Humidity conditions must be watched. Useless handling simply results in excessive costs. With these things in mind, the method of handling paper stock was also completely changed.

Formerly this paper stock was stored in two separate rooms, one of which was located at a point remote from the pressroom, which naturally necessitated excessive trucking and handling. In the rearrangement and enlargement of the various departments the paper stock room was relocated in a single room immediately adjoining the pressroom.

The practice of storing the stock as delivered from the mill—namely, in bundles, cases, and on skids—was abandoned. Instead, the paper is laid out flat, ready for the presses, in a room adjacent to the pressroom which is adjusted to predetermined temperatures. As a result, the paper comes to the pressroom free from wrinkles, properly seasoned, with expansion and contraction due to differences in temperature eliminated in so far as possible.

An important change was made in connection with the handling of waste paper, which runs into considerable tonnage in the form of shavings, from the trimmers and from other sources. The waste paper or salvage room formerly occupied an area of approximately 3000 sq. ft. in the main plant and was so located as to require trucking of the baled paper through two or three departments to the loading platform for shipment.

The location of this room also constituted a serious interference with any plan for a straight-line flow of production. In the general plan of improvements a new building was erected to house this department located on the side tracks serving the main building. Shavings are now carried to this department through pipes by blast fan from the trimmers and after baling are loaded directly into cars for shipment. The relocation of this department was an important factor in working out the production plan, and incidentally it permitted a reduction of two people in this department.

In the foregoing there have been discussed only such steps in the scheme of production engineering which already have proved themselves. There are other steps now in the process of completion. To discuss the results that will accrue from these would be only to hazard a guess. However, it is certain that with the completion of the manufacturing rearrangement in all its various ramifications, as has been outlined in the foregoing, there is under way the development of a real technique.

All work is being analyzed into elementary operations and accurate production standards are being established, from time and motion study, as a basis for wage incentives. More accurate costing is being set up, budgetary control is being established, and improvements are being made in all of the company's record systems.

A very casual study of the floor plan of our plant, upon which the flow of material and the progressive operations are indicated, will show the comparative simplicity of what a well-engineered production scheme means to the management of an institution such as this. However, it has possibilities of accomplishment far beyond merely the elimination of a few people, the betterment of the product, and the reduction of costs.

The greatest possible thing that can be said regarding the application of sound production-engineering principles in the printing business is that the application of these principles provides as good and as sound a merchandising factor as anything that can be considered.

It is fundamental that men and institutions have two basic requirements placed upon them regardless of the industry of which they are a part. These basic requirements are the ability to make money and the ability to serve the world at large while making money.

Regardless of all the other reasons as to why one should improve the quality of his work and his methods of operations, this one important factor remains—the man who pays for doing a certain piece of work is entitled to receive the very best for his money that it is possible for him to get. It is an obligation to see that he gets it. One can make money by giving it to him only in relation to the manner and to the extent to which it is made known to him that one is in a position to do this. By doing this it is better for the individuals who are a part of the producing organization. Therefore, the finest thing that can be said for the application of correct production-engineering principles in the printing industry is that it is a factor which can be very definitely merchandised to the business world as a whole.

The Munder System for Paper Selection

By NORMAN T. A. MUNDER,[1] BALTIMORE, MD.

There are many makers of paper, and each one sends out sample books. These books are generally addressed to some individual in a printing or advertising house and become his property. The Munder system for paper selection provides a cabinet containing the paper-sample books of 54 paper makers. These books, over 400 in number, are indexed by uses, qualities, and prices, and provide an easy reference for all in an office who are interested in the selection of paper for various uses.

THERE is hardly a more important or a more perplexing question, hour by hour, than finding just the right paper for the purpose, in texture, color, price, and other required characteristics, together with the name of manufacturer and merchant. The Munder system for paper selection meets this problem with minimum effort and maximum speed. The author has built this system after a continuous experience of over forty years.

The most popular papers for advertising purposes are book and cover papers; provision has been made principally for this kind of paper, and from paper makers offering mill brands with national distribution. Such papers, made in large quantities to supply the whole country, must have the best quality with fair prices. While this receptacle of the Munder system holds over 400 sample books representing 54 paper makers, it will also hold many others; furthermore, papers of all kinds can be substituted for any items not desired.

In nearly all offices the very useful sample books become the property of the individual who happens to receive them. With the Munder system these books become official ones and are filed for the use of the entire organization. They are labeled, and the one using them must replace them in the numbered compartment to which they have been assigned.

Offices having installed this sytem can readily find the latest styles in paper. A buyer asking for a certain kind of paper can be handed that very paper at once and not a substitute.

Two books a day, on the average, are received in the office of the user of paper, either through the postman or a salesman, and it takes two minutes to file a book; the index cards, revised twice a year, on which are printed all of the nationally advertised mill brands, offering a quick and complete aid. This means that an average of four minutes a day keeps an organization up to the hour in paper styles. The advertising expert or printer is expected to be up in paper styles, just as all other lines of business are expected to be.

The Munder system places before the user one receptacle. Its many compartments in four rows hold over 400 sample books of mill brands with a national distribution.

In another series of compartments just beneath are two rows that will hold 50 sets of dummy sheets. While these two bottom rows are planned for dummy sheets and finely printed specimens of all kinds in large strong envelopes, they can be used for more elegant and larger sample books if desired. These shelves are 13½ in. in height, 22 in. deep, and of adjustable width. There are two cupboards on the upper sides of the cabinet in which shelves can be placed. These cupboards are 9 in. wide, 17 in. deep, and 36 in. in height.

This is a national system, serving equally well for any part of the United States. Alphabetical indexes, revised and published in January and July, make possible the securing of any one of the books in from six to eight seconds. One index is for cover papers, being a complete list, and a second index has a complete list of book papers. The makers' and agents' names appear with each paper.

Another extra feature of the Munder system is the book paper chart (a cover paper chart may be developed later) revised and published quarterly, size 24 × 27 in., to be posted up for general office reference or placed under the glass top of a desk. This chart places in a group, graphically, nearly 300 book papers, in seven divisions: Enamel, Dull Enamel, Antique, English Finish, Machine Finish, Super, and Offset, and each class is placed under relative price headings, from 8 cents to 70 cents per pound.

An interesting code locates without sample books the paper with the characteristics needed. Thus: D, "deckle;" C, "more than two colors;" H, "also heavy weight;" S, "two sizes or more:" W, "wove;" R, "rib;" P, "plate finish;" HM, "handmade finish;" M, "medium finish;" L, "laid;" SP, "special finish;" Env., "envelopes to match;" etc. After the paper has been considered by this means, one turns to the filing cabinet and finds in from six to eight seconds the very paper in book form, full of demonstrations of what the paper will accomplish. Several papers of a similar nature can be compared and the best selected.

There is no system similar to this one for paper education. Those just coming into the printing, paper, and advertising business can select seven different classes of paper found in the sample books of the cabinet. When these papers are compared, the real difference in the seven kinds, and what can be accomplished on each one, can be seen readily. This can be done in a few moments, and can be repeated, using the different books until the beginner really knows paper; it would take years in an ordinary experience. There are many new processes today, all of which are represented in these hundreds of interesting books.

The Munder system develops executives, and places them in a position to become most efficient salesmen for printing.

The receptacle, or filing device of the Munder system, is ornamental and can be made in color to match the other furniture. This cabinet can be delivered unstained or jet black for decoration along modernistic lines. In size it is 36 in. wide, 26 in. deep, and 81 in. high. A smaller size receptacle will be made for smaller plants.

The paper makers are constantly planning and are having made by the best printers in the country fine sample books which show the trend of design in direct mail advertising. These sample books are mailed to a special list of printers and advertising organizations, from ten to thirty thousand at a time. A limited number of these books are retained, but not many. The books are so valuable that they should be properly kept and frequently referred to for inspiration and real guidance in making appropriate things. These original copies should be placed in the Munder

---

[1] President, Norman T. A. Munder & Co. Mr. Munder has been an employing printer since 1887 and has grown up with the American paper-making, printing, and engraving industries. He made the first large edition, two carloads, of sample books for the Mittineague Paper Company, now the Strathmore Paper Company, in 1906; a sample book still in use. The Munder organization has helped to develop important papers and has made sample books for nearly all the great paper makers.

Contributed by the Printing Industries Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

system and not allowed to lie around and be abused, perhaps lost. Sometimes these books are given to a customer, only to be discarded. When one of these books is wanted, and cannot be found, there is small chance for the use of that paper; it might be the one most needed. It is not extravagent to say that in these 400 books there may be found thousands of fine ideas in types, borders, and decoration, each a real inspiration.

As soon as a sample book is found offering a suitable paper, a dummy is planned and dummy sheets are needed. The Munder system provides strong dummy envelopes, 14 × 24 in., each of which is numbered, and belongs in its own numbered compartment. These envelopes hold full sheets, 25 × 38 in., folded twice, or 20 × 26 in. folded once; most dummy sheets are too small to be useful. Interesting dummies can be made on the spot and loose sheets can be passed to the presses for immediate experimental work. Say that the question arises, "Have we dummy sheets of 'Grandee'?" On the index opposite "Grandee" appears a second number just below the first one—the upper number refers to the sample book compartment, the lower number, for example No. 133, would mean that there were dummy sheets for "Grandee" in envelope No. 133. Paper salesmen supplying these sheets now have a better way to sell.

Printing-Plant Operation Without Alibis; Is It Possible?

By HADAR ORTMAN,[1] DES MOINES, IOWA

The author describes printing-plant operation as "the industry of alibis," and he asserts that it is easy to designate duties and to prepare specifications and instructions so that responsibility may be placed where it belongs and mistakes may be properly traced and their repetition prevented. He summarizes the principles of successful management and operation under eight heads.

SOME time ago while I was in Chicago I overheard two paper salesmen making fun of some simple-minded newspaper publishers in Iowa who insisted in putting on their paper orders "static-free paper." Not long after my return to Des Moines I found the result of our chemist's analysis on an ink cure which, according to letters of recommendation, was successfully used by prominent printers in New York and Chicago. His finding was that it contained a very ordinary ink base plus a certain amount of organic oil added solely for the purpose of mystifying the product; it did not contribute additional qualities to the compound. However, the ink cure was selling for five times that of the useful ink base.

Conversations with printers in other parts of the country convince me that the problems we have in Iowa are exactly the same as you have here in New York. So let us try to agree on a common basis for the later discussion.

The purpose of the printing plant is to produce as near perfect printing as possible at the lowest possible cost. This, you might say, is an axiom of all production managers, but it does need repetition as such. However, the relative importance of the cost and quality factors varies somewhat for different jobs.

The next step in our reasoning is that perfect printing is produced by transfer of ink from a subject plate to a sheet of paper. As the thickness of paper is being measured in thousandths of an inch, the press operation is necessarily such that all factors involved have to be expressed in thousandths of an inch and fractions thereof rather than in inches.

Imperfect bed, imperfect plates, imperfect cylinders, imperfect packing, imperfect rollers and roller setting, imperfect ink, imperfect mechanical motions of the press, imperfections in the sheet—none of these, of course, can contribute to perfect printing.

The struggle against all these imperfections is incorporated in a series of operations which is called make-ready. It can readily be seen that it covers a multitude of sins, and if not intelligently performed introduces new imperfections with additional need for make-ready, and so on.

A temporary condition with apparently satisfactory running result is finally obtained. But what happens without all the working conditions in perfect balance? Through wear and knocks new imperfections are caused, making it necessary to stop a $1 to $50 an hour press to make an approximate correction of some kind which will take care of the situation until the next delay. The more imperfect the printing conditions and the higher the speed, the more apparent the evil results are going to be, as vibration of the machine accentuates the errors, and vice versa. And, furthermore, while a run is being made without perfect equilibrium, even though with repeated corrections the printing results might be acceptable, the press parts are steadily wearing out, as the machine was designed and built for certain balanced conditions.

With machine speeds varying between 1000 and 100,000 an hour, pile after pile of printed sheets are manufactured, each varying in degree of perfection. One peculiarity in our industry is that if a sheet is printed imperfect there is no corrective operation available that can make it right. It is either accepted or scrapped. Imperfections of the kind discussed have to be discovered by careful, almost microscopic, examination of delivered sheets. With the tremendous speed frequently involved and the high cost of idle machine time due to delays, it is quite evident that preventive measures are extremely important, and, furthermore, sufficient checking of delivered sheets must be done to prevent thousands of imperfect sheets going through.

Some time ago the web on one of our presses was repeatedly broken off, causing an unusual amount of delays. The reason was found to be an unevenness in the thickness of the paper. At certain spots it was as high as 25 per cent above standard.

Complaints were received from the inspector to the effect that certain two-color rotary pages were offsetting, not trapping, and of poor quality. A large amount of time was spent in trying to correct it. It was found that, unknown to the manager, the pressman was using color ink purchased for flat-bed presses.

We had an order to produce a print job on oilcloth. Uncertain about how it should be done, the foreman and job pressman experimented for two months to find the correct ink. Finally the job was run, but because of imperfect ink nearly one-third of the job was rejected. Less than one day's work on the part of our chemist resulted in an ink which produced perfect results.

On two of our two-color Miehles it was necessary to change rollers every two or three days. The printing at times was perfect, and at other times it would slur and show other deficiencies. It was found that not only had the wrong composition been ordered, but also that rollers had been accepted which were green.

On one of our Babcock presses it seemed at one time impossible to maintain register. Local temperature and humidity conditions around the press, the condition of the paper, cylinder, bed, and so on were investigated, but no explanation was found. Finally it was discovered that the cylinder bearing was worn, causing this condition.

One form was worn out before we had obtained one-fourth of a run. An investigation showed that the foundry had rushed

---

[1] Director of Operation and Finance, Meredith Publishing Company. Mr. Ortman was born in Sweden, June 20, 1898. He studied at the University of Stockholm, Tuck School of Business Administration, and Columbia University. He has held a number of executive positions. As engineer with the Leffingwell-Ream Company, New York City, he served in a consulting capacity some of the leading organizations in the East; as supervising engineer with the Thompson & Lichtner Company, Boston, he supervised the engineering work in four Middle Western states. Mr. Ortman joined the Meredith Publishing Company, publishers of *Successful Farming* and *Better Homes and Gardens*, in October, 1928. His present duties include the supervision of the manufacturing, clerical, and financial departments of this company.

Presented at a meeting, April 4, 1930, New York, N. Y., of the Printing Industries Division, American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the production of plates; consequently it had delivered plates with soft shells.

On a duplicate run one subject was produced with two different screens, and the cuts had been made by the same engraver. Another was reproduced by two engravers with the same screen. In each case one of the reproductions was very superior to the other.

A pressman was complaining that the speed of the motor for his press varied. It was found that the voltage of our intake lines varied 10 per cent.

I could go on for hours telling you about past experiences of this kind, and so could any of you. I am not ashamed to tell them, for they are common, daily occurrences in most printing plants in the country.

And then the average production manager goes down to Pressman Jones and says, "Bill, your run last month was 10 per cent below standard speed."

"Well," answers Jones, "the paper stretched, the rollers weren't any good," and so forth and so on.

And then what does the production manager have to say? The average production manager just does not know for sure whether he supplied Bill with uniform paper, or good plates, or suitable rollers. Consequently, how can he honestly blame Bill for the outcome of the run? In order to free his own conscience he might insist on blaming Bill for the result, but Bill might rightly think that his boss is unfair. Perhaps the production manager knows that the materials and supplies and even the press were perfect, and perhaps the poor result was due to improper roller setting or make-ready, but is he sure that Bill was properly taught how to master each step in the press operation or that Bill had the time to perform them as instructed? Of course, you all agree that these are also responsibilities of the production manager.

While our production manager is looking over the printed sheet with offset here, a broken letter there, and a mud picture representing the pretty garden spot, the red being out of register and causing an old-fashioned illumination around the nose of the semi-nude hosiery girl, he might clear his conscience by drawing some of these conclusions:

1 The art department certainly did not get a good photograph that time.

2 It certainly seems impossible to get a real, honest-to-goodness pressman any more.

3 I wish that the electrotyper, the roller-maker, the paper-maker, the ink-maker, the engraver, the pressmaker, and the smut-roll manufacturer would learn their business.

Perhaps at this time the quack salesman comes along and pictures the glories of his paper without static, his press without evils, and his all-cure ink medicine. We grab them, and for a few months we are enthusiastically insisting that our troubles are all over, until we finally have to classify the last savior with the engraver and the rest of the evil-makers.

And when we print-shop managers get together to discuss means and ways to improve the industry, we start the same story in chorus: "If only the artist, the paper-maker, the ink-maker, the roller-maker, the electrotyper, engraver, and the pressman would learn their business." Very little is being said about: "What can we do to be sure that the materials and supplies are exactly what we want? What can we do to get our own organization to use these machines, materials, and supplies intelligently and correctly?"

Because of the multitude of materials and operations involved in the series of crafts, the final result of which is the printed sheet, and because of the extreme accuracy required by each—really beyond the working capacity of the average brain employed—the printing industry is a virgin field for quacks and magicians and offers wonderful opportunities for alibis, throwing the blame for imperfect sheets back, successively, to operations preceding the press operation. Even though I agree that many of those alibis are well founded, I still maintain that we printing-plant managers and others of our profession are primarily responsible for imperfection in the printed sheet.

If we all insisted on uniform and suitable materials, the vendors would be forced to supply them, because it can be done in most cases. If we are checking the quality of our supplies and materials before they are sent down to the pressman to be used, the cause of a large part of his alibis has been eliminated. If we utilize sound organization principles in our plant covering the division of labor, employment, training, maintenance, controls of various kinds, we have eliminated a lot of the causes for the alibis which we now are handing out to customers or that we hear daily from our subordinates.

A prominent electrotyper who recognized the evils of poor engraving for his profession decided to head it off by employing the best engraver in town, with the instructions to correct the engravings before they were sent to the electrotyping operator, or whenever possible to reject them and insist on getting new cuts. Incidentally, he told me that the temptations were too great in doing this without the customary faking methods, and when caught the engraver said that he could not see what the pressmen would do if he made such perfect engravings. But the electrotyper's idea, I think, was good, and I believe if we would apply the same thought to all jobs in relation to printing, we would eliminate a large part of the print-shop alibis.

In purchasing blocks for some of our presses we specified that they should be within one-half of one-thousandth accuracy. The block manufacturer accepted our requirements and supplied us with the desired number within the specified accuracy. In accepting the order the manufacturer said that most of the printing plants did not have such requirements, and if there were any of the blocks in the batch that were not acceptable to us, he could easily get rid of them.

Discussing certain features of make-ready with a precision-tool manufacturer, certain qualities of his tools were criticized. Defending his position, he stated that most printing plants were not able to handle tools with such precision, and that he, in order to commercialize his product, had to build them in their present form. These examples will serve to illustrate my point that real progress could be made if we all increased our demands on the auxiliary industries.

Let me now describe to you some of the things that we have tried to do in our plant for the purpose of eliminating causes for alibis. Let me first state that I do not in any way want to intimate that we have gone so much further than all other printers—perhaps not as far as the majority—but my instructions were to talk about the application, and that is what I want to do. The time is short, and it would not be possible to mention even all phases of the work. My purpose is to discuss some of the things we have done to eliminate causes for alibis, which will illustrate some conclusions which I shall draw at the end of the discussion.

Let us start with reviewing the procedures concerning engravings. You will probably think by now that I have some grudge against the engravers. I have none. I do not think they are to blame for using the old Washington proof press which last year celebrated its centennial birthday, and for smearing it up with ink ten times as costly as we can afford to pay. I think that we ourselves are to blame for not insisting on better engravings and honest proofs.

We know our pressroom conditions. This means that we ought to specify to our engravers the screen, the depth, and the type of retouching that we need. This is being done by our

organization through a purchase order. Furthermore, when an engraving comes in we have an engraver in our plant who tests the cut by pulling a proof on an honest proof press and who examines the cut for depth, etch, and so on. If it is not satisfactory, we reject it. If we would all do this, would you not think that the Washington press and engravers' special ink would be two items of the past?

Of course, the engraver comes back every so often and says, "If I could only get good photographs to make good cuts from," etc. We are trying to head off this alibi by systematic instruction to our art department, which places orders for engravings in the various phases of the printing problems.

One of the most effective ways of doing this is, we have found, by having monthly meetings. As soon as the first copy of an issue comes off the press, we call in the art director, the engraver, the plate inspector, the pressroom superintendent, press foreman, and pressman. Each page of the book is criticized. If necessary the original photographs and engravings or the plate proofs are brought in to enable us to reach a decision. These meetings give every one concerned an understanding of the problem of the other fellow, and, particularly, the art director is supplied with the necessary knowledge to start the printing routine correctly when he places orders for engraving.

We thoroughly realize that imperfection in a form locked up in the composing room is transmitted to the printing plate, as electrotyping really is a duplicating process. The logical thing to do, consequently, is to be sure that all types used, whether for machine or hand composition, are uniformly type high and otherwise perfect. This is easily accomplished by daily inspection, aided by the Hacker gage, which is a part of the equipment in our so-called plate-preparation department.

The principles of the procedure in handling purchased electrotypes are fundamentally the same with engravings, but of course the inspection is made by another man thoroughly versed with electrotyping. Paralleling what I said about engravings, we specify when we order electrotypes if we want wax or lead mold and whether nickel plated or not.

Let us now for a moment review what we have done to eliminate alibis concerning engravings and electrotypes:

1 We accept responsibility for specifying to our engraver and electrotyper the standards desired for certain variable qualities in their products so as to fit our printing-plant conditions. This eliminates alibis about mistakes made because of lack of knowledge of our problems.

2 We are expanding efforts on perfecting the originals submitted to engravers and electrotypers so as to eliminate alibis on their part that the originals were poor.

3 We have developed specialists in our plant who are able to inspect intelligently engravings and electrotypes received. In the case of engravings this inspection eliminates alibis on the part of the electrotyper regarding the originals. In the case of the electrotypes it eliminates alibis on the part of the pressman of imperfect printing due to imperfect plates.

Let me illustrate what we have done to eliminate alibis concerning run-down or inefficient equipment. Each month before a run is started the press must be carefully checked by a skilled mechanic. In order to be sure that this is done correctly, we have provided him with a checking sheet showing all the parts that are to be inspected. A copy of the same check sheet is hanging near the press during the run so that the pressman can check items which will need attention according to his observations of the press. The pressman's check sheet is then given to the mechanic at the time of the monthly inspection. You notice here again that some of the same principles are used as were given in the preceding paragraphs in regard to engravings and electrotypes, as follows:

1 We have a specialist who can more ably, and at a saving of time, attend to the mechanical features of the press.

2 We have enlisted the cooperation of the pressman and have also placed a certain share of the responsibility on him for the maintenance of the machine.

3 We have systematized this work by making it a regular routine which prevents oversight of detail and conserves time.

The most important feature of paper control from the standpoint of printing is without doubt the question of uniform quality. When a paper has been decided upon for a certain purpose, all other factors involved have to be adapted to this paper. As publishers of magazines we are naturally using the same kind of paper for a long period of time without changing. Because of the volume and the speed requirements, it is naturally of extraordinary importance to us to get paper of uniform quality.

Our chemist, in cooperation with the purchasing and manufacturing departments, has agreed upon the standards which should be maintained for each of these qualities. The chemist is equipped, in his laboratory, with instruments so that he can measure these qualities. The standards so agreed upon with the organization have also been accepted by the paper mill with the understanding that all paper that is delivered which is not in accordance with these standards shall be returned. There is nothing new about this, but let me in this connection stress that only qualities of importance to printing should be checked. Time can be and is often wasted by measuring qualities of no practical importance to the finished result. Naturally this testing is carried on as a definitely mapped-out routine with suitable forms for work sheet, test summaries, monthly reports, and so on. Here again we have applied the same principles:

1 A specialist who can intelligently check paper.

2 Standards for qualities which the pressman has agreed are acceptable for printing and which the paper mill agrees to meet.

3 A definite checking routine whereby we are reasonably sure that all paper delivered to the pressroom is of acceptable quality.

I said "reasonably" sure. It is of course realized that each sheet cannot be checked. But with the procedure as outlined, the alibis on the part of the pressmen, referring to quality of paper as a hindrance to production, have been greatly reduced.

Let me in this connection remind you that paper is a primary factor in the printing operation. A great number of factors have to be adjusted whenever paper stock is changed. I just want to mention such items as screen, body of ink, setting of ink fountain, packing, and so on.

In years past we had an illuminating experience. We were working with a paper mill to improve a certain grade of paper. Each month an improvement was made, while many of the secondary factors were maintained. Finally we woke up to the fact that, while the paper stock had been improved, the printing was not up to standard. It was found necessary to adjust, primarily, screen and ink, in order to again obtain printing of standard quality.

Ink and rollers are handled very much in the same way as paper. The large majority of qualities of these mentioned materials can be measured. Some, however, must be judged, but the more systematically this latter procedure is performed the better the results. Sometimes, for instance, high and low can be stipulated by means of samples which are kept in the laboratory and with which incoming shipments are compared.

How often have you complained to your paper-mill man because of paper stretching, and, consequently, poor register. And how often has he told you that humidity and temperature conditions in your pressroom are causing these troubles. And how often has your pressman told you that he could not obtain register, that he was delayed because of static, and so on.

We have met this problem by installing temperature and humidity control in both paper stockroom and pressroom. Furthermore, we have specified that paper must be stored under these controlled conditions for a certain length of time before it is used. It is also necessary to maintain control of temperature and humidity conditions in order to carry on the careful checking which we have previously discussed. Humidity affects the various qualities of paper, and accordingly it would not be fair to the paper mill to set up standards if temperature and humidity varied at the time the measurements were made. It is your task to specify to your paper mill that standards should be met under certain specific temperature and humidity conditions.

Another item along the same line is often neglected. Your pressman might be required to look at his color sheet under a certain artificial light. Your inspector has looked at it with an even north daylight. This is not fair. The pressman can properly say, "How can you expect me to produce a certain result which I cannot accurately judge?" We have made real efforts and progress to equalize light conditions for pressmen, foremen, and inspectors, in fairness to every one concerned. Along this same line, are you sure that all your color men have a normal visual conception of color? It is an easy task to find out.

All of you know that temperature, humidity, and light conditions are oftentimes causing alibis for poor printing results. We have found that through the installation referred to a large part of these excuses have been eliminated.

Here is one point I want to stress. Through our humidity and temperature control we control these conditions approximately eight months of the year. Because of the high cost of refrigeration equipment we have not felt justified in installing such equipment, but eight out of twelve months means that 66 per cent of the time we can maintain a uniform condition, and if you add to that the capacity of the apparatus to reduce to some extent humidity and temperature during the four summer months, I think it is fair to say that we control these conditions 75 to 80 per cent of the time. This, you must admit, is considerably better than no control at all.

In many print shops it is very common to hear the superintendent and the foreman tell you that they do not have time to follow up closely on the work, procedures, equipment, and results of their subordinates. In most cases their tale is true. The fault, therefore, of course, lies primarily with the upper management, as it either depends on the fact that too many duties have been assigned to them or that their work is being performed unsystematically. We have tried in our plant to eliminate these alibis by freeing our supervisors from some of the duties usually assigned to them and by assisting them in planning the day's work.

Equipment maintenance, for instance, is among the responsibilities of our building superintendent. Janitors are working under the direction of the building superintendent. Ink, rollers, and paper, in so far as storing, record keeping, issuing, quality checking, and so on, are duties handled by our chemist and the purchasing department.

Investigations of new equipment, layout of floors and working space, and construction of new procedures are all problems which are handled by our methods or our engineering department.

Under this type of organization, with functional division, it is of course necessary to establish intelligent cooperation between the line and the staff workers. It is definitely a duty of foremen and superintendent to bring to the attention of the department or individual concerned items needing correction or suggestions which will improve the operations of those allied functions.

It is equally important to discuss any change in procedures contemplated by a service department with the line supervisors concerned. Quite frequently valuable suggestions are made to the procedure by these supervisors, and it always furthers cooperation between the line and staff functions.

A common alibi on the part of the supervisor is that a rush order came in and he had to get paper cut, see about plates, call in men, and so forth. All this work is handled in our plant by our production department, so that when the order reaches the foremen it has been scheduled for a definite press, plates are in, paper and ink have been moved to the pressroom floor, and men have been assigned to the job.

It is very much easier for a competent office worker to lay out machine schedules, analyze the material requirements, and arrange the preliminaries for the running of a job than it would be for a foreman with all the interruptions which he has in the course of a day's work. I think these principles are quite well accepted by printing plants, even though there is a considerable difference in degree. In our particular case we are taking the attitude that the less of this work the foreman has to do the better off we are.

One item I have mentioned I would like to discuss further. Supervisors frequently are so loaded with routine work that they do not have the time to work out improved procedures for performing operations or to concentrate on elimination of causes for alibis rather than to just work out temporary relief for an unsatisfactory condition. Quite frequently, even though they might have time to do this work, they lack the necessary analytical ability. This I feel is one of the most fundamental weaknesses in most printing-plant organizations.

In the past discussion I have tried to enumerate some results from such an analysis. But this last point brings up the fundamental need in organizations to carry on such analysis constantly so as to obtain results of the kind I have previously indicated.

To me it is not essential that an individual analyst or a staff of functional engineers be employed for this purpose. The vital point is to have competent ability with sufficient time allowed for constructive thinking so as to obtain constantly permanent relief from imperfect conditions of various kinds as they are brought to surface. Consequently, it might be a line supervisor to whom this duty is assigned or it might be assigned to a separate staff function.

Quite frequently we criticize a common practice among pressmen to dope inks with secret fluids. It is true that very often the doping is effective. But is this not an admission that our purchasing department is asleep when it is buying improper ink? Furthermore, how can we expect the average pressman to do doping intelligently when it requires a thorough knowledge of chemistry. In our plant neither foremen nor workmen are allowed to dope inks. This is the privilege of our chemist only, and because of the close cooperation between our chemist and the purchasing department, it is a very rare occasion. The same holds true about color matching. Ink formulas are determined before a job reaches the press.

I do not need to say that these procedures are saving considerable amount of press time as, under the old procedures, the press was usually standing idle while the pressmen were playing with the mysteries of ink. When the duties of the pressman have been limited to such operations that he logically and economically can perform, then the next step is to train him thoroughly in the method of these operations. Whenever this is not done, we usually have almost as many methods in use as there are men. And still there is positively only one best way to do each operation. We complain of the fact that we cannot get trained pressmen, but whose fault is it, if not that of the pressroom management?

Personally, I feel that training is one of the greatest opportunities in pressroom management for obtaining improved results, and I cannot strongly enough urge production managers to give this matter very serious consideration.

Some other items concerning the workmen have been previously discussed. Such operations as washing rollers, cleaning blocks, and moving materials are often assigned to pressmen. These operations do not require a pressman's skill, for which he is paid. Consequently, it is not economical to assign such duties to him. Furthermore, the performance of such duties many times means that an expensive press is standing still instead of producing. It is of great importance to observe these principles:

1 To assign work in line with ability. (*a*) To assign specialists' duties to specialists. (*b*) To assign routine duties, which can be performed independent of the press operation, to others than pressmen.

2 To train each man thoroughly in the standard method of performing each operation.

Of course, the production manager in a good-sized printing plant needs his tools for seeing that all assignments are carried out in a satisfactory manner. This requires records of various kinds.

I am sure that all have had some sad experiences with your record controls. When your cost clerk finally brought in the statement for the month two weeks or so after its close, and you started to question your foreman regarding certain red figures, did you ever hear him reply, "I don't remember?"

Or did you ever find in analyzing causes through cost records that some items were combined to such an extent that no conclusion could be drawn? Or did you find sometimes that in the computation of a unit cost some additional variable element was injected because of improper selection of a factor on which to base your unit cost?

One of the most helpful reports we have in our plant is what we call our daily production record. Each morning this is placed on the desk of the production manager, superintendent, and foreman, and posted on the bulletin boards. This report shows the expected and actual production of each of the last three shifts and also the same accumulated figures for the month. It also shows allowed waste and actual waste for each shift and accumulative.

It is very easy to overburden your organization with records. But do they all assist you to make more money? I think that any control figure that is compiled must be isolated in scope so that a definite conclusion can be drawn from it. Furthermore, it must be of sufficient importance to warrant the work involved to compute it. And lastly, it must be computed without delay so that it is fit to serve as a current tool of management rather than a fact of historic interest.

Another point, of course, is that the figures must be presented to a person who is thoroughly competent to use them. Without a complete knowledge of how the printing operations are performed and the surrounding conditions, it is easy for foremen and workmen to present plausible but false alibis for a poor record showing. The men who handle the control must be able to verify the explanations given so as to place responsibility definitely for an unsatisfactory showing where it rightly belongs.

I have tried to give you the reasons why printing can be called "the industry of alibis." I have tried to describe different types of alibis. And finally I have demonstrated some of the methods we are urging in our plant to eliminate causes for alibis. Let me assure you that whatever we have accomplished along this line is just a modest beginning, and there are a number of great opportunities for further improvements awaiting us. But so far as we have gone, it has not only aided in straightening out friction and creating greater happiness in our organization, but it has also proved to be profitable from a monetary standpoint and has improved the quality of our printing considerably.

I am convinced that many of you will have objections to raise against some of the points of view I have expressed; perhaps the particular way we have organized our force would not suit your conditions. This might be true. Whatever has proved to be successful in our plant might not successfully be duplicated in yours. Imitation, anyway, is one of the greatest dangers in management.

The real purpose has been to illustrate some principles of vital importance to print-shop operation, the application of which will eliminate causes for alibis. Let me summarize these principles:

1 Develop absolute or relative standards for all materials and supplies which go into the printing operation, the physical conditions of the printing plant, the working parts of the machinery, and so on.

2 Develop definite procedures so that purchased materials and supplies are checked against these standards before they are used and so that physical conditions and machines are checked frequently enough to maintain standards.

3 Develop standard-practice instructions covering the method of performance of all work connected with the printing operations.

4 Narrow each task down in line with actual ability of the available personnel and place definite responsibility for certain defined results. This applies to supervisors, workmen, and technical staff.

5 Develop specialists whenever the scope of a technical task can warrant the employment of such a person. (*a*) If you do not have sufficient volume, contract for the services of some outside agency, either an independent professional or some one connected with a reliable vendor company. (*b*) The knowledge available to your organization should be broad enough to cover not only the problems of your own department, but also the details of the auxiliary industries so that you can intelligently check their contributions to the printed result and thoroughly understand the limitations of their industries.

6 Functionalize the simpler routine operations, such as material, handling, cleaning of presses and so on by relieving the highly skilled, high-priced technical men from these duties and assigning them to cheaper labor.

7 Train each job holder thoroughly in his tasks and instruct him in the principles of other tasks in so far as they affect the performance of his own.

8 Inaugurate controls that are definitely and actually usable in terms of completeness and promptness in showing whether assigned responsibilities have been fulfilled. This includes production follow-up, quality checking, and cost analysis.

Probably many are disappointed because I have not gone into any details as to how we actually do certain things, what instruments we use for measurements, what the different steps are in our make-ready procedure, how we set our rollers, and so on. To me these items are of minor importance in comparison with some of the principles which I have illustrated.

Well, now, what is the answer to the question we started out to discuss. Is it possible to operate a printing plant without alibis? Personally, I think that we have not yet reached such a stage of mechanical perfection in the printing industry that it is possible to operate our printing plant and interrelated plants entirely without alibis. Many factors employed in printing are still controlled by human judgment, and so long as this is the case, there will always be room for alibis.

However, I am thoroughly convinced that the largest part of the alibis that are now daily heard within our industry could be eliminated by removing the causes for them, or at least by narrowing the effects of allocated causes down within certain known limits.

Paper and Printing

By E. O. REED,[1] DALTON, MASS.

Paper must have certain physical properties to be suitable for use with the different printing processes. Technical specifications for paper and paper testing have been developed to secure proper quality for a specific purpose, but it is not possible to standardize paper made by all mills on a few physical and chemical tests. Such factors as appearance, color, feel, finish, formation, or printability are distinctive mill characteristics. The qualities discussed by the author are paper finish, moisture content, and relationship to printing inks.

THE art of paper making is one of the most important and essential industries of the present day. Printing is frequently referred to as "the art preservative of all arts." This honor, however, should be shared with the art of paper making, since without paper the present-day printing could not exist. Paper is the chief raw material used by the printer and the lithographer.

The Chinese are generally credited with the introduction of the art of paper making from fibrous materials first reduced to the condition of pulp about A.D. 105. The art of paper making therefore predated the present printing art, the origin of which is generally accredited to Gutenburg of Mainz, Germany, in the fifteenth century.

The printing industry is now one of the world's largest and most essential industries, and in order to meet the paper requirements of the various printing processes in use today, the paper industry is required to furnish many different kinds of paper. Paper must possess certain physical qualities to be suitable for use with these different printing processes. It must also be of the proper quality to meet the service and permanence required, and which varies with the uses to which it is to be subjected.

During recent years considerable attention has been given to the development of technical specifications for paper and paper testing to control and measure its quality and probable durability. However, most attention has been directed to tests on paper for kind of fiber, physical tests for strength such as folding resistance, tensile strength, stretch, bursting strength, tear, and other physical characteristics in order to measure its strength, and to a limited extent to chemical properties and tests for probable life or permanence.

It is essential that large consumers of paper have a knowledge of the quality of paper as determined by such technical tests, and the use of specifications is advocated by paper manufacturers as a guide to the user in securing the proper quality of paper for any particular purpose and to furnish the paper manufacturers with definite information as to the requirements of the printer or his customer.

However, to the printer there are many other factors of more importance in his daily use of paper than the physical and chemical tests usually included in present-day paper specifications. Physical tests in specifications are frequently met by sacrificing other qualities important to the printer in securing satisfactory and artistic printing results. Paper mills have different standards and practices, and it would not be possible to standardize the paper made by all mills on a few physical and chemical tests, especially the fine papers including bonds, ledgers, writings, and high-grade printing papers. It is not possible to standardize the method of drying of high-grade papers, or such important factors of paper quality as general appearance, color, feel, finish, formation, or printability, which are all distinctive mill characteristics of the art of paper-making and important factors in the cost of manufacture. No reliable test methods have been developed for measuring these qualities, most of which it will not be possible to measure by technical tests.

It is not possible to determine definitely the quality of rags or pulp in a finished paper. Physical tests are the only aid, and because of the effect of various sizings and other factors on the results of these tests, they do not always furnish reliable information as to the quality of a paper.

A reference to the following qualities of paper should prove of interest to the printer or lithographer: (1) Paper finish, (2) moisture content of paper, (3) relationship of paper to printing inks.

Paper Finishing

Probably the most important characteristics in paper which are noted by every user of paper and especially the printer himself are color, finish, feel, and formation or "look through." With the use of dandy rolls attractive watermarks and laid-marks may be produced on the paper machine. High or special finishes on paper are produced by calendering or plating the paper after leaving the paper machines.

The finish of paper is a very essential feature to the printer, and the quality of his finished work depends upon the selection of paper which will give the best results with any particular character of printing. The finish on paper may be classified into three kinds, based on method of finishing: machine finish, supercalendered, and plater finished. The finish on machine-finished paper is produced by passing the paper through a stack of steel calender rolls at the end of the paper machine. Considerable variation in finish may be secured in machine finishing, from a rough or antique finish to a smooth or high finish. For ordinary printing from type or plates without halftones the low machine finish is satisfactory, and the highest machine finishes are suitable for coarse-screen halftones such as are used in newspapers and some magazines.

For the printing of fine-screened halftones it is necessary to secure a much higher finish or surface than can be produced with the calender stack on the end of the paper machine. Supercalendered paper is produced by passing the paper through calender stacks slightly moistened to aid in securing a smooth finish. A paper intended for supercalendered finishing is usually run through a few nips of the rolls at the machine, and is dampened before it is run on the reel. The supercalender is a stack of rolls, usually eight in number, but sometimes built with as many as sixteen. These rolls are alternately of iron and composition, although sometimes two composition rollers may be run together. Composition rolls are made of paper or cotton.

A high finish on paper and also attractive special finishes are

[1] Technical Director, Crane & Co. Mr. Reed was for several years the Technical Director of the Government Printing Office at Washington, D. C. His research in the materials of printing has been of great value to the industry. He has contributed reports on paper, ink, roller composition, metals, and adhesives. Since 1929 Mr. Reed has been with Crane & Co.

Contributed by the Printing Industries Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

produced on high-grade rag papers by plater finishing. The sheets of paper, after being dried either in loft or by air-drying equipment, are placed singly between copper or zinc plates or press boards, and a pile of these is passed several times through heavy rollers, great pressure being applied during the operation. The amount of polish or finish imparted by this plater finishing process can be varied considerably. With a high pressure and few rollings, the sheet of paper can be turned out having a fairly smooth surface and without a conspicuously shiny appearance. By employing great pressure and with repeated rolling, a much higher surface is attainable. If the plates are hot, a still higher finish is possible.

Special finishes, such as linen finish, are produced in plater finishing by inserting a piece of linen cloth or other material between the paper and the metal plate, and an impression is left in the paper after passing through the heavy iron rollers. These special finishes may also be produced by passing the paper between embossed steel rolls.

There is no available test at present which will satisfactorily measure the finish on paper. Practical printing tests are necessary to determine whether the finish on paper for halftone printing or map work is satisfactory.

Moisture Content of Paper

Considerable has been published relative to the effect of variations in moisture content of paper. Paper is a hygroscopic material, readily susceptible to variations in the atmospheric conditions to which it may be exposed. The effect on paper of changes in the relative humidity of the air is greater than that of temperature.

The moisture content of paper bears a direct relation to the relative humidity of the air to which it is exposed. For instance, printing paper exposed to a condition of 35 per cent relative humidity would contain a definite amount of moisture, probably between 3.5 and 4.5 per cent. Paper exposed to a condition of 20 per cent relative humidity would contain less moisture, and paper exposed to a condition of 50 per cent relative humidity would contain a greater amount of moisture. Therefore, if paper containing a certain percentage of moisture should be taken into a pressroom the relative humidity of which is considerably lower than would be required to maintain the moisture content of the paper itself, there would be a tendency for moisture to leave the paper; or if the humidity of the pressroom should be higher than would be required to maintain the normal moisture content of the paper itself, the paper would tend to take on moisture from the air. The results of this changing moisture content of paper, and the fact that paper in stacks will not adjust itself to the atmospheric conditions uniformly in the same length of time, cause curl, wrinkles, cockling, wavy edges, bulging centers, and changing dimensions of the sheet. Furthermore, the normal temperature and relative humidity indoors are not uniform and change from time to time.

In the production of newsprint and book papers in rolls it is possible for the paper manufacturers to maintain a definite moisture content of the paper within a variation of approximately $^1/_2$ to 1 per cent. With the use of water-resistance wrapping on roll paper there is practically no change in the moisture content of the paper from the time of manufacture until the roll is unwrapped by the printer for use, provided the roll is not exposed to excessive dampness or heat. However, unless the relative humidity of the pressroom is sufficient to maintain the moisture content of the paper, the moisture of the paper in the outer portion of the roll will change if the wrapper is removed previous to use. It is therefore advisable in pressrooms in which the relative humidity is not controlled not to remove the wrapper until the roll is placed on the printing press. In fact, the moisture content of paper will change so quickly that difficulty may be experienced while the paper is traveling the short distance through a high-speed web printing press provided considerable difference exists between the relative humidity of the air in the pressroom and the moisture content of the paper.

With cut ream paper it is more difficult for the paper manufacturer to maintain a uniform moisture content in paper. This can be done only by handling the paper after manufacture under controlled relative humidity conditions which will maintain in the paper the moisture content present when it was removed from the paper machine. Although ream paper may be wrapped or packed in boxes with waterproof case-lining paper, it is essential for best results that the printer store and handle the paper under controlled relative humidity conditions which will maintain the moisture content of the paper.

With high-grade papers which are tub-sized, it is more difficult for the manufacturer to produce finished paper with a definite moisture content. With loft-dried or air-dried paper it is necessary that the paper before finishing be exposed to humidified conditions which will allow the paper to absorb the desired moisture and that this moisture content be maintained throughout the processes of finishing, sorting, and packing.

The paper manufacturers are powerless to remedy difficulties experienced by the printer due to this moisture variation in paper without the cooperation of the printer. It would be advisable to install humidifying equipment in his warehouse, pressroom, and bindery, and for the printer to advise the paper manufacturers as to the condition under which he will handle his paper. Many plants have installed humidifying equipment, and it has been proved beneficial both as to quality of printing and as to economical production. From a study made in this connection it has been observed that relative humidities between 45 and 55 per cent are found most satisfactory. A condition as high as 60 per cent is used in some localities during the summer months if dehumidifying equipment is not used.

For certain types of work requiring exact registry it is essential that the paper be seasoned thoroughly in the pressroom by hanging the sheets in racks or by treating in paper-conditioning machines.

Relation of Paper to Printing Inks

Little has been published as to the relationship of paper to printing inks, and this subject is attracting the attention of manufacturers of printing papers at the present time. Considerable research has been conducted relative to the sizing quality of writing papers, and several methods are available for measuring the degree of sizing of paper as applied to water-base writing inks.

Bonds, ledgers, and writings which are tub-sized with glue or starch are resistant to absorption of oil-base printing inks, and for printing on such paper it is essential that there be used job or bond printing inks which dry chiefly by oxidation owing to their low oil-absorption quality. However, with newsprint and various types of book paper, including machine finish, supercalendered, and coated papers, the printing inks used contain little or no drier and dry chiefly by absorption.

From a study which has been made as to the relationship of paper to printing inks the following conclusions have been secured: (1) That methods proposed for measuring the degree of sizing of paper will furnish reliable information as to the relationship of writing inks to paper, but cannot be used to measure the ink resistance of paper to oil-base printing or mimeograph inks; (2) that rosin sizing does not render a paper resistant to oil-base inks; (3) that the printing inks used by the printer may be broadly divided into three classes: (*a*) inks which dry chiefly by absorption, (*b*) inks which dry both by absorption and oxida-

tion, (c) inks which dry chiefly on the surface of the paper by oxidation.

However, there is a need for a better technical understanding or standardization of printing inks before the paper manufacturer can satisfactorily control the ink-resistant quality of paper.

Although methods have been proposed for measuring the relationship of paper to printing inks, no standard test procedure has been adopted. A recent report on newsprint indicated that with this kind of paper a measure of the air permeability of the sheet would probably furnish a measure of the penetration of the printing ink. Newsprint inks dry almost entirely by absorption.

The research chemists of the paper industry are devoting considerable work to a study of this feature of paper which is of prime importance to the printer. However, the close cooperation of the printer from a technical standpoint will be required in the study of this problem, and all influencing factors should be carefully considered.

Permanence Standards for Printing and Writing Papers[1]

By B. W. SCRIBNER,[2] WASHINGTON, D. C.

Experience with printed and written records has shown the necessity of having adequate standards of permanency for selection of record papers. Sufficient technical knowledge is available for the formulation of such standards, and there is sufficient interest in their establishment to make such a project feasible. This paper outlines the available information on the permanence of papers and indicates how it may be applied to formulate definite technical specifications for permanence qualities. The history of paper making is traced to show its relation to the deterioration of papers, and the causes of deterioration as shown by the history of papers and by research are outlined. From this information is shown the necessity of dependence on performance and purity tests for selection of papers. The strength of paper and its purity, both cellulosic and non-cellulosic, are the important factors in its aging quality. A classification based on strength and purity is suggested, which places papers in the following four groups: (1) Papers of absolute permanence, (2) papers having a minimum life of 100 years, (3) papers having a minimum life of 50 years, (4) papers for temporary use.

THE question of permanence enters into all grades of printing and writing papers; even the lowest grades must have a certain degree of permanence to enable them to fulfil the service for which they are intended. There is, and has been for some time, an insistent demand for some standards by means of which a paper purchaser can have a reasonable assurance that the paper selected by him will have the necessary degree of life, and by which the manufacturer can be guided in making the paper.

The problem of fixing permanence standards is not a simple one, however, and no doubt this accounts for the present rather chaotic condition respecting such standards. It must be acknowledged that the technical and scientific knowledge desirable as the foundation of such an enterprise is not as complete as we would like to have it. However, this is generally true of most commodity standards. The establishment of them cannot await the development of complete knowledge of them; therefore standards for immediate use are usually set up, based on the best knowledge available, with the idea that they will be further modified as increased knowledge of their suitability is gained by their use and by research. Very little progress is made with any commodity standard until it is put into use; its usage stimulates study of it and is the most potent agent for its correction and development. It is believed there is sufficient knowledge available now to establish quite satisfactory technical standards for paper, including permanence. This discussion is for the purpose of outlining the information available and showing how it may be applied to permanence standardization.

Present Status of Permanence Standardization

The question of the permanence of paper has been a very live one ever since the introduction of wood-fiber papers and modern methods of making papers, which occurred during the latter part of the nineteenth century. Shortly after this took place, those concerned with the preservation of valuable documents and publications began to find that many of them were turning yellow and crumbling to dust. This continued to be noted by librarians throughout the world, and even as far back as the eighties we find investigators and librarians expressing alarm over the situation. From that time on there has been continuous discussion of the subject, and much study of it, but, as will be shown later, nothing very conclusive has resulted.

At present, the subject is being actively considered in nearly all civilized countries, and the demand is becoming more and more insistent that some criteria of permanency be established. The League of Nations has actively taken up the subject as of world-wide importance and has established an international committee to deal with it. This subject was given considerable discussion at the First World Library and Bibliography Congress held in Rome last year. It is being actively considered by various library associations, both abroad and in this country. In this country active research is being conducted by the various government laboratories, by the Rag Content Paper Manufacturers, and by a number of separate paper manufacturers. Last year the Department of Commerce was requested by various representatives of the paper industry to extend its assistance in a systematic effort to formulate commercial standards of this kind, and such assistance is being given.

Development of Modern Papers

As previously indicated, practically no difficulty was experienced in the preservation of papers up to the introduction of the use of wood and the speeding of paper-making processes in the latter part of the nineteenth century.

There are well-preserved papers made from a variety of materials dating back a great many centuries. Some of these are Chinese papers made from the mulberry tree, Egyptian papyrus papers made from a swamp grass, and papers from many sources made from linen or cotton rags. The earlier papers were made slowly and carefully by hand, and without use of chemicals. The fibers were separated by hand, and their bleaching and drying were by the action of sunlight and air only. Later, materials such as animal glue and starch were employed to give the papers better writing and printing quality; the use of alkalis to assist in cleaning and defibering the raw material and chemicals for bleaching it was initiated; and the Fourdrinier paper machine, with other paper-making machinery, was developed to speed the paper-making processes.

In spite of these advances, due to the limited supply of raw materials in use and the high production costs, paper remained an expensive commodity. The chief raw material used at this stage was rags, even newspaper being printed on rag paper. As

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

education advanced, the demand for cheaper papers increased, and this resulted, starting early in the nineteenth century, in a determined effort to find cheaper fibrous raw materials and less expensive ways of making paper. The vigorous attempts being made now to utilize various waste-plant materials is reminiscent of that period. Straw was successfully made into good grades of paper, but the desired results were not secured until means of pulping wood were discovered, as here was an extremely abundant and inexpensive raw material which was well adapted for mass production in an inexpensive way. This rapidly supplanted very largely other materials for all except the very highest grades of printing and writing papers. The use of straw in paper was quite common around 1830. This was quite largely supplanted by wood pulp, produced by caustic soda treatment, in the sixties; ground wood, and chemical pulp produced by the acid-sulphite process, came into being between this time and the eighties. These last two developments gave the very inexpensive paper ideally suited for newspapers so far as manufacture and cost are concerned, but the ground-wood pulp, or mechanical pulp, as it is also called, considerably complicated the permanence situation, as will be explained later. With the development of processes for utilizing wood, came the development of the inexpensive rosin, aluminum-sulphate sizing, and increase in size of machinery and speed of its operation. Most wood-fiber papers are produced today by a practically continuous operation, on a huge scale, rapidly and with a minimum of labor.

A recent development in the pulping of wood is the production of fibers from wood simulating in purity, strength, and other paper-making qualities the cotton or linen fibers. These wood fibers are produced by combinations of the usual chemical pulping processes, and some variations in the usual after-treatments, with careful attention to each detail. Another fairly recent development is the sulphate pulping process, which is an alkaline treatment employing, in addition to caustic soda, sodium sulphide. This, in various modified forms, is in quite extensive use for the treatment of pine woods as it is particularly well adapted for woods having a high rosin content.

With increase in depletion of wood and consequent increase in its cost there is today, as previously noted, a recurrence of the extensive efforts made a hundred years ago to utilize grasses, straws, and other plant stalks. This class of materials is used to an appreciable extent in countries deficient in forests, but their use in this country is still in a process of development. Nevertheless, this class of raw material should be considered as it may possibly be a factor in the near future.

At the present time, then, the three main sources of paper-making fibers, so far as writing and printing papers are concerned, are rags, wood, and grasses and straws. A brief description of the processes used in isolating the paper-making fibers may help to a better understanding of the following more technical discussion.

Rags are classified into a number of different grades depending on their cleanliness and purity. Cotton rags are largely used, but linen rags are used to some extent. After sorting and examination to eliminate extraneous materials, they are cooked with lime or caustic soda, washed, defibered in a beating engine, and bleached, usually with chlorine or calcium hypochlorite. The highest grades of rags are termed "new rags," and are clippings, threads, etc. obtained directly from textile manufacturing operations. The lower grades are used rags, and being more or less dirty and sometimes colored, they require more severe chemical treatment than the new rags for isolation of clean, white fibers.

Likewise there are various grades of pulpwoods, but their grading is more particularly in respect to the nature and amount of fiber in the wood. As mentioned, both alkaline and acid pulping processes are used, and the chemical treatment is otherwise much the same as for rags, except that it is necessarily much more drastic because the cellulose of trees is associated with a far larger amount of organic impurities than that of rags. The ground-wood or mechanical pulp is produced, as the name implies, by simply defibering the wood by grinding, with no chemical treatment.

The other main source of paper-making fiber is esparto grass, which is used quite extensively abroad, particularly in England. It is pulped by the caustic-soda process, and the chemical treatment in general is similar to that for wood but is less drastic.

The paper-making processes are essentially the same for all classes of papers so far as the main details are concerned. The fibers are beaten; the sizing materials, usually rosin and alum, fillers, coloring matter or other materials used, are added to the beater; the paper is formed on a Fourdrinier wire and then dried on steam-heated cylinders. In the case of writing papers, the paper may be "surface sized" by passing it through a tub of animal glue or starch before drying it. Such papers are usually further dried and seasoned by hanging the sheets on poles and letting them "air-dry" or by various modifications of this operation.

Aging Properties of Papers

The evidence is clear, as before stated, that the period when deterioration of printing and writing papers first became noticeable is coincident with the introduction of modern paper-making processes and the use of wood fibers. The evidence is very contradictory, however, as to the cause of the deterioration. There is general agreement that the paper should be as free as possible from active chemicals such as iron, sulphur from cooking processes, chlorides from the bleaching processes, rosin and aluminum sulphate from the sizing processes; and that no matter how high the initial quality of the fibrous raw material may be, the fibers may be ruined so far as permanence is concerned by poor practice, in cooking, bleaching, or beating. In respect to influence of the fiber components of paper, however, the literature reflects the same difference of opinion as exists today. There is quite general agreement that crude fibers such as ground-wood fibers—that is, fibers having little or none of their large content of impurities removed—are very impermanent, but there is wide difference of opinion as to the aging qualities of fibers from different raw materials, refined by chemical pulping processes and by bleaching. Many express the view that cotton fibers are essential for permanence, basing their opinion on the excellent record of such papers in the past, on the fact that the high initial purity of this fiber minimizes the further purification required, or in some cases on experimental evidence that the wood fibers as usually prepared are less stable than the cotton fibers.

Unfortunately, experience with the actual aging of the modern types of printing and writing papers does not in any case extend back very far. The present types of rag-fiber papers probably were not duplicated more than 125 years ago at the most, as the use of rosin sizing and aluminum sulphate now employed in their manufacture originated about 1807. The modern types of wood-fiber papers are younger, the newsprint grade originating apparently about 40 years ago and the fine wood-fiber writing and book papers a few years later. Herzberg, however, reported in 1907 results of retests of papers stored by the German government paper laboratories. These showed that there was no marked difference between the all-rag fiber papers and the all-wood fiber papers. A. D. Little stated in 1903 that properly purified wood fibers such as bleached sulphite and soda fiber have shown no sign of change in twenty years.

The National Bureau of Standards is making a systematic study of papers of various ages secured from libraries and other sources. While this has been in progress only a short time, the

tests so far made indicate that fibers from low-grade materials as prepared by the modern processes may have quite a long life. A sample of soda-sulphite book paper 30 years old was found to be apparently as good as when first made. Sulphite bonds around 15 years old were likewise very well preserved. The most significant test results, however, were those made on specimens from old newspapers secured from the files of the New York Public Library. These papers were published during the period 1866–1880. Those published from 1866 to 1873 were in excellent condition and were composed entirely of chemical fibers from a wide variety of materials, rags, esparto grass, straw, and wood. Two of these papers composed entirely of esparto-grass fiber and one containing 80 per cent of straw fiber are of particular interest as further evidence that papers having considerable permanence were produced from low-grade materials. The papers issued from 1874 to 1880 all showed more or less deterioration and contained ground-wood fiber mixed with the various chemical fibers found in the previous papers. Similar results have been obtained in tests of old books. In many cases several different kinds of paper were used in the same book. When composed of chemically refined fibers, whether from rags, esparto, straw, or wood, in most cases the papers were well preserved, but pages containing ground-wood pulp are usually badly deteriorated. There are exceptions, however. That is, occasionally papers composed of refined fibers from all the sources mentioned have been found badly deteriorated. It appears that when ground-wood fibers were first introduced they were used indiscriminately in all classes of publications, even those of permanent value, and that this use continued until the evident instability of this class of fibers became apparent. No doubt this practice has been largely instrumental in forming the opinion held by so many librarians that all fibers from wood and similar materials are very impermanent, no matter what their character may be.

Tests of representative samples of the present commercial writing and printing papers were reported recently in a Bureau of Standards publication. These tests were made along the same lines as those reported by Kohler and Hall of the Swedish government. They included, in addition to the usual strength and purity tests, an accelerated aging test made by heating the papers and finding the degree of stability as indicated by the degree of retention of the strength and desirable chemical properties. While the applicability of the latter test is questioned by many, it, together with the other tests, indicated the same thing found by tests of old papers, that low-grade fibrous materials may be so processed as to have a high degree of permanence, and, on the other hand, that high-grade fibrous raw materials may be so processed as to produce impermanent papers. Highly purified rag and wood fibers were found to be similar in cellulosic purity, that is, content of alpha cellulose, and in paper-making characteristics. They reacted similarly in the paper-making processes, both forming in the beating treatment the fiber fibrillae necessary for high strength and endurance, without excessive shortening of the fiber and without excessive impairment of the cellulosic purity. Chemical and physical tests of papers made from such fibers showed the same similarity in results. But tests of fibers from the same sources and of papers made from them, having a lesser degree of purity and strength, showed gradings downward similar to each other. All of these findings are in line with the predominating evidence that, chemically, cellulose is the same no matter what the source, and that celluloses very similar in both chemical and physical properties can be isolated from widely different materials.

All of this review of the available information on the qualities that make for permanence of paper leads inevitably to the conclusion that the degree of stability of paper is dependent primarily on its purity. The degree of purity of the fiber and the purity of the paper in respect to active chemical components are the prime considerations.

Any one who wishes to review in detail the literature on permanence of paper will find the "Bibliography of Pulp and Paper Making," by C. J. West (Lockwood Trade Journal Company), and "Causes and Prevention of Deterioration in Book Materials," by Robert P. Walton (New York Public Library), prolific sources of information.

Estimation of Permanence of Paper

Following is an outline of complete procedure suggested for estimation of the permanence of papers. This takes into account the more important factors affecting the permanence of paper indicated in the preceding discussion.

The first consideration is whether the paper has sufficient strength to withstand the mechanical stresses incident to its use. Bond and ledger papers, for example, must have a very high degree of strength as they are often folded repeatedly and are subjected to considerable handling in general. Such papers are usually surface-sized with glue or starch, and considerable increase in the strength of the paper is secured in this manner. As in some cases this increased strength may not be permanent owing to the use of faulty materials or to faults in the sizing process, whenever possible a sample of the paper not having the surface sizing is secured, and this, as well as the sized paper, is tested for strength. The strength of book papers, on the other hand, is of lesser importance, because they are well protected by the binding. Particular attention is given of course to the color, texture, and cleanliness of papers intended for long use.

The next consideration is to judge how well the paper will retain its strength and color, as both of these properties are subject to deterioration induced by chemical reactions within the paper.

The permanence of the color, so far as light effect is concerned, is tested by subjecting the paper to an artificial light which simulates sunlight but which has greater intensity of active rays. Care is taken in this test to avoid excessive heating of the paper. The paper is exposed to light from a carbon-arc lamp for a period of 24 hr., at a temperature of 40 deg. cent. A numerical measure of the fading is obtained by means of a colorimeter.

The testing for resistance to chemical deterioration is more involved. The basic constituent of paper fibers is cellulose. Pure cellulose is the most permanent organic material occurring in nature. By itself, it will remain unchanged under normal conditions indefinitely. It is very susceptible, however, to deterioration induced by certain associated impurities. Degraded celluloses, such as oxycellulose and hydrocellulose, apparently have a very harmful effect. The presence of modified celluloses of this kind may be due (1) to insufficient purification of the fiber and (2) to changes in the pure cellulose caused by adverse influences in the paper-making operation. The content of pure cellulose, commonly termed "alpha cellulose," is determined by dissolving the other fiber constituents with caustic soda. The "copper number" is used as a measure of the degraded celluloses. It represents the amount of copper reduced from a copper solution by a given amount of the paper. Resinous materials, either introduced as rosin sizing or associated with the fibrous raw material, are known to have a deleterious effect. The paper should contain a minimum of any material that is active chemically. Acids are particularly harmful. The amount and the nature of the ash content are important. If no mineral filler has been used, a low ash content is an indication of careful cleansing of the paper materials. A chemically inert filler, such as the china clay commonly added to book papers, is regarded as harmless and, in fact, as having some fiber-protective value in respect to chemical influences.

Complete information cannot be obtained by analysis alone,

as at present little is known of the deteriorating effect of any given combination of paper constituents. For this reason an accelerated aging test is considered a valuable supplementary test. This is made by heating the paper and finding the degree of deterioration of its physical and chemical properties. This treatment is presumed to simulate the chemical effects of many years of natural aging. The paper is heated for 72 hr. at 100 deg. cent., and then the pertinent chemical and physical tests are repeated. While this is merely an empirical test and its time relation to actual aging is not known, its principle appears to be sound theoretically, and the gradings obtained with it are consistent with the permanence history of papers. A high degree of resistance to the heat effect, particularly respecting retention of folding strength and alpha cellulose, as well as a minimum increase in copper number, are regarded as favorable indications of permanence.

The procedure outlined is used by the National Bureau of Standards and is practically the same as that used by the Bureau of Standards of Sweden. It is also being used by several commercial testing laboratories.

The strength of the bond and ledger papers is usually determined by the folding test. This test is not satisfactory for most book papers owing to their lesser degree of strength, but no doubt should be used for the higher grades. The tensile test appears to be the most satisfactory measurement of strength for book papers in general as it is readily applicable to all grades and appears to be more in line with the stresses to which such papers are subjected in their use.

Determination of copper number of paper and of its alpha-cellulose content has not been studied very much until recently. Considerable work on such methods by the Bureau of Standards has resulted in development of procedures by which results of copper number determinations can be reproduced within 0.1, and results of alpha-cellulose determinations within 0.3 of a per cent. This is quite satisfactory for the purpose. Quite satisfactory procedures for acidity are also available. The other tests required are covered adequately by the official paper-testing methods of the Technical Association of the Pulp and Paper Industry, except of course the accelerated aging test. As mentioned, this is an empirical test, and its applicability for the purpose cannot as yet be definitely proved. It is, without a doubt, a very severe test. From experience obtained with it, it would appear that any paper which satisfactorily withstands it without appreciable loss of its desirable physical and chemical properties must be very resistant to deterioration. On the other hand, a paper that shows considerable deterioration under this test is not necessarily suitable for temporary use only, but may give many years of service. This test or any one of the others suggested cannot be relied upon alone. They must be considered as a whole as apparently they all give valuable information. With further knowledge, a single test or a simpler combination of tests may be found which will give the desired result without such extensive and rather complicated procedure as that outlined.

Suggested Bases for Standardization

Probably the most complete technical specifications for the domestic printing and writing papers are the purchase specifications of the United States Government. More than twenty years ago, the Joint Committee of Congress on Printing appointed a committee to fix standards for printing and writing papers to be used as purchase specifications for the Government Printing Office papers. This committee has been continued and makes such annual revision of the specifications as are found to be advisable by experience with the papers, increased technical knowledge, changes in paper manufacture, or changes in the requirements of the Government departments. These specifications have recently been approved by the Federal Specifications Board for use by the other Government departments. The range of papers specified appears to be adequate for most commercial purposes, and as the specifications represent many years of experience and research they warrant careful consideration in formulating commercial standards.

The Government standards, as was necessary due to lack of experience with fibers from the lower grade materials, were initially based primarily on specification of source of fiber. The trend more recently has been in the direction of adding requirements for purity of the papers. At the present time the specifications for papers desired for the highest degree of permanence contain limits for acidity and sizing materials and have other requirements designed to obtain papers having as high degree of purity as possible. In all the fine paper grades, however, fiber composition and other composition requirements are still retained, although consideration is being given to modification in this respect.

In view of the present knowledge of papers and improvements of technic in manufacture of papers from the lower-grade materials, it is now possible in judging the quality of papers to rely on performance tests, and on such composition tests only as are indicative of the degree of purity. This is of course desirable in all specifications. When a purchaser tells a manufacturer how he must make material purchased, he, rather than the manufacturer, assumes the greater responsibility for the serviceability of the material. With elimination of composition requirements, the manufacturer is fully responsible for the performance of the material, but is unhampered as to the means he shall employ to ensure the required performance.

The technical details of importance in respect to permanence of papers have previously been touched upon more or less. The degree of strength is of prime importance. More than any other one test it reflects the grade of raw materials used and the technic used in the manufacturing processes. In addition to strength, acidity and content of rosin appear to be sufficiently important to warrant specification in all grades of paper except the lowest grade suitable for temporary use only. Inert mineral fillers or coating materials required for certain printing effects are almost universally considered to be protective rather than harmful as regards chemical deterioration of papers; therefore, the amount present is immaterial providing the desired strength is maintained, for of course addition of mineral matter weakens paper. Limits as to mineral contents were dropped from the German standard paper specifications in 1904. While probably the content of animal glue or of starch used for sizing paper should be as low as possible, there is little evidence that either of these has a harmful effect on paper. There is some evidence, in fact, that they, like most minerals, have a protective effect. As mentioned by Kohler and Hall, the Swedish Government investigators, there appears to be considerable difference in the effect of acidity due to internal sizing (that is, added to the paper-beater stock) and that imparted in surface-sizing the paper. The latter appears to be much the less harmful, and this should be taken into account in formulating acidity requirements for surface-sized papers. Mention has previously been made of the value of ash determinations in the case of writing papers containing no added mineral matter, as an evidence of how thoroughly the paper stock has been cleansed by the washing treatments.

For all except the highest grade of papers, specification of strength, acidity, and rosin content would appear to be sufficient. For permanent papers, in addition to these requirements, it is believed that content of alpha cellulose and copper number should be specified, as well as the constancy of these properties and strength, when the paper is subjected to a heat test. While such tests are time-consuming and expensive, these circumstances

should be disregarded in view of the importance of taking every precaution to make certain that papers of this grade will be of the highest quality.

In consideration of both usage of papers and the grades of papers available, it is suggested that they might be classified in four main groups according to their degree of cellulosic and non-cellulosic purity, as related to their service requirements. According to such mode of classification, the present domestic printing and writing papers may be grouped as follows:

Grade I. Permanent papers, having a maximum degree of purity; free from unbleached fibers, and highly lignified fibers such as ground wood. Indicative chemical properties: Alpha cellulose, 90 per cent; copper number, 1.5; rosin, 1 per cent; acidity, 5 pH; changes on heating 72 hr. at 100 deg. cent.: decrease in content of alpha-cellulose should be not more than 1.5 per cent; decrease in folding endurance not more than 25 per cent; increase in copper number not more than 0.5.

Grade II. Papers quite highly purified that may be expected to have a minimum life of 100 years; free from unbleached fibers, and highly lignified fibers such as ground wood. Indicative chemical properties: Alpha cellulose, 80 per cent; copper number, 2.5; rosin, 1.5 per cent; acidity, 5 pH.

Grade III. Papers having a fair degree of purity that may be expected to have a minimum life of 50 years; free from unbleached fibers, and highly lignified fibers such as ground wood. Indicative chemical properties: Alpha cellulose, 70 per cent; copper number, 5; rosin, 2 per cent; acidity, 5 pH.

Grade IV. Papers having a low degree of purity containing considerable organic impurities, suitable for current use only. This grade includes papers containing unbleached fibers, and highly lignified fibers such as ground wood.

All figures given for chemical components in these grade descriptions are upper limits, except for alpha-cellulose contents which are lower limits. Alpha-cellulose content and copper number are based on total cellulose content.

As stated in these grade descriptions, the purity limits are given merely as indicative and are not suggested as specification requirements, for the fixing of specification details must necessarily be done by the consumers and manufacturers directly concerned. In each of these grades, the establishment of two or more strength requirements for each weight of paper is necessary. Also, as less strength is required in book papers than in writing papers, different strength ranges are necessary for these two classes of paper. The strength requirements, of course, must be fixed with consideration of the kind and extent of mechanical stresses to which the paper will be subjected in its use. The strength gradations of the Government papers should be of particular assistance in this respect, although as they refer to a testing condition of 50 per cent relative humidity, they should be modified for commercial use to accord with the standard commercial testing condition of 65 per cent relative humidity.

Conclusion

Although this system of grading papers in respect to their permanence may appear to have a rather revolutionary aspect, it nevertheless seems to accord with the present state of knowledge of causes of deterioration. The composition standard has not proved adequate, since it does not definitely insure that a chosen paper will be permanent nor that a rejected one will fail to have satisfactory life. The usual viewpoint in connection with the composition standard limits permanent papers to a single class, and leaves wide open and without control all the other types of paper, which represent the bulk of printed matter in libraries and record files, and which, without doubt, include papers which are reasonably permanent. The suggested system of grading includes all types classified according to their probable degree of permanence as understood in the light of present knowledge. While obviously tentative, this system would appear at the time to best meet the practical aspects of the whole problem of maintaining permanent records, whether written or printed.

Technical Specifications for Paper Users

By B. L. WEHMHOFF,[1] WASHINGTON, D. C.

This paper is a discussion of the use of technical specifications in the purchase of paper for use in the printing industry. Data are given to show the wide variations in quality between papers sold under the same designation. The experience of the Government Printing Office during the past 20 years is cited as an example of the practicability and value of technical specifications in the purchase of 50,000,000 pounds of paper annually. Benefits to be derived by the printer by a standardization of grades of paper and their purchase under technical specifications are described, as well as the benefits which would result to the manufacturers. Since standardization of grades of paper would be of considerable assistance in the purchase of paper under technical specifications by small consumers, reports from committees of the American Pulp and Paper Association are quoted to show the present attitude of part of the paper industry toward standardization.

PAPER is one of the most important materials manufactured today, both as regards its uses and its monetary value. The Department of Commerce states that paper and paper products manufactured in 1927 were valued at more than $800,000,000. The printing and binding industry in which paper is the principal raw material takes fifth place among the major industries of this country on the basis of value added to the raw materials by manufacture.

Practically all industries have standardized the purchase of their raw materials on the basis of technical specifications. The paper manufacturer, for instance, buys his materials such as pulp, rags, chemicals, and dyes in this manner. Printing and binding is the only large industry in this country today which does not buy raw materials on technical specifications. With the exception of the Government Printing Office and a few other large consumers, the printers of this country still purchase paper, their most important raw material, by rule-of-thumb methods.

It is possible to form an impression of various samples of paper by look and feel, but it is impossible to determine relative cost values or relative quality, permanency, and durability of different papers by any method except technical tests. The purchase of paper under such broad terms as bond or ledger, even when qualified by such terms as sulphite, rag, or rag content, will permit the delivery of paper of quality inferior to that desired or required. For instance, there are many sulphite bonds on the market today which will not comply with the Government specifications for this grade of paper. There is probably an even greater difference in the qualities of rag papers containing the same percentage of rag than in the case of sulphite papers, due to the difference in the quality of the rags used in their manufacture.

The test results on commercial brands of paper given in Table 1 show the wide difference in quality between papers having the same fiber content and sold for the same purpose.

For over 20 years the Government Printing Office has been purchasing paper under technical specifications. A study of the specifications in use today shows a considerable difference from those used several years ago. The bursting-strength test was formerly considered most indicative of the strength of paper. In recent years the folding-endurance test has been recognized as being much more indicative of the physical quality. For a time fiber analysis, weight, and folding endurance were considered ample tests for quality in such papers as bonds and ledgers. Recently, however, there has come a realization of the fact that chemical as well as physical tests indicate wide differences in the same kinds of paper. These tests are of special importance in those intended for permanent record use.

The Government specifications for paper are drafted by the Paper Specifications Committee of the Joint Committee on Printing. This committee makes an annual report to the Joint Committee covering the specifications for the following year. The changes recommended include results of research by members of the committee and any other improvements or changes necessitated by new developments in paper manufacture and in the printing and binding industry.

As a result, the Government specifications for any grade of paper represent the latest development in that particular grade. The Federal Specifications Board recently adopted the Government Printing Office specifications to cover all paper purchased by the various Government agencies in the field service, in order to eliminate any confusion which might result from the use of two sets of specifications.

The Government specifications for paper are composed of two parts: First, technical requirements covering physical, chemical, and microscopical tests which show the quality and character of the fiber used and insure their proper treatment during the process of manufacture; and, second, standard samples which show the desired characteristics of color, finish, formation, cleanliness, and watermark. Each individual specification has been drawn to cover the desired quality of paper for the purpose intended.

The experience of the Government during the past 20 years has proved definitely that not only can paper be purchased successfully on technical specifications but that it is the only method by which both buyer and seller are assured fair treatment. It assures the buyer that he will receive paper of the specified quality, and it assures competing firms that their competitors must quote on and deliver the desired quality. An added advantage of this method of purchase is that it invites competitive bidding.

Testing deliveries for compliance with specifications is as important as specifying the characteristic desired. This, of course, applies to any material purchased on technical specifications. Tests on deliveries insure the furnishing of paper of the quality specified, since all paper not complying with the specifications is rejected.

Technical specifications for paper should cover every desired quality. If surface characteristics are of primary importance,

---

[1] Technical Director, Government Printing Office. Mr. Wehmhoff is a chemical engineer, a graduate of University of Washington in 1914. Experience prior to graduation was in mechanical and operating departments of newspapers in Idaho and Washington. Served as chemist in commercial laboratories on the Pacific Coast and also with the du Pont Smokeless Powder Company. Engaged in research on toxic gases at the Chemical Warfare Arsenal, Edgewood, Md. Located at the Government Printing Office since 1925. Appointed Technical Director on October 15, 1929.

Contributed by the Printing Industries Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

TABLE 1 TEST RESULTS ON COMMERCIAL BRANDS OF PAPER

Fiber content		Sizing		Ash, per cent	Weight (17 × 22, 1000), lb.	Bursting strength		Folding endurance	
Rag, per cent	Bleached coniferous chemical wood, per cent	Glue	Starch			Points	Ratio (1000 average sheet basis), b.s. ÷ wt.	Machine direction (average), double folds	Across machine direction (average), double folds
				Bonds					
100		Present	None	0.7	39.4	73.5	1.86	2311	2133
100		Present	None	0.7	39.2	37.0	0.95	171	95
	100	None	Present	0.5	39.6	36.0	0.91	268	287
	100	None	Present	0.8	39.8	26.0	0.65	7	7
				Ledgers					
100		Present	Trace	1.0	56.2	91.0	1.62	1615	1695
100		Present	Trace	0.4	55.0	59.0	1.08	613	414
	100	None	Present	1.3	56.8	50.0	0.88	212	575
	100	None	Present	1.0	55.8	40.0	0.72	20	55

the physical and microscopical requirements should be so modified as to permit the manufacturer to achieve the desired results. All Government specifications are based on maximum and minimum requirements, and indicate the minimum quality of paper that will be accepted in each of the different grades. Specifications are not intended to be formulas for manufacture of paper, but merely define the minimum quality acceptable. Manufacturers may, of course, supply better qualities if they so desire.

At the present time technical specifications for paper are little used by small consumers, as manufacturers have not standardized their products on the basis of technical tests. The fact that the average printing plant is thus handicapped has been recognized by the United Typothetae of America, which cooperated in a research program with the Government Printing Office to standardize bond and ledger papers. The standardization refers to quality only and not to sizes and weights, which are fairly well standardized. The results of this work were utilized in Government paper specifications in 1925 and subsequently.

With the exception of chemical tests for the presence of certain sizing materials, the original recommendations covered only physical and microscopical tests. These recommendations have been slightly modified, and chemical tests have been added to aid in insuring maximum serviceability. Five grades each of bond and ledger papers have been found ample to meet all requirements of the Government service.

Another advantage which would be gained by the standardization of bond and ledger papers by the manufacturers is a considerable reduction in the number of grades, which would in turn result in savings in mill costs.

Since the general use of technical specifications in the purchase of paper would be aided to a considerable extent by the standardization of grades by the paper industry, the following is of particular interest:

The committee on Simplification and Standardization of the American Pulp and Paper Association, in a report submitted to the association last February, stated that the committee "is in favor of any practical standardization in the future—but that after a thorough investigation throughout the trade, it is found that the standardization of grade of paper is impractical at this time, as evidenced by the reports of the subcommittees." An examination of the subcommittee reports referred to as covering a thorough investigation throughout the trade shows them to represent the views only of the manufacturers, no expression having been obtained from the consumers.

Among the reasons for the impracticability of standardization cited in these reports are the following:

1 Paper making is an art and therefore intangible.

In some cases it may be an art, but the resultant product is the principal raw material used by the printing industry, and as such, its qualities can and should be expressed in definite technical terms.

2 Physical tests are not entirely significant elements in quality.

This is a well-known fact, and as stated, is but a half-truth, since modern technical specifications for paper do not depend on physical tests alone.

3 The life of paper is affected by the conditions of its use and the process used in correcting it into the finished job.

The fact that certain factors, at present not controlled, affect the life of paper is all the more argument in favor of making paper to comply with technical specifications which will insure the maximum service under such conditions.

4 Specifications for strength and durability would be misleading in the purchase of paper where appearance and attractiveness are the primary desiderations.

This argument is fallacious. Every paper must have a certain strength and durability, and properly drawn specifications include these qualities, even in the grades of paper mentioned, as well as the particular appearance or characteristic desired.

Particular emphasis is laid in the reports on the fact that printing and binding processes have not been standardized to the extent that the paper committees apparently think they should be and that as a result the processes have a variable effect on the life of the paper used. It is our opinion that such matters are not solely for the consideration of the paper manufacturers.

The paper committees further recommend that users should state their requirements to the manufacturers and allow them to determine the quality of paper required. This method of purchase is out of the question for the average printer that buys paper from a jobber who may or may not be acquainted with the properties of the papers he handles. The standardization of quality based on technical specifications and its purchase thereunder is the only assurance the printer has of obtaining paper of the desired quality.

In contrast to the report of the Committee on Simplification and Standardization is the first semi-annual report to the American Pulp and Paper Association of the work of their fellowship at the Forest Products Laboratory, Madison, Wis. Following are a few points from the report:

"To evaluate a material is to determine its fundamental properties and to express the results in numbers, technically correct and precise. These tools for the satisfactory measurement of properties are a prerequisite for sound technical advance in the industry.

"The whole structure of the pulp and paper industry depends upon the capacity of the sheet as marketed to fulfil the requirements imposed by the particular conditions of use. These requirements can always be translated into corresponding physical or chemical properties.

"Each mill is faced with the necessity for determining precisely the physical and chemical properties of the finished sheet in order that it may know for a certainty that the sheet will satisfy the requirements of the trade.

"Therefore the field of research selected is that of new and improved methods . . . for the evaluation of paper. This field touches directly the business of every mill . . . and holds excellent possibilities for results of large practical value.

"It is self-evident that the physical properties of the sheets are as a rule much more important than the chemical properties, and the problem is therefore limited by considerations of maximum utility to physical properties only.

"In considering paper as a structure, we have a material which is to a considerable extent analogous to the usual materials of construction. It is no more nonhomogeneous or discontinuous than timber or ceramic materials."

Mr. S. L. Willson, president of the American Pulp and Paper Association, in his address at the recent annual meeting of the association, made this significant statement:

"We shall hear today regarding a new departure in research work in paper chemistry, which I wish to commend to you. Like other activities, this has been neglected in the past. The mysteries of the world are being gradually unfolded through scientific research. Considerable progress by individual mills has been made, but no concentrated effort in the industry has ever been instituted until the present time."

The experience of the Government Printing Office is ample evidence that paper not only can be standardized but that in so far as the Government is concerned it is now standardized.

It is interesting to note that some of the paper mills represented on the committee which claims that standardization is impossible are regular bidders on approximately 54,000,000 pounds of paper purchased annually by the Government Printing Office, although these bids must be made strictly on specifications.

The following observations should be of interest to all paper purchasers:

1 Paper can be purchased on technical specifications as proved by the experience of the Government Printing Office for the last 20 years.

2 The purchase of paper on technical specifications and the testing of deliveries is the only assurance the purchaser has that he is receiving paper of the desired quality.

3 The use of technical specifications guarantees fair treatment to both buyer and seller. It assures the buyer of competitive bidding on the same quality of paper and likewise assures the manufacturer that his competitors are bidding on the same quality.

Discussion

K. A. Taylor.[2] From the standpoint of the paper manufacturer, specifications, if reasonably drawn up, are of distinct advantage in that they tell him exactly what the customer requires of his paper. If the printer could state all of his requirements in the form of specifications based on physical measurements, it would help the paper manufacturer a great deal.

For specifications to be of real value, they should be based on a careful study of the use and requirements of each grade of paper. The properties of importance in meeting these use requirements should be determined, and methods for their evaluation, if not already available, should be set up.

All of the properties of paper which are important in printing can be measured and the results expressed numerically. However, the writer believes that in the past most of the emphasis has been placed on strength tests in the evaluation of printing papers and not enough on certain other important properties, One of the most important properties in paper for fine printing, especially in a paper with a fairly rough surface, is the ability to yield enough under light compression to take a perfect impression during printing. The coefficient of elasticity under compression gives a numerical expression of this property.

[2] Oxford Paper Company, Rumford, Maine.

William R. Maull.[3] The paper industry, not unlike other industries, has made strides since the World War. Competition has hastened this, with a necessity for more accurate control of results and quality. Prices were lower before the war, and it was less costly to make mistakes. The users of paper are more exacting, and rightfully so. Their costs in turn are dependent on the workability and uniformity of their raw material on higher speed presses; and it was during this period, say the past fifteen years, when the chemists, chemical engineers, and other technicians were introduced, not as a replacement of any existing personnel, but rather to find out the reason for things and set up their control stations and testing laboratories. Mighty good work has been done during this period, and it is predicted there will be more to come.

Let a word be said here on behalf of the old paper makers, the machine tenders, beatermen, and superintendents who made paper and excellent paper previous to this period. They were the skilled help who through experience, the feel of the pulp, gaged its slowness or freeness, and they knew when to dump the beaters, how to set up the Jordans, and other important factors to get the closing up of the sheet or other characteristics desired.

These men of the old school will always be with us if we are building the higher grade papers. They are the skilled mechanics, as in the automobile industry of which this city is the center. If one is building a fine car, there are assemblies to be made, scraping of bearings, and exact fits that require the highest skilled mechanic; and so it is in the paper industry—it has a similar problem. The skilled help may use and is using the technical help and the instruments provided. The quality paper maker today has the experience of the industry, together with the science that has been developed.

Now we are facing the future and must aim to further improvements. To accomplish this we must go into even a closer contact with the printer and user. There must be more work done in standardization; research requirements must be defined and a better understanding result so that progress can be always forward—for without that inspiring hope and determination a healthy growth will not exist.

R. F. Reed.[4] Few modern industries can afford to purchase their raw materials without carefully drawn technical specifications. The printing and lithographing industries are, in general, behind the times in this respect. Many of the difficulties arising in the lithographing and printing operations would disappear if paper could be purchased on the basis of qualifications for the desired purpose, and these qualifications can undoubtedly be expressed in terms of technical specifications in conjunction with samples.

The reason for the present lack of standardization is obvious. The great majority of printing firms are small, and there are relatively few technically trained men employed in them. The same is true of lithographing firms, although, on the average, individual lithographic houses are much larger than print shops. Both are highly specialized industries and are based on methods which are largely empirical. Paper technologists in general know little about the paper requirements of lithographers and printers, and the latter know little about the technology of paper. When paper troubles arise in lithography or printing, contact with the source of the paper is usually through salesmen who are not technically trained and who can be of little real assistance to

[3] Vice-President and General Manager, Dill & Collins, Philadelphia, Pa. Chairman of Paper and Pulp Committee, Printing Industries Division, A.S.M.E.

[4] Director, Department of Lithographic Research, University of Cincinnati, Cincinnati, Ohio.

either side. Consequently, there is little background upon which to base technical specifications.

For this reason, the Lithographic Technical Foundation and the Bureau of Standards have planned a program of research for the development of technical specifications and tests for lithographic papers. It is expected that work on this project will begin at the Bureau on July 1, 1930.

W. G. MacNaughton.[5] On the desirability of specifications to cover every desired quality, the writer is in entire accord. It is when they enter into the question of the nature and source of the fiber constituents that reasonable objection can be raised.

The author states that there may be a greater difference in the qualities of rag papers with the same percentage of rags than between rag and wood fiber papers, due, in his opinion, to the difference in the quality of the rags used. He might also have said that there is a difference in papers made of identical fiber constituents of any furnish. The test specifications should determine the quality regardless of the composition.

The author would appear to want the specifications to determine the relative cost of production as well as the suitability for use, which, it must be admitted, is outside their province.

The only possible justification for requiring a paper to be made from specified fiber is that this is a relic of the "rule of thumb" period of purchasing as well as the making of paper.

[5] Manufacturing Department, International Paper Company, New York, N. Y.

Author's Closure

It would be desirable to have the specifications include tests which would show definitely the probable life of papers intended for permanent records. Such tests have as yet not been developed to the extent that they are usable.

The accelerated tests described by Mr. Scribner may possibly be of value in this respect. However, they should not be assumed to give the desired results until they have been checked against actual aging tests.

Our attitude with reference to permanent record papers is that the best rag papers have proved their permanency by actual aging, whereas the other paper-making fibers have not given such conclusive proof of their permanency. Therefore for all permanent record work we specify not only that rag fibers shall be used, but that the rags shall be new and that the finished paper must have certain physical characteristics as well.

The author does not agree with Mr. MacNaughton's statement that specifying the fiber content of papers, particularly those used for permanent record use, is a relic of the "rule of thumb" period of purchasing as well as the making of paper, since no definite proof is as yet available to show that fibers other than rag possess the required permanency.

It is true that there is a wide difference in physical qualities of paper made from different grades of rag as well as from different grades of wood pulp. The physical and chemical tests in the specifications are drawn to insure the desired physical qualities.

PI-52-7

The Printing Engineer and Printing Profits

By W. L. CHURCHILL,[1] NEW YORK, N. Y.

While the average earnings of printing and publishing plants is above the average of manufacturing industries, fully one-third of the businesses reporting showed a deficit averaging 9.26 per cent of their sales. Here is a highly technical industry manned by those who have had to devote years to specialized training and that operates with a high average of loss and with earnings insufficient to perpetuate the business. The engineer should be trained to think in terms of profits. Profits do not necessarily follow savings. Proper management requires that the engineering mind discover and eliminate the factors that prevent or destroy profits.

THE printing industry, in common with all of our manufacturing groups, is, as an industry, making a very unsatisfactory showing for its stockholders and owners.

According to the recently released Corporation Returns for 1928, 10,299 corporations under the general classification of printing and publishing earned a net profit equal to 8.36 per cent of their gross sales. The average earnings on the sales of all manufactured products for 1928 was 5.8 per cent. This places printing and publishing in a class better than the average of all manufacturing industries. Despite this comparatively high showing, 3511 firms, or 34 per cent of the 10,299 printing and publishing firms reporting, reported deficits averaging 9.26 per cent of their sales.

There were 6788 printing and publishing firms that reported profits averaging 11.17 per cent of their gross sales. These firms, representing 66 per cent of the total number reporting, were assessed income taxes upon net profits of $223,607,076. The remaining 34 per cent reported deficits of $29,815,071. The average earnings of the profit-reporting firms is approximately $32,000 per year. The average losses of those reporting no net earnings amounted to $8500 each.

From the standpoint of the dollar volume of business done by the firms reporting no profits, 13.8 per cent of all printing and publishing business is done at a loss averaging 9.26 per cent.

Even when the best possible interpretation is placed on these figures, the fact remains that one out of every three printing firms conducted its business at a loss during 1928, a very good business year.

It is possible that the losing group contains a much larger proportion of small firms not fully established. Offsetting this, however, is the fact that a very few large publishers are chiefly responsible for the good showing of the earning group. One of these large firms alone earned approximately 10 per cent of the reported net income of the entire industry.

Despite the apparent better position the printing and publishing industry holds over many other industrial groups, its profit showing as a whole is not one to be proud of, especially when the character of its work and its personnel are considered. Here there is a highly technical industry manned by people who have had to devote years to specialized training in order to conduct their work with skill and efficiency. Obviously there is something wrong when one-third of the firms in such an industry employing this exceptional skill and ability report deficits from their operations.

Here is a group of over 3500 firms that conducted their business at an average loss of 9 per cent of their gross receipts in 1928. Their customers obtained printing from them below the cost of its production and sale. These 3500 firms depleted their assets, and robbed their stockholders and owners to the extent of $8500 per firm, or an aggregate of nearly $30,000,000.

In addition to this distressing and indefensible situation, a large portion of the firms reporting profits have earnings that are insufficient to insure the perpetuation of their businesses. They lack sufficient surplus to invest in modern equipment that will enable them to keep pace with the developments in their industry and with the growth in demand for printing products. If these firms and the losing firms should be placed on an adequate profit-earning basis, manufacturers of printing equipment would no longer be hungry for business to fill their plants.

If it were possible to list the firms in the printing and publishing industry doing their full duty to society by earning adequate profits, the number would be very small. It has been estimated that less than one firm in twenty-five continues to operate upon a sufficiently profitable basis to enable it to remain in business for a period of 30 years without reorganization, refinancing, or some major change involving loss to stockholders and owners.

We are so accustomed to this situation that we give it little thought or concern. We accept it as a matter of course. We look upon it as an inevitable consequence of competition. We even in this enlightened day talk of the "survival of the fittest" and of "price wars."

There is no inherent reason for this condition in the printing or other basic industry. Engineering must see its outstanding opportunity and step in and correct this condition. This statement would seem to imply that the engineer is responsible for the present general lack of adequate profits in industry. He is responsible to the extent of failing to realize that he should long ago have assumed this responsibility.

To date the engineer has not been trained to think in terms of profit. His training has been directed toward lowering costs,

---

[1] Economist-Engineer. Mem. A.S.M.E. Mr. Churchill has been connected in executive capacities with the American Pneumatic Service Corporation, Boston; The National Pneumatic Service Co., Chicago; Schreiber & Conchar Mfg. Co., Dubuque, Iowa; Yale & Towne Mfg. Co., Stamford, Conn.; McKinnon Dach Co., St. Catherine, Ont., and has served as industrial engineer and consultant with Stephen T. Williams & Staff, C. E. Knoeppel & Co., and the McDonald-Churchill Corporation. As industrial engineer and consultant Mr. Churchill has served a large number and variety of industries including gold-dredging in the Yukon, land reclamation in California, and during the war specialized on the development of shipbuilding, especially on the Pacific Coast. Since 1920 Mr. Churchill has devoted the major portion of his time to research into the economics of profits. In this work he has had the cooperation of a number of manufacturers associations as well as many private manufacturing firms. His discoveries in this branch of economics have resulted in his being called upon to address many associations interested in the improvement of industries and his written contributions have been widely read.

Presented at a meeting of the Metropolitan Section, New York, N. Y., April 4, 1930, sponsored by the Printing Industries Division, The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

increasing output, improving quality, and effecting savings. He has generally assumed that the accountant and salesman could be depended upon to see that his efforts resulted in profits.

Profits do not necessarily follow savings. The most perfect plant designed for the most efficient operation and operated with the greatest skill and economy can still fail to earn profits. It is not sufficient to condemn management as the cause for unprofitable operation. Management needs enlightenment on the specific and fundamental factors that destroy or prevent profits. It requires the engineering mind to discover and eliminate these fundamental factors.

The engineer's training and aptitude peculiarly fit him to determine and correct fundamentals that are responsible for the low average returns to stockholders and owners in the operation of industrial enterprises.

The engineer will need to study these causes and add to the range of his activities the ability to detect them and prescribe for their correction.

When the engineer fortifies his knowledge of engineering elements with a knowledge of how to convert these elements into earning power, he not only multiplies his own value and earning power, but increases the earning capacity of the institution with which he is connected. He increases the earning power of the employees, and he benefits business and society at large.

All of our material progress depends upon profits. Firms with ample profits reinvest a large portion of them in new buildings, equipment, research, and special services, making business for their suppliers and insuring their own growth, development, and perpetuation.

The author will briefly touch upon a few of the profit factors that at present are practically unknown and will endeavor to indicate why the engineer is specially qualified to understand and apply them. Take the question of the amount of profit that should be earned. If you are seeking a startling revelation of the ignorance existing in regards to what constitutes proper profit, the author will suggest that you ask various heads of enterprises with which you are connected this simple question: "How much profit should your business earn per year?" Not one business executive in ten will quote a figure sufficient to meet the requirements of business perpetuation.

This statement is based upon experience covering several hundreds of such business questionnaires. The inadequacy of the profit conceptions of these business heads explains the cause for many of the failures to attain profit levels that are safe.

A second question to ask is: "On what should the profit of each product be based?" Replies received from 125 manufacturers answering this question in combination with the first elicited 42 different bases and rates for profit determination. Not one of these 125 firms, whose businesses averaged over $1,000,000 each, had a correct basis for profit determination although 11 of these firms had a sufficient amount as an objective.

There is one definite basis for correctly determining the amount of profit that should be earned by any enterprise engaged in a profit-making industry. The formula is as complex and yet as definite as determining the horsepower of an engine. It is not dependent alone upon investment, sales volume, number of employees, or any other single factor. It requires a knowledge of values of equipment and facilities, of operations involved, of personnel requirements, and an understanding of the economics of production and distribution.

Obviously we should not ask the accountant or sales executive to add these typical engineering functions to the list of their attainments in order that they may arrive at profit objectives and be able to determine the profit to include in the prices or charges for all transactions. The engineer must include this among his duties. He needs only to acquire a little further understanding of economics in addition to the functions already included as part of his activities.

There are only some 8 or 10 fundamental questions of the nature of the two already mentioned that have to be understood in order that any worthy enterprise may function profitably. When they are all understood, "price wars" and "survival of the fittest" become obsolete phrases. There is no destructive price competition, and all worthy firms may survive because all become fit.

The engineer has concentrated chiefly upon means for cost reductions and improvement in quality and volume of output. He has been very successful along these lines, but all too often the improvements are directly or indirectly the cause of profit shrinkage through failure to secure such improvements for the betterment of profits.

One engineer recently examined a medium-sized plant to find means to improve the subnormal earnings of the firm. He found a way to reduce the cost of all of the products 5 per cent. He reported his findings to the president in the presence of the plant's sales manager. The latter spoke up and said: "Fine! Now we can reduce our prices 5 per cent and sell a whole lot more goods." The engineer said: "Hold on. I thought you asked me to find ways to restore your profits to their proper level. This cost reduction will enable you to do it if you sell no more than at present and get only the present prices. If you intend to throw these profits away in an effort to take business from other people, you shall not have the benefit of the plan."

To many it may sound like asking the engineer to usurp a function that belongs to others when it is said that the pricing of products and services must be based upon engineering and economic elements readily understood by the engineer. This statement is made, however, after several years' intensive study of the causes of sub-normal profits, covering first-hand knowledge in over a hundred manufacturing plants, including many printing establishments and printing departments.

Revising prices to accord with the known engineering and economic elements has in many instances converted losses to substantial profits almost overnight. This has been particularly true with plants whose engineering activities had developed a high level of efficiency, yet where profits had continued at subnormal levels or actual deficits were the order of the day.

There are as many cases of unintentional overpricing as there are of underpricing. Overpricing drives away business and abnormal profits with it. Underpricing encourages business, but with resultant losses that go with underpriced efforts.

Determining the correct basis for pricing is an engineering task, but when properly applied, insures continuous profits to any reasonably well-managed plant or industry. Under such conditions, super-management brings super-profits, indifferent management brings indifferent profits, but the proportion of enterprises so poorly managed as to make no profits will be very small. The engineer needs to become not only profit-conscious, but needs to assume the profit responsibility. Profits will more than ever call upon the additional abilities of the engineer. He need not forsake the special activities upon which he is engaged in order to insist upon such efforts as occupy his attention resulting in the full profit that should be obtained for these efforts.

No other profession or group is at present assuming the responsibility for profits, at least with any degree of success, as is evidenced by the limited profits of the industry as a whole. The fundamental factors that govern profits are quickly learned and easily understood. Application becomes a matter of simple routine.

The printing industry may be likened to a malarial district where a large portion of the individuals exist in a semi-sick state while a comparative few seem to continue in robust health.

We used to think that there was no help for this condition. It was in the air, and we took quinine and all kinds of patent medicines to minimize the effects and with the hope of prevention or cure. When the cause of malaria was discovered and malaria carriers were removed by drainage and similar measures, these districts were converted into healthful communities, in which any one may now live without fear of this ailment, by simply keeping the community free from the conditions which allowed the mosquito to thrive.

Likewise with industry, remove the fundamental cause of the low state of profit health (ignorance of profit economics), and all may enjoy the full vigor of successful endeavor. Industry needs to have the cause removed rather than administration of periodic doses of quinine.

The printing engineer, which includes not only the graduate engineer, but all whose activities are responsible for the efficient operation of a printing plant or plant manufacturing printing equipment, has an excellent opportunity to lead the way in the development of profit responsibility in the engineering ranks. He is dealing with people of above the average understanding, and cooperation is more readily assured than in industries manned by a less skilful class and where there is less interest in their own work.

Any printing establishment can place itself upon a profitable basis if it will indulge in sufficient study and application of sound engineering principles in the conduct of its operations. The engineer can bring about this desirable and necessary condition to the betterment of his own position and remuneration as well as to the benefit of all business and of society as a whole.

Profits mean progress. The greater the profits, the greater and more rapid our progress. There is a difference, however, between profits and plunder. Profits are profits only when all parties to the transaction benefit thereby.

The profitable industries pay the most profitable wages; that is, wages that provide a surplus to the worker over and above his necessities. This condition in turn encourages the best workers to flock to that industry and in turn develops their employing interests to higher profits and their products to greater demand because of their greater value.

These facts are splendidly illustrated in a comparison of the average earnings of workers in the various industrial groups as reported by the United States Department of Commerce for 1927.

The average yearly wages in manufacturing industries, including printing and publishing, were approximately $1300 in 1927. The average of all wage earners in the printing and publishing industry was $1782. Including salaried people (this industry pays nearly 40 per cent of its people by salary), the average earnings of all workers in the printing industry were $1847.

The textile industry, comparable in many ways to printing and publishing, paid an average of $1040 to each worker in 1927. The average profit earned by each worker in the textile industry for stockholders and owners amounted to $115. In the printing and publishing industry the average was $354, or more than three times the per capita profit of textile workers.

You are fortunate in being in an industry that has already displayed leadership in our industrial advancement and in demonstrating that high profits induce high wages and that the combination of both spells low costs that the consumer profits generously by as well.

We read about the wonderful value per dollar in our automobiles produced by another comparatively high-profit and high-wage industry; yet where will we get comparable value for the pennies and nickels spent in the printing industry?

Even with printing's enviable position in relation to other industries, we must not overlook the fact that one out of every three of the printing and publishing firms is losing money. We have a long way to go to put the entire industry upon a profitable basis and still further to bring the industry up to its full measure of profit so that it can continue to progress and add to the sum of our human development.

Discussion

MARTIN E. POPKIN.[2] This illuminating paper has opened a subject of paramount importance to business in general. The economics of profit has been so sadly neglected that we can be greatful to the author for his efforts in bringing the issue to the attention of the engineer as he has.

We engineers, in a broad sense, supply the world with its conversion tools, in one form or another. We create them, and consequently are responsible for their operation and for their effect upon those whom they intend to serve. As their parents we understand them best and organize their work so they will behave as all good tools should. In short, we are accountable for their being, but not accountable for what they make of themselves.

The great need for cooperative engineering administration in industry is equal only to the engineers' need to recognize the fact as such. The social economy of our age is conscious of the industrial influence upon our whole society and its culture.

Industry today is the very backbone of our civilization, and no other plays a greater part in our general economy than the engineer. Every political credo is vitally concerned with the relation between industrial structure and its part in the current need and welfare of society.

In the last decade the thought has preoccupied the minds of our most gifted scholars is concerning man and his machines.

It is an engineering age in which we are living. Engineers should recognize their obligation to industry only in so far as it serves society. Seeing that capital is intelligently used in the service of industry is part fulfilment of the engineer's responsibility.

Our whole art may be reduced to the premise that its intent is to supplement labor in the interest of a growing and more enlightened civilization. Any influence that may jeopardize this alliance is distinctly out of harmony with the engineer's concept of his work.

According to recently released corporate returns for 1928, a large percentage of the workers and technicians employed by one-third of the firms in the printing industry were insecure in their employment. While this is not peculiar to the printing industry, it is not a condition to which engineers need subscribe. The engineer as a supplement to labor must keep vigil to the end that it meet with no hazard which may be in his power to avoid. Profitable operation is the answer.

Our work is defined as "the art of organizing and directing men and controlling the forces and materials of nature for the benefit of the human race." With this as his creed, the engineer who does not concern himself with earning power breaks faith with labor, his greatest trust.

It is my privilige to be informed on the author's keen insight into the proper utilization of capital. His facts and his views, when known, are so startling in their simple truths that it is difficult to conceive how some one has not shouted them from the housetops heretofore.

Though the printing and publishing industry ranks better in profit earnings than the combined average of all manufacturing industries, it nevertheless showed one-seventh of its total dollar volume to be done at a loss.

[2] New York, N. Y. Assoc-Mem. A.S.M.E.

It is only reasonable to look to the engineer in matters of this sort. Profitable operation of industry is as much his concern as any other phase of his work. The printing engineers can render their industry invaluable service by bringing the need for scientific profit control to the attention of their principals and associates.

PI-52-8

Some Problems in Printing Standardization

By FRED S. ENGLISH,[1] NEW LONDON, CONN.

The lack of standardization of certain factors which enter into the design and use of cylinder printing presses is discussed in a general manner, particularly relative to the standardization of plates and bases, diameters of cylinders, depth of impression surface below cylinder bearers, height of bed bearers, sheets, forms, and names of parts.

IN considering the general subject for this session, i.e., "The Design of Flat-Bed Cylinder Presses," it appears that there are certain fundamental principles which are dependent upon various established or non-established standards. Undoubtedly these standards will be assumed or taken for granted in the development of the papers for the session. It seems, therefore, that a paper along these lines will be appropriate, considering particularly the lack of uniformity of many of these so-called standards.

Apparently little work has ever been done along the lines of standardization in the printing industry. To be sure, there is a standard height for flat forms, and the industry is approaching a standard thickness for flat plates and bases; there also is something in the way of standard sizes of sheets, and partially standardized catalog, book, and magazine pages.

The U. S. Bureau of Standards, cooperating with various organizations, has recommended standard sizes for paper, catalogs, commercial forms, checks, etc., but apparently they are not closely followed.

Practically everything else has been left to the varying ideas of the different equipment and material manufacturers or to the users of such equipment and material.

This paper will deal with some of the difficulties which, due to this lack of basic standards, face the manufacturer and user of printing machinery, with the hope it will have a part in the development of much more complete standardization than we have at the present time.

Type Height. The height of flat forms is already standardized in this country at 0.918 in., and this, of course, applies to both type and plates.

Height of Bed Bearers. The height of flat-bed bearers, however, is not standardized, some manufacturers apparently considering that they should be exactly type high and others that they should be just a trifle lower.

It is possible that some makes of presses run better with bearers of one height, and others with bearers of another height. Still, it would seem that the pressman would be better off if he always knew the exact relation of the top surface of his type-high form to the top surface of his bearers.

Standardization of bearer height, coupled with standardization of the depth of the impression, which will be considered later, would certainly tend toward more uniform make-ready and more uniform impression.

Height of Bases and Plates. An inspection of the catalogs issued by the various manufacturers of patent bases discloses the fact that some of these bases are made 0.757 in. high, while others are 0.759 in. high; and, what is possibly more serious, it is not uncommon to make bases to special heights to suit the whims of some particular customer. These special heights vary all the way from 0.688 in. up to 0.759 in. In addition there is still another height for original halftones. This, it seems, is absolutely necessary.

However, the International Association of Electrotypers is now working toward the standardization of the height of bases and plates. In order to invite discussion, its Standardization Committee has rendered a tentative report recommending the height of bases as 0.759 in., and the corresponding height of plates as 0.154 in. This leaves 0.005 in. for interlay or underlay.

This association feels that scientifically there should be no allowance for interlay, but recognizes that many pressmen demand it, and therefore allows for it. The fact is recognized also that light work may not require quite as heavy an impression, and therefore a plate thickness of 0.151 in. is recommended for such work.

Much confusion will be saved in the pressroom when this or some other standard is finally adopted and comes into general use, as it certainly will be more convenient for the pressman to know that he will find the same underlay conditions no matter what style of base he is using.

Curved Plates. When one comes to consider curved plates he finds one of the most unsatisfactory conditions with which the industry has to deal, both as to plate thickness and as to cylinder diameter. The International Association of Electrotypers reported that they found 7 different thicknesses of plates and 20 different diameters of cylinders as standards in fairly constant use in *one foundry*. These plate thicknesses varied from 0.152 to 0.375 in., and the cylinder diameters from 5 to 48 in.

The U. S. Bureau of Standards reports that it found one printing establishment in Baltimore which had 26 different curvatures or thickness of plates.

At first glance it would seem that the small-diameter cylinder would require a thicker plate than the large cylinder, on account of the greater tendency to buckle on the small cylinder. However, the evidence submitted by the Electrotypers Association does not prove this to be true, and it is making a tentative recommendation of 0.166 in. as a uniform thickness for all plates.

In this connection consideration also should be given to the depth of the recess in the cylinder for these plates, i.e., how much if any should be allowed for underlay.

Diameters of Cylinders. Standardizing the diameters of the cylinders on rotary presses presents a much more difficult problem, because the diameter of the cylinder is dependent upon the maximum size of sheet which the press is intended to print. This is especially true in the case of web presses, where the diameter of the cylinder is absolutely dependent upon the size of the page or group of pages which it is intended to print. Therefore in this case the sizes of magazine pages must first be standardized.

---

[1] Chief Engineer, The Babcock Printing Press Manufacturing Company. Mem. A.S.M.E. Mr. English was born in 1873. He was graduated from the University of Vermont, in 1896. He has been with the Babcock Company since January, 1899, first as mechanical draftsman and in later years as Chief Engineer.

Contributed by the Printing Industries Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

In the case of sheet-fed rotary presses it is true also that the diameter of the cylinder is dependent upon the maximum size of sheet which the press is intended to print, and in general every press manufacturer is striving to get the largest sheet possible on the smallest diameter of cylinder, because the speed as well as the cost of his press is dependent upon the cylinder diameter.

Notwithstanding all this, it would seem that 20 different diameters are more than is necessary and that a series of cylinder diameters could be worked out which would adequately cover all requirements, provided the size of the pages of magazines and mail-order catalogs, as well as flat sheets, were properly standardized.

Even suppose it were found that 20 different cylinder diameters were necessary, is it not possible that standardization of these 20 sizes would prevent the future addition of more odd sizes?

With the thickness of plates and the diameters of cylinders properly standardized, the plate maker would have an opportunity to equip with standard plate-making machinery, which could be used for the requirements of many different customers, instead of being obliged to provide new equipment every time a new size or style of press is brought out, and having such special equipment stand idle except when it is being used for one special customer or group of customers. The cost of plates would undoubtedly be reduced, and at the same time the quality of the plates would be improved.

Depth of Impression. The depth of the impression surface on impression cylinders, i.e., the distance from the surface of the bearers to the body of the cylinder, is different in different makes of presses. This means a different total thickness of the tympan, and consequently a varying degree of solidity, so that the pressman who works on different presses must carry these varying conditions in his mind. Possibly this is of minor importance, but certainly standardization would be helpful, and it should not be a difficult thing to achieve.

Height of Cutting and Creasing Rules. There is no standard height of cutting rule for use on cutting and creasing presses. Two heights are in common use, 0.923 in. and 0.937 in., but in addition there are several other heights in fairly common use, running all the way from 0.916 in. to 1 in.

On account of this lack of standardization, cutting and creasing presses must be flexible, i.e., they must be built so that they can be adjusted readily to accommodate these different heights of rule, and the manufacturers must carry a miscellaneous assortment of bearers in stock.

It would not be difficult for the manufacturers of these presses to build them for a standard height of rule, but it is difficult to persuade the proprietor of a folding-box plant to use any height of rule but that to which he is accustomed.

Creasing rule is not so easily standardized, because the height must vary somewhat with the thickness of the stock being run. Besides, there is another element which enters into this situation, and that is the fact that different pressmen have different ideas as to the best height of creasing rule for any particular thickness and grade of stock.

Possibly these ideas could be standardized, and this, with standardization of the cutting rule, would reduce the number of sizes of creasing rule materially.

Standard Sheets and Forms. There are certain standard sizes of sheets in fairly common use, but it is not uncommon for a printer with a large contract to order stock especially suited to the job. Why? Simply because the job itself is non-standardized.

To be sure, there have been attempts to standardize catalogs, but the standard sizes do not seem to be followed very generally. This may be because the advertising experts do not fully understand the importance of such standards, but it is more likely due to the fact that a large proportion of printed matter is laid out by non-experts.

If the printer would adopt certain standard sizes of printed matter, both in sheet and form sizes, and then insist that all jobs be made to those sizes before considering them, it would assist very materially not only the paper mills and jobbers but the plate makers and the press manufacturers as well.

For instance, suppose the press manufacturer is designing a new press to take, say, as maximum, a 25 × 38 in. sheet. The first problem he encounters is, How large a form must be printed on that sheet? The present answer is 25 × 38, which all know is almost impossible. Notwithstanding the practical impossibility of doing it, sooner or later some printer is going to take such a job and try to run it on that press. He will get in endless trouble, and probably wind up by running it at a slow, expensive speed and with less than the full number of rolls covering the form.

Suppose it were thoroughly understood that it cannot be done and that no printer would consider the job until it was made to standard size; just imagine how much trouble would be saved for all concerned.

One might go a step further and insist that invoices, bills of lading, bank checks, and a thousand and one other things of that kind should all be in conformity with the U. S. Bureau of Standards recommendations.

Names of Parts. Except for a few of the larger and more prominent parts, the names which are used in describing the various parts of printing machinery and which must be used by the printer in ordering repairs vary according to the ideas of the manufacturer. To be sure, each different style of machine has some parts which are unlike those on any other machine, and for these the manufacturer must coin a name, but if the basic units had standard names it would greatly assist the printer in ordering his repairs.

For instance: A printer orders a fountain roll. He actually wants the composition roll which transfers the ink from the fountain, but he gets the roll which works inside the fountain proper and delivers the ink to the composition roll in question. Why? Because the manufacturer who received the order calls this roll, which works inside the fountain, a fountain roll; according to that manufacturer's code, the printer really wants a duct roll.

You can readily imagine how the printer goes "up in the air" and the harsh names he calls the manufacturer. Some people call this roll which works inside the fountain a "ball" or "bole" instead of a "roll."

Some manufacturers call the parts on which the bed runs "tracks;" others call them "way frames." We have "feed guides," "side guides," "drop guides," "drop fingers," "lazy fingers," "grasshoppers," etc., without limit and all mixed up. Why not unscramble the mess, make a fresh start, and then try to teach the printer to use the correct names?

Summary. No attempt has been made in this short paper to cover all the possibilities or to define just what the various standards should be or how the work should be done. It is intended, rather, to show the vital need for more standardization in the printing industry, with the hope that it will help lead the way toward standardization of many units which are now left entirely to the imagination of either the printer or the equipment manufacturer.

Discussion

OTTO W. FUHRMANN.[2] A standardization of the distance between bearer top surface and body of cylinders, viz., the

[2] Director, Division of Graphic Arts, New York University, New York, N. Y. Assoc. A.S.M.E.

thickness of packing, is highly desirable, in view of the variable factors in the compressibility of the packing material and the "make-ready" and also in the varying heights of such printing elements as wooden blocks, type, slugs, and plates on patent bases. The pressman's greatest trouble lies in getting a level surface of his form, particularly if it is of a mixed character. His "make-ready" could be reduced to next to nothing if his forms were precisely level. But that is a different story with which we are not concerned here.

Mr. Eney's[3] suggestion that every cylinder be marked plainly with the amount of packing it is to carry so as to have the printing line on that periphery of the cylinder that corresponds to the length of the form is excellent; if it were followed the pressman would never be in doubt whether to add to the underlay or to the packing, and this would prevent the all too frequent overpacking with its resultant troubles of wear on plates, stretching of sheets, and pulling out or tearing of top sheets.

The lack of standards among presses of different makers means that the education of pressmen to a more uniform procedure of make-ready is made difficult. The writer is speaking from the standpoint of the practical printer who finds the great majority of the shops equipped with a variety of models and makes. The various standards for packing, height of bases, and thickness of plates should not be fixed arbitrarily, but on the basis of a sensible procedure of make-ready that has as its aim perfect contact of all printing surfaces and not the idea of bettering the photoengraver's work.

Charles H. Cochrane.[4] There seems to have been little or no thought on the part of printing-press designers to provide for sheet heaters and electric neutralizers on their machines. Usually no space is left for these attachments, and this adds to the fire danger of gas heaters, which can be made wholly safe where there is room. If the machine designers would leave such space and also provide uniform means of attachment, as bolt holes or crossrods of uniform diameter, this would go far toward standardizing heaters and neutralizers. One manufacturer has cited seventeen sizes of their flat-bed presses. The writer's company has to make over 250 sizes and styles of heaters to fit all of the familiar types of printing machines.

One discussor has inquired as to the cause of static electric troubles and the desirable heat to employ in the pressroom. A recognized standard of heat and humidity for the printer would help everybody. The writer's experience suggests that most pressrooms are kept too hot, and in winter far too dry. He recommends 70 deg. fahr. as the ideal temperature, with 50 to 55 per cent relative humidity. May we hope that some time soon the A.S.M.E. Printing Industries Division will be able to give an entire session to the problems of static electric troubles and offset and the several cures. Humidification appears to be looming larger and larger as the fundamental remedy.

Dewey Thibault.[5] The pressman is entirely at the mercy of the allied trades as to what he is supplied to turn out a good job of printing, and everything that he performs in make-ready is done to make up the discrepancies of the material that is furnished him. It would be a great help and saving to his employer if some method of standardization on evenness and thickness of plates, bases, press bed, and cylinders of presses could be accomplished.

The writer is much impressed with the meeting and everything that the engineers are doing to produce precision machinery, but there seems to be a lack of investigation on the part of the engineers as to possibilities of overcoming the pressman's greatest difficulty, offset.

The speeding up of machinery has added greatly to this difficulty as the sheets are delivered to the jogger so fast that there is no time for the ink to set. This difficulty had to be contended with when machines were hand fed and were running slowly, so it can readily be seen what the fast machines have added to the hazard.

An investigation of this difficulty on the part of press engineers will certainly result in some method of overcoming it, and will greatly help the printer in getting maximum production from these fast presses. The paper and ink manufacturers are doing everything in their power to solve this problem, but the press manufacturers with their high-speed machinery are making it doubly hard for them to do so.

Ernest F. Trotter.[6] The most interesting paper by Mr. English seems to call for a crystallization of the valuable suggestions therein made, and therefore two resolutions, on the subject of machinery and equipment standardization and on printing sizes of paper, are offered, as follows:

Resolution on Standardization of Equipment

WHEREAS, no standards for various types of equipment used in the many branches of the graphic arts have ever been adopted, and

WHEREAS, the lack of concrete information as to the requirements of the industry has caused endless confusion and the creation of many equipment units for which there is little or no justification, as well as tremendous expense to manufacturers who have to service such equipment, and

WHEREAS, it is obvious that better printing will result when all branches of the industry can cooperate in observing certain recognized standards; therefore be it

RESOLVED that we request The American Society of Mechanical Engineers to appoint a committee to investigate and report upon the need for standardization in the printing industry.

Resolution of Thanks to Paper Mills

WHEREAS, the paper read by Fred S. English, chief engineer of the Babcock Printing Press Manufacturing Company, on "Problems in Standardization" points out that any effective program of standardization in the printing industry is dependent upon adoption of standards in magazine, book, catalogue, and form printing sizes, and

WHEREAS, several large paper manufacturing companies have undertaken extensive advertising campaigns direct to the consumer on the subject of standardization of paper sizes; therefore be it

RESOLVED that this meeting go on record as commending these campaigns and further that the paper mills be officially advised of our appreciation of their splendid efforts.

Both resolutions were unanimously adopted.

Author's Closure

Since the paper was written, the International Association of Electrotypers, at a meeting held in September, 1930, adopted the following sizes as standard:

Thickness of flat plates when made for patent bases (plus or minus 0.002 in. tolerance), in.	0.154
Height of patent bases	0.759
Thickness of curved electrotypes (plus or minus 0.002 in.) for cylinders of usual diameter	0.187
Thickness of curved electrotypes (plus or minus 0.002 in.) for very large cylinders	0.250

PI-52-9

Design of the New Harris Automatic Two-Color Flat-Bed Press

By ALFRED S. HARRIS,[1] CLEVELAND, OHIO

A recent design of two presses, one a single-color and the other a two-color press, includes the standardization of parts and units to such an extent that 72 per cent of these parts are common to both presses. A few of the points described in the design are those contributing to rigidity of frame, impressional strength, uniformity of bed travel during the printing stroke, evenness of ink distribution, and accuracy of register. Accessibility to its adjustments and convenience for make-ready also received attention.

THE Harris-Seybold-Potter Company recently announced to the trade the manufacture of a single-color and of a two-color 20 × 26 two-revolution automatic flat-bed press complete with pile feeder and pile delivery. A general description of these presses together with some details of the mechanical construction may be of interest.

Early in 1928, the design of these presses was started with the idea in mind to make available for the printer a single-color and a two-color press of small size capable of producing the finest quality of printing at high speed. A few of the points in press construction contributing to quality printing are rigidity of frame, impressional strength, uniformity of bed travel during the printing stroke, evenness of ink distribution, and accurate register.

The speed of production not only depends on the ability of a press to rotate at a high number of revolutions per minute, but also on the accessibility of its adjustments and the convenience for make-ready. Particular attention also was given to the standardization of parts and units. How well this has been accomplished is evidenced by the fact that 72 per cent of the parts are common to both presses.

The general specifications of the two-color presses are:

Maximum size of sheets press will handle, 22 × 30
Maximum form locked on the bed completely covered by four form rollers, 21 3/4 × 29 3/4
Center locked in chase, 21 3/4 × 28 1/2
Bed size, 27 5/16 × 31 1/4 width
Cylinder diameter, 17 in., ground to take a 0.065-in. tympan and equipped with tumbler grippers in first-color cylinder and breathing grippers on the transfer and second-color impression cylinders
Harris-type pile feeder accommodating a 46 in. height pile
Receding pile delivery accommodating a 38-in. pile.
Actual measurements on the base, 12 ft. 10 in. × 3 ft. 10 in.
Net weight of the complete press, 16,000 lb.

The side frames of this press (Fig. 1) are of extra-heavy construction and are designed so that the complete weight of the machine is supported by the frames. The feeder and delivery are of cantilever construction, attached to and supported on these frames.

The cross-members consist of two end girts and two center girts, one center girt directly under each impression cylinder, these in turn supporting the four tracks on which the bed travels. These tracks are cast in pairs and are rigidly fastened to the center girts, end girts, and press side frames.

The cylinders are held in positive contact with the bed bearers by means of a solid-steel toggle (Fig. 2) mounted directly above the cylinder center and so designed that when on impression there is no strain, either push or pull, on the cam or connecting rod which operates it. This rigid-impression toggle lock, together with the framing construction, has proved a factor in the overcoming of such trouble as guttering, building up of impression, and working up of type forms.

The main drive shaft is centrally located and journaled in three large bearings. All units of this press, such as impression cylinder, transfer cylinder, bed drive, and reverse, are driven direct from this shaft. The cylinders are rotated by a pinion on this drive shaft through an intermediate gear direct to the cylinder gear (Fig. 3).

This intermediate gear is swung on an arm pivoted around the drive shaft as a center and connected to the cylinder box by a link which insures the gears running on correct pitch line at all times, on or off impression.

The transfer cylinder is driven by a pinion on the same drive shaft through intermediate gears to the transfer cylinder gear. The registration at the transferring point from first color impression cylinder to transfer cylinder and from transfer cylinder to second color impression cylinder is controlled by register racks.

These register racks are not a part of the press drive, but are located on the end of the cylinder body.

The bed is driven by means of a pinion on the drive shaft meshing with the horizontal shifting bed gear. The reverse mechanism is also driven from the main drive shaft by a pinion through an intermediate gear.

The bed motion of this press is a 3 to 1 movement; that is, one revolution is used for the print stroke, one for the return or idle stroke, and one-half at each end for reversing. Two of the major reasons for using 3 to 1 movement in preference to a 2 to 1 movement were the conservation of floor space and the simplicity of the operating mechanism required.

The saving of floor space is due to the fact that a longer bed stroke is required with a 2 to 1 bed movement, when printing the same form and using the same size and number of form rollers. Where a 17-in. diameter cylinder is used in this press with the 3 to 1 movement, a 2 to 1 movement would require a cylinder approximately 1 1/2 in. larger in diameter.

---

[1] Vice-President in Charge of Engineering, Printing Press Division, Harris-Seybold-Potter Company. Mr. Harris was born in Warren, Ohio, on June 10, 1891. After finishing grade school, he prepared for college in Morristown School, Morristown, N. J., and attended Princeton University and the University of Virginia. Since 1913 he has been with the Harris Automatic Press Company and its successor, the Harris-Seybold-Potter Company. During this period of time he has been connected with the following divisions of the company: Engineering, press installation, service and repair work, manufacturing, and sales engineering work.

Contributed by the Printing Industries Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The bed-driving mechanism consists of a horizontal shifting bed gear meshing with upper and lower bed racks fastened to the rack hanger, the bed being controlled on the uniform printing stroke by the upper rack and on the return stroke by the lower. While the bed motion is 3 to 1, the bed gear is 6 to 1, giving the added advantage of a shallow rack hanger with a corresponding reduction in reciprocating weight and allowing the use of high center girts to more rigidly support the bed under impression.

The reversing of the bed is accomplished by means of a crank-pin and block working in a Scotch yoke (Fig. 4). This yoke makes three complete reciprocations to each printing cycle. Fastened to this yoke is an arm carrying a block, and by means of corresponding blocks located on the rack hanger, the bed is controlled during the reverse. As the bed reaches the end of its uniform travel the block on the rack hanger comes into contact with the block on the Scotch yoke, the bed gear leaves the rack, and the slowing down and reversing of the bed takes place. To insure these blocks staying in positive contact, a locking mechanism is used. The reversing of the bed is assisted by air cushions, two at each end.

For the inking of the forms, a pyramid-type inker is used. This inker consists of four form rollers $2^1/_2$ in. in diameter completely covering the maximum-size form, together with three vibrating steel storage rollers, four composition distributing and duct rollers, and two steel riders.

The construction of this inker, together with the method of vibration used, has proved of assistance in the uniform inking of the form, which materially assists the overcoming of such printing troubles as shadows, ghosting, and offsetting.

The ink fountain is of ample capacity, rigidly built, easily adjusted, and so designed that it gives a continuous agitation to the ink supply in the fountain bowl. The inker as a whole is of run-back construction, which makes the entire inking mechanism, including the form rollers, accessible for wash-up and roller adjustment.

The delivery is of cantilever construction, making easier the removal of the printed pile. The sheet is stripped from the second color impression cylinder in the usual manner and is conveyed to the delivery pile by reciprocating finger-carrying tapes (which roll out from under the sheet on the return stroke), delivering the sheet to the pile, where it is jogged by means of side and rear joggers.

Sizes and Tolerances for Metal Fits

Advantages of Standardization for Manufacturing Practice—Controlling Influences and Application to Existing Conditions—Analysis and Reference to the Practice in Other Plants

By C. R. REIMAN,[1] RIDGEWOOD, N. J.

This paper discusses comparisons of metal fits. The matter of working fits being left in many plants largely to the opinion and ability of the workman, the need of standardization in consequence asserts itself as organizations are entitled to records of these matters. The comparisons of the practice of other standards and the analysis that influences the conclusions are given in a simple way. Simplification for better understanding is aimed at, and the need for a standard common practice throughout our industry is recognized. Controlling influences are considered, and various features for which advantages are claimed are stressed. The use of the basic size to under hole system, and the basic shaft are discussed. Different kinds of fits are compared, and the reasons for differentiating between straight shafts and turned studs are given.

THE cause of two mating parts fitting either properly or improperly has been and still is a subject of real interest and one on which many thoughts and suggestions have been offered for discussion. Much of the work by others has been of a more general nature, in which more classifications or kinds of fits have been treated. Unquestionably a great amount of this work has been far more vast than ours, while many of the papers of others have dealt with this subject in a somewhat less extensive scope. All have nevertheless proved valuable contributions to so important a project, the final conclusions and solutions of which will be a boon to those interested in production and manufacture.

The work of the various standards committees and associations, as well as of individuals and concerns, gives evidence of the whole-hearted attempt to clarify and bring into being a practical and easily comprehensible understanding of this matter.

This paper makes no attempt to deal with the subject either as a national and much less as an international solution, but is offered as a contribution in which we give our findings as applied to our work and our methods principally. While it will apply to certain other kinds of machinery bearing a similar classification, we have held this part of it a secondary consideration.

Many good reasons for these attempts at standardization are known, probably not the least among them being the dangerous and costly condition existing in many plants of permitting assemblers to enlarge holes to compensate for oversized companion pieces or to correct inaccurate alignments.

The standardization of sizes by limit is necessary where production schedules and costs are considered. This concerns not only the making of the part itself, but reflects as well into assembly advantages and the replacement problem for service and repair.

Tolerances specified for all studs and shafts and their mating parts should provide for the fits that are required for proper assembly and function. Dimensions giving high and low limits should in all cases be specified on the drawing so that they will be correctly sized where they are machined. A careful check of all assemblies is necessary and the sizes should be chosen to agree with the condition. In order to help make the plan a success and to obtain the best results, all interested should familiarize themselves with the principles of the plan and the importance of working to the blueprint specification. If this practice is followed throughout, there will be but few occasions to use reamers in the assembly departments.

Controlling Influences

Our study is influenced by *the functional requirements of the device, the nature of the work, the quantity, economics, and the available equipment.*

The first of these is of greatest importance, since the rightful existence of the part makes all else possible. The nature of the work to be done on the part ties up closely with its functional requirements, and quite often advantages can be taken of sound and practical engineering to which the design of the part lends all possible favor. Large quantities of course are desirable, but are not always in demand, in which case economics requires full consideration. Available equipment if unsuited to assist readily and properly must be modified or replaced so that full advantage may be derived. Reverting to the functional requirement, the modern high-speed high-grade automatic printing press requires fine accuracy in many of its components, comparable with other devices in the machine and tool building industry, and while parts lots do not run into quantities as large as for some other devices, the need of their fitting properly manifests itself; hence our study of sizes and tolerances.

Reference to the Practice of Others

As a further preliminary, reference to tabulations for running and tight fits as practiced by others was helpful. A comparison of tabulations in a graphical way showing the tendency of leaning to looser or tighter fits is based in a general way on the data available. The following have been consulted:

1 Brown & Sharpe Mfg. Co., L. D. Burlingame, Trans. A.S.M.E., 1910.

2 General Electric Company, L. P. Alford, "Bearings and Their Lubrication," p. 91.

4 Tentative American Standard, "Tolerances, Allowances, and Gages for Metal Fits," B-4a, 1925.
5 S K F Ball Bearing Co., Bulletin 98-B.

Table 1, under the heading, "Comparison of Clearances With Other Standards," gives their largest and smallest clearance or running fits and has been compiled from the references mentioned. With the exception of General Electric's allowance, all are in the range of our study. The allowances given by them are considerably larger in comparison to the other tabulations, and as their activities are quite diversified, we have no knowledge of their particular application, so we will make no further reference to the General Electric allowances. Figs. 1 to 9, inclusive, deal with comparisons of running fits, each one indicating its particular comparison.

[1] L. D. Burlingame, Trans. A.S.M.E., 1910.
[2] "Bearings and Their Lubrication," L. P. Alford.
[3] Eng. Divn. Standards, A. M. & F. Co.
[4] Tentative American Standards, Class 3, Medium Fit, "Tolerances, Allowances, and Gages for Metal Fits," B-4a, 1925.

The graph, Fig. 1, compares the Tentative American Standard, Class 3, Medium Fit, tabulations as given in the standard. The horizontal gives nominal diameters up to 6 in., and the vertical clearances in ten-thousandths of an inch. The curves are developed from the formulas given, the lower representing allowance or minimum clearance, while the upper represents the maximum clearance, or the allowance plus tolerance for both mating parts. The space between the upper and lower curves is the desired field in which the tabulations for the various sizes should fall to produce the preferred condition. The various points on or near the curves are the positions that the tabulated figures indicate. Slight variations over or under the curves occur, as the figures are given to four decimals only. These differences are negligible, since the amounts are smaller than are usually employed in practice. It does show, however, that the committee which established this standard has been generous in its allotment of the number of steps. This was because of the desire to follow the guiding curves as closely as possible.

On the graphs that follow in this discussion the various steps are fewer, which is intended to simplify the practice. Greater variations from the true line, however, will occur because of this, but it still is considered conservative practice.

In Fig. 2, which compares Brown & Sharpe's running fit for ordinary speeds, we again use the Tentative American Standard, Class 3, curve. In this case their step-up occurs less frequently than in our first case, they having but five steps for the range up to 6 in. Their allowances are indicated by the lower range of steps up to the 1/2 and 1 in., which sizes are somewhat below the comparing curve, while at 3 1/2 in. their maximum clearance takes a decided jump upward, being looser than the greatest limit for this diameter allowable by the curve. This, however, is for the extreme limit. The mean of the minimum and maximum clearance is fair to the curve. The intermediate portion is comfortably well within the desired field. An intermediate step between this and the 6 in. diameter would have

shown better uniformity. On a general average the tendency is toward greater looseness.

Fig. 3 shows comparisons of the practice of the American Machine and Foundry Company, on machines of similar class, with the Tentative American Standard, Class 3, curves. The data available here are somewhat meager as no figures beyond the $2^1/_2$ in. diameter are given. On the allowance steps, four are used, while the upper or maximum clearance has five. The tendency in this case up to the $1^1/_2$-in. size is to greater tightness, as that part of the steps shows below the curves, while from $1^3/_4$ in., the leaning is toward greater looseness. This is of course on the extremes in both cases. Their mean average would fall nicely within the desired field. In completing the steps to the 6 in. diameter we probably would again have numerous changing points according to the set-up on the available figures. No further reference, however, need be made to this as it would merely be conjecture.

Fig. 4 compares maximum and minimum clearance of Kelly

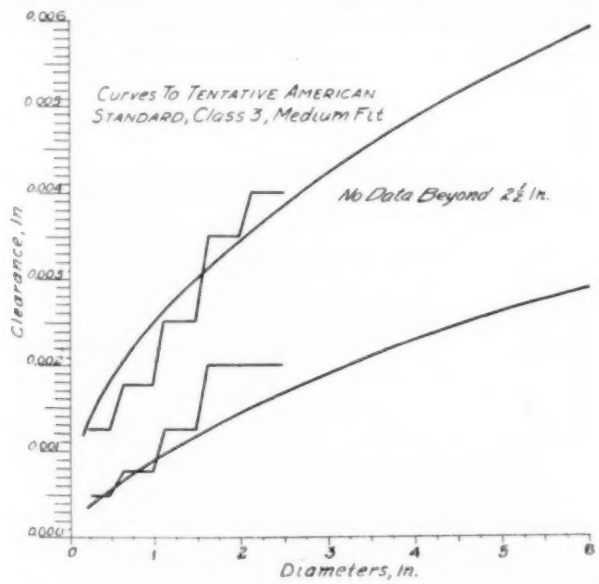

Fig. 3 Running Fits, American Machine and Foundry Company, Engineering Division Standards

Press practice as enumerated in Tables 2 and 3, with the guiding curves, which are again taken from the Tentative American Standard, Class 3. There are five steps used for the range up to 6 in. The indications by this comparison show a decided leaning toward closer fitting than those of the standard. The lower steps, which represents minimum allowance, fall, on an average, below the given curve, while the upper steps, representing allowances plus tolerances for both mating parts, are considerably below the upper curve. On the 6 in. diameter this difference is measured as being 0.0014 in. The two causes that bring this tendency to a lesser looseness are that the allowance is less and the tolerances are held closer. In reality it is nothing more than a finer or closer fit than that used by the curve. When fits are made closer, allowances and tolerances are reduced accordingly. We find it good practice to fit rather closely as there are many components that demand a considerably higher degree of accuracy than the average running fit. After the exercising period, which consists of running the press idle at normal speeds for 50,000 or more impressions, the stiffness caused by accumulations of slight irregularities wears off, with a result of a nice fitting condition rather than that of one already half-worn out by having the fits rather free to begin with. We will find by comparing some of the following graphs how this class of fits averages with some of the other known classes.

In Fig. 5 the steps representing the minimum and maximum clearance for running fits by Kelly Press are the same as on Fig. 4 and coincide with the figures of Tables 2 and 3. The curves, however, differ, they having been constructed to revised formulas. For the lower or allowance curve, we use a constant 0.0008 in place of 0.0009, as used in the Tentative

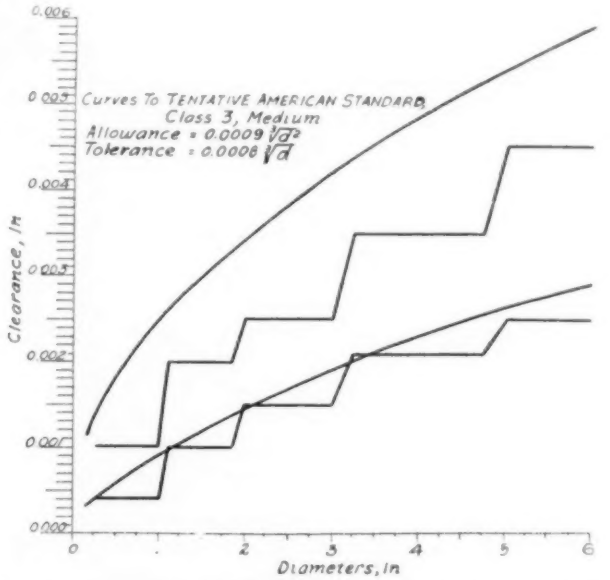

Fig. 4 Running Fits, Kelly Press Division, American Type Founders Company

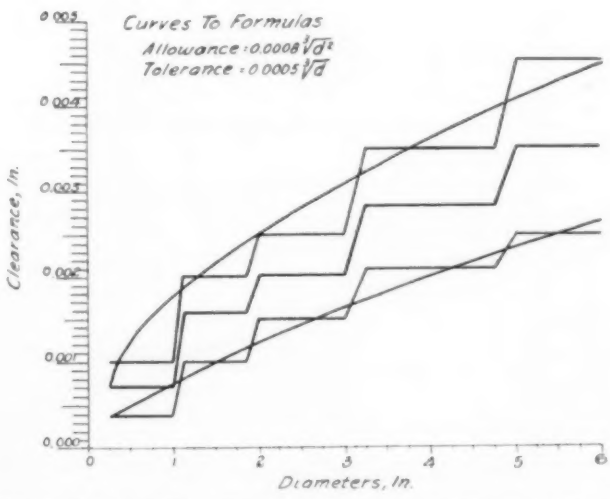

Fig. 5 Running Fits, Kelly Press Division, American Type Founders Company

American Standard, Class 3. The tolerance is based on substituting constant 0.0005 instead of 0.0008, as used in the same standard. While this results in smaller tolerances and less clearance, we are still within conservative practice for tolerances, the small sizes being to 0.0003 and the largest to 0.001. The intermediate range from $1^1/_8$ to $4^3/_4$ in., in which much of the work occurs, has tolerances of 0.0005 and 0.0007, the tolerances for both mating parts being the same. The averages of the

steps which represent the extremes for maximum and minimum clearance compared with the guiding curves are fair, the mean average of the two being favorable to the desired field.

Fig. 6 is slightly more complex than those previously referred to. In this case, we deal with the S K F recommendations for Housing Mounting Fits, comparing them with the Tentative American Standard, Class 3, and the running-fit curve of Kelly Press constructed from the revised formula. We are all quite familiar with the kind of fit usually employed when mounting the ball bearing into its housing. S K F refers to it as a

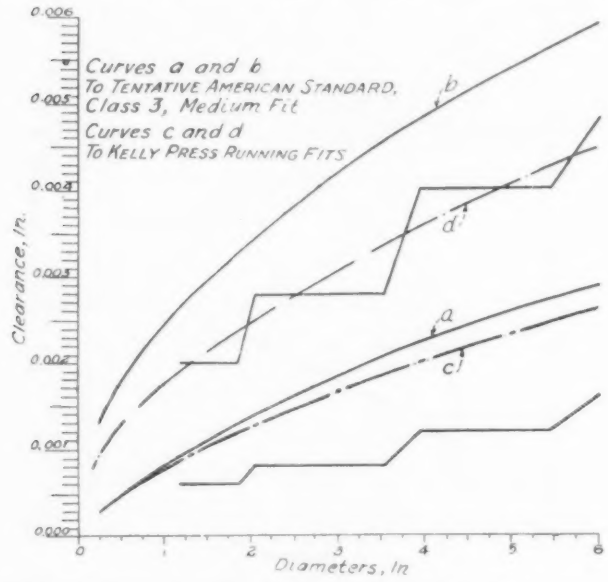

Fig. 6 Housing Mounting Fit Practice, S K F Industries

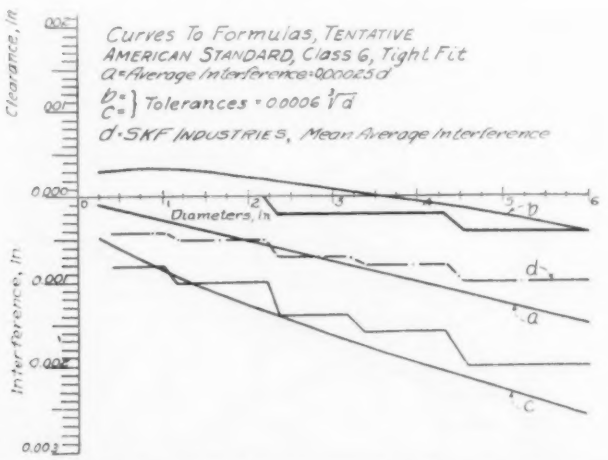

Fig. 7 Press Fits, S K F Industries, Ball-Bearing Mounting on Shafts

sucking fit. Our purpose in making the comparison in this way is to demonstrate an intermediate condition between the Tentative American Standard, Class 3, fit, which is looser than that of Kelly Press for running fits, and the Housing Mounting Fit of S K F, which is tighter. While the Housing Mounting Fit allows the outer race to creep or slide for compensation, it certainly would not be used for a running condition.

The steps in the graph agree with the minimum and maximum clearance by S K F given in millimeter sizes in their bulletin. (For our study we have transposed these sizes into inches for uniformity with our diameter scale, omitting the millimeter graduations.) Having visualized the Housing Mounting Fit, we compare it with the curves *a* and *b*, which again represent the minimum and maximum clearances of the Tentative American Standard, Class 3, and find an expression of a considerably tighter fit, while the fit obtained by the Kelly Press running-fit curves shows looser than the steps for S K F and slightly tighter than the Tentative American Standard, Class 3, curves *a* and *b*. In this way the intermediate class is easily visualized. In summary, the Kelly Press running fit is looser than the S K F Housing Mounting Fit practice, but tighter than the Tentative American Standard, Class 3, fit.

This concludes our discussion and comparisons on running fits, and before entering on that part of the subject dealing with other kinds of fits, we mention that, to avoid complication as much as is possible, only three kinds of fits were chosen. These are the running fits, which have been discussed, and the force and wring fits which are to follow.

The establishment of a standard for general practice throughout the industry must of necessity provide for that number of

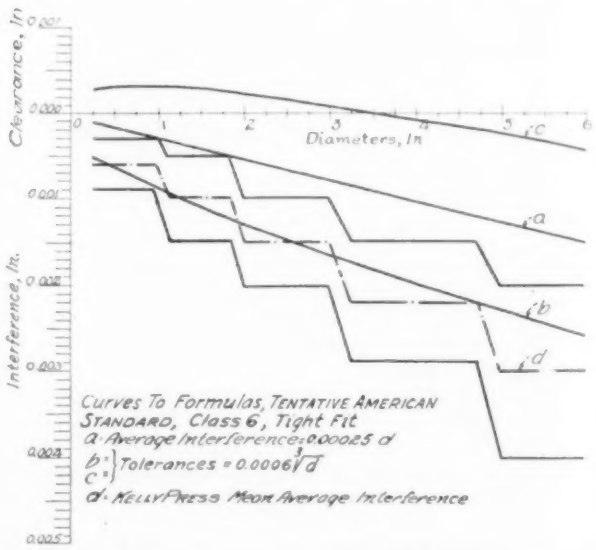

Fig. 8 Force Fits, Selective, Kelly Press Division, American Type Founders Company

classifications that are required by the various branches. As we are dealing solely with our own part of the problem, we have chosen but three. The American Tentative Standard gives eight, and from what has been demonstrated in the foregoing it is evident that more than that number of classifications should be available.

The German National Standard—generally referred to as the DIN system of fits—we understand, gives 22 fits, specified both in the "basic hole" and the "basic shaft" system. This raises the question whether the existing Tentative American Standard should be supplemented by a "basic shaft" system.

We have found such a provision desirable for our work, and undoubtedly many others find the same.

This part of the subject, however, may better be left for discussion under another heading, but as our arrangement uses this feature we find it necessary to mention the need.

Force Fits

Before taking up the Kelly Press practice on force fits, we refer to the S K F fits of ball-bearing mounting on shafts as

compared to the Tentative American Standard, Class 6, tight fit. Fig. 7 makes the comparison in a graphical way. As we have both interference and possible clearance to contend with, the graph is divided. The upper part (above the zero) indicates clearance, as before, and the lower section (below the zero) interference. The values for the graduations remain the same, and the millimeter sizes have again been transposed into inches. The line *a* gives the mean average interference up to 6 in., and is based on the formula average interference = 0.00025 *d* as given in the standard. Curves *b* and *c* represent the loosest and tightest fit, respectively, and are also based on the standard.

The steps show the practice of S K F for the high and low limit, as given in their bulletin, while the intermediate step *d* is the mean average for their practice. A study of the graph discloses the reason for the necessity of the fit being selective according to the Tentative American Standard, as part of curve *b*, up to about $3^1/_2$ in. diameter, falls within the clearance zone. Tight fits can have no clearance, of course, and selection is therefore necessary.

The upper step, representing minimum interference for S K F, shows zero interference for part of its length, but by this

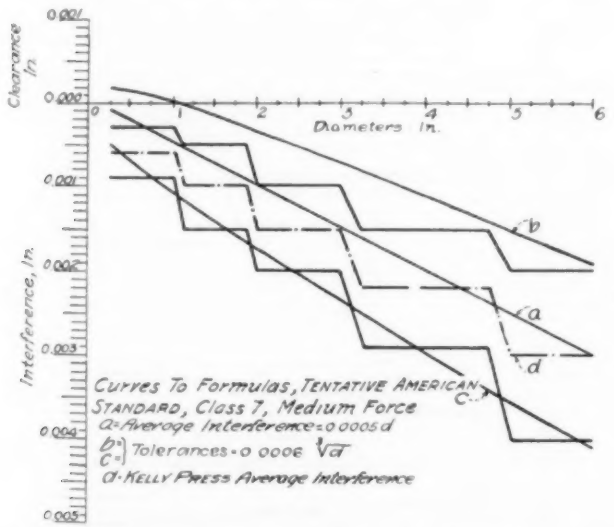

Fig. 9 Force Fits, Selective, Kelly Press Division, American Type Founders Company

arrangement fits need not necessarily be selective, though this may be desirable for this work. If the parts are rugged enough to withstand the pressures, no selection should be necessary. The S K F practice, according to the comparison, fits nicely within the American Standard curves, being if anything slightly looser throughout an average and never loose enough to give actual clearance.

Fig. 8 compares the Kelly Press force fits, the figures for which are given in Tables 2 and 3, with the Tentative American Standard, Class 6, tight fit. The line *a* represents the average interference, and the curves *b* and *c* the tightest and loosest fits. All are constructed from the formulas of the standard, as in the preceding case on Fig. 7. The possibility of clearance is again in evidence as before.

The various steps show the loosest and tightest fit according to our tabulations, and throughout there is a decided leaning toward a tighter fit than allowed by the Class 6 curves.

Fig. 9 shows the average interference line and the minimum and maximum interference curves *b* and *c*, according to the Tentative American Standard, Class 7, Medium Force Fit. The various steps are again taken from Tables 2 and 3 of the Kelly Press practice, with the mean average shown by line *d*. A possible clearance up to $1^1/_4$ in. is again in evidence on the minimum curve of the Standard, which would again indicate the necessity of selection. This graph shows the Kelly Press force fit to be slightly tighter than the medium force fit of Class 7. Otherwise the agreement is good.

Fig. 10 compares Kelly Press force fit with the Tentative American Standard, Class 8, Heavy Force or Shrink Fit. The curves and steps representing their factors are as before. The

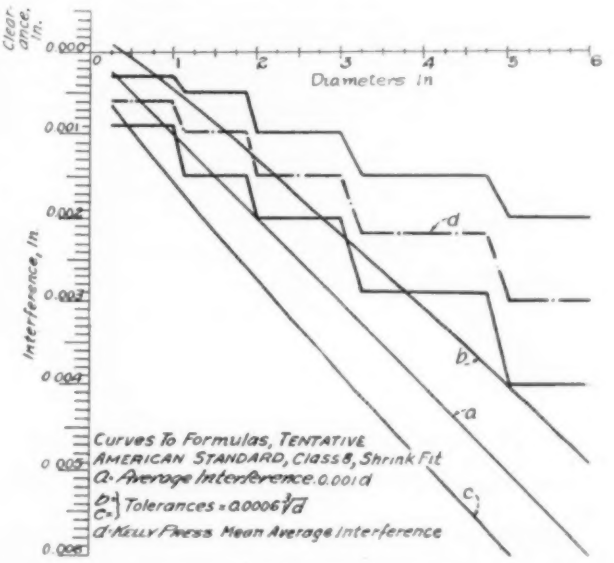

Fig. 10 Force Fits, Selective, Kelly Press Division, American Type Founders Company

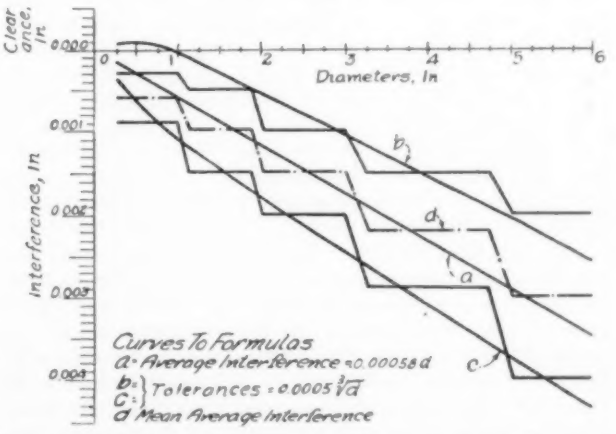

Fig. 11 Force Fits, Selective, Kelly Press Division, American Type Founders Company

curves show the Standard to provide for considerably more tightness than in our case. The purpose of making this comparison is to show that there is a vast difference between these two classifications; otherwise it serves no purpose.

Fig. 11 gives both curves and steps to Kelly Press practice for force fits. The curves, however, have been reconstructed from revised formulas. For average interference we have 0.00058 *d* as compared to 0.0005 *d*, used in Class 7. The tolerance is closer and is based on 0.0005 $\sqrt[3]{d}$ in place of 0.0006 $\sqrt[3]{d}$, as used in the same class.

While the curves are quite similar, the resulting fit is tighter than that of the medium force of Class 7 and not nearly so tight as that of the heavy force fit of Class 8. No effort is made to control these fits by designation of tonnage pressure, as our factors deal only with average work in this class.

Wring Fits

This section of our work requires closer study because of a greater exactness required for this kind of a fit than either the running or force class. Any attempt at strict interchangeability

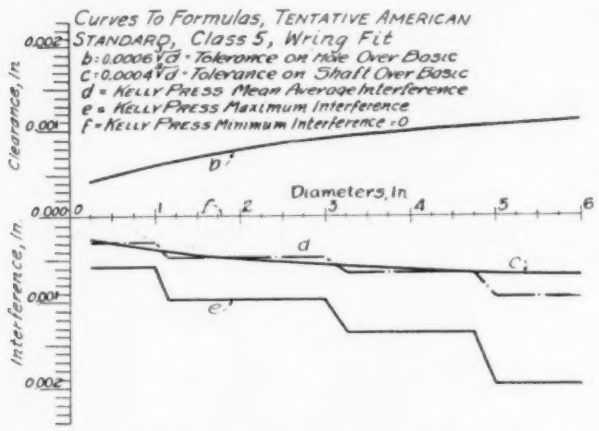

Fig. 12 Wring Fits, Selective, Kelly Press Division

is passed on, as manufacturing costs become prohibitive in our case.

Generally speaking, we apply the term wring fit in the manner of two parts going together by slight exertion in pushing and twisting one part onto or into another.

Fig. 12 shows curve *b* representing the loosest fit and curve *c* the tightest according to the Tentative American Standard, Class 5, Wring Fit. Curve *b* shows clearance while Curve *c* indicates interference. The mean interference according to the tabulations in the Standard is zero, and the possibilities of a tight or loose fit are governed by tolerance and selection. Curve *b* also represents the tolerance on the hole over basic, and curve *c* the tolerance on the shaft over basic. Both are constructed from the values given in the Standard. Kelly Press practice has a minimum interference of zero, instead of clearance as in the Standard, represented by line *f*. The step *d* is mean and *e* represents the tightest fit. In either case, the classification becomes purely selective, perhaps a little more so in the Standard because of the possibility of clearance. In the case of the Kelly Press practice, when selection has been exhausted and the extremes of the sizes on the remaining parts cause too tight a fit, recourse to resizing, usually by the ball sizing method, is resorted to. This works out in a practical and convenient way, since the leaning of fits is to the tight side. In the case of too great looseness possible with practice of the Standard, no recourse is available except to hold the parts for the next lot or possibly for salvage.

Fig. 13 is a composite in which the lower part below the zero line compares the S K F press fits on shafts with curve *c* of the Tentative American Standard, Class 5, Wring Fit, curve *c* showing the interference value of that class. The steps represent the values as given by S K F for the tightest and loosest fits. The intermediate step *d* is the mean of these. The tendency here is toward a tighter fit of the ball bearing on the shaft than on the interference curve *c* of the Class 5, Wring Fit, of the Standard would provide for.

The upper section above the zero line compares the S K F recommendations for Housing Mounting Fits for the outer ring of ball bearings in their mounting with curve *b* of the Class 5, Wring Fit, of the Tentative American Standard. Curve *b* shows the clearance obtainable in Class 5. The steps represent the sizes given by S K F for the tightest and loosest fits, the intermediate step *e* being the mean.

In summary, the step *d* is the mean average interference on the shaft mounting, and the step *e* the mean average clearance for the housing mounting of S K F for ball-bearing practice.

These various steps, when compared with the interference and clearance curves of Class 5, Wring Fit, of the Standard, show the difference in the three types of fits. The lower section shows greater tightness and the upper one more looseness.

The comparison in Fig. 14 is between S K F practice for Housing Mounting Fit and the Tentative American Standard, Class 4, Snug Fit. The curve *a* shows the maximum clearance of this class, while the minimum clearance is zero. Step *b* is the S K F mean average clearance, while the upper and lower steps give the loosest and tightest fit, respectively, for their practice. The graph shows the Housing Mounting Fit to be looser than the

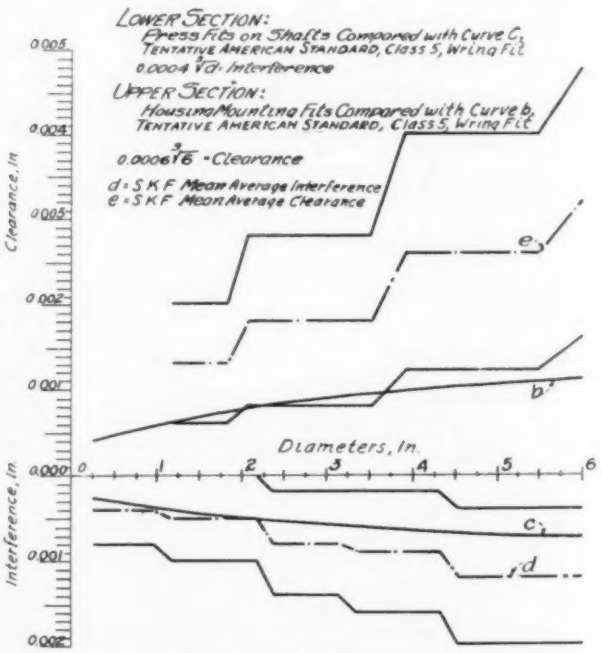

Fig. 13 S K F Industries

Class 4, Snug Fit, of the Standard. As no data are given below 30 mm., no comparison is available below that size.

Fig. 15 makes a comparison of the Kelly Press Wring Fit with the Tentative American Standard, Class 6, Tight Fit, the line *a* representing the average interference and curves *b* and *c* the loosest and tightest fits according to the Standard. Curve *b* again shows clearance for part of its length. From about $3\frac{1}{2}$ in. upward its range is from zero to interference. In the Kelly Press steps we have zero as minimum interference, the greatest interference being shown by the lower steps *d*, while the mean is shown as intermediate *e* between zero and the maximum tightness *d*.

The average tendency of the Kelly Press Wring Fit is for less tightness than shown by the Class 6, Tight Fit, of the Standard, and even while this lesser tightness is in evidence, our wring fit is again on the safe side for further resizing when selection has

been exhausted. There being no indication of possible clearance, we again find this feature desirable, particularly so because of the small quantities of parts sometimes in work.

This concludes our discussion on the various comparisons, on which analysis the tabulations for the three kinds of fits have been prepared. We appreciate that with only three kinds of fits available, some special cases exist where certain unusual fits are necessary, which require other allowances or tolerances than those given. In such cases they arbitrarily become special and are treated as such by reference to precedent or other accepted standard practice.

No Oversize Holes

It will be noticed that, in all cases, holes are basic to under or smaller. There are desirable and practical reasons for this.

We have the three classes of fits for both the basic hole and the basic shaft standards, and deal with a standard hole (basic to under) for all cases of female parts used with studs or short length diameters (whether running, wring, or force fits) and running fits on straight shafts, all without exception. This provides for four major cases out of six, the remaining two being

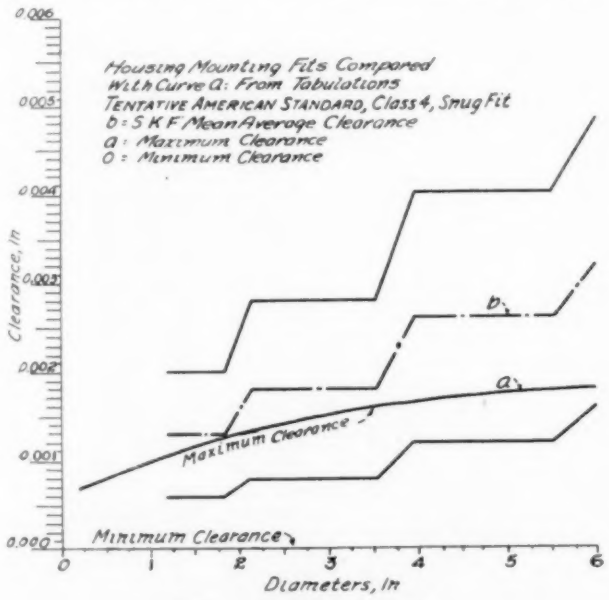

Fig. 14 S K F Industries

wring and force fits on straight shafts and which are in a minority in so far as number goes. The cases of the latter two are treated by varying the hole size as the shaft is standard (basic to under) where straight shafts are involved.

Plug gages do not increase in size through use, and when worn have no further value except by possible salvage. When worn and undetected, parts gaged by them are small and are subject to further resizing, which additional operation must be considered because of economics. This condition is probable when holes are basic to over. Where hole sizes are varied to produce different classes of fits, the variety of sizes of gages becomes more numerous, whereas the fewer number of classifications for hole sizes requires a correspondingly less variety of sizes for the gages. Standard gages by Kelly practice when worn below tolerance are resizes for the wring or force fit class of the shaft standard. The hole for these being smaller than basic to under are the only cases where the hole is *exceptional to standard.*[2]

[2] For our practice, standard holes are basic to under.

Reamers unless ordered to specification must be sized to produce given diameters. Commercial or catalog reamers, as they are sometimes called, produce sizes over standard, some of this oversize being added to prolong the life of the reamer. This practice is distinctly an encroachment by the reamer manufacturers on the rights of the user and compels acceptance of sizes for holes up to and sometimes over the largest limit. Such holes when gaged by standard plugs show a decided leaning to being too large and suggest unsatisfactory work, as the hole is too loose on the gage.

Then, too, we have materials with their varying densities to

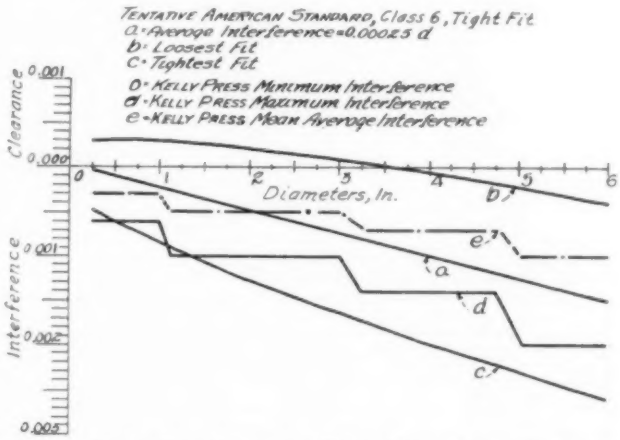

Fig. 15 Wring Fits, Selective, Kelly Press Division, American Type Founders Company

consider, as well as whether the reaming is to be done wet or dry. These factors have a vast influence on determining the cutting sizes of reamers, and unless the specifications covering are clear and complete, the result is negative. When a hole is gaged by plug, it should fit to be called standard, and it is not standard when free on a standard plug. This is often the result when the influences pertinent to practice are ignored or neglected.

Another factor influencing and favoring the basic to under standard for the hole is the use of commercial bars of both the ground and the cold-drawn quality. Such bars generally do not run over the nominal size, but basic to under, which is advantageous when holes are made basic to under. Bars or shafts whose sizes run over nominal usually are burdened with an extra cost because of the special handling involved.

Studs and Short Length Diameters

Table 2 applies to studs and short length diameters, giving the maximum and minimum dimensions of both the male and female member from $^1/_4$ to 6 in. For this group, the maximum hole diameter is basic, and the tolerance is applied so the hole will be basic to under. While figures are given that establish tolerances in tenths of thousands, they are accepted as an interpretation of a wring fit on the standard plug under manufacturing conditions. The tolerances and resulting clearances or interferences are given as a matter of convenience, it being intended that only the high and low limit be given on the drawing.

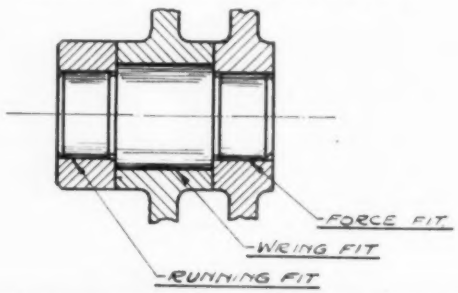
This table applies to diameters in which no association with straight shafts is involved as it is used only for studs and such diameters that would not be classified under straight shafts and their members.

In this case, *the hole size is common* to all three kinds of fits while the stud size changes agreeable to the kind of fit.

Table 3 applies to *ground straight shafts only* and is not used for commercial cold-drawn or cold-rolled bars or for studs or short length diameters. Diameters from $^1/_4$ to 3 in. are given for this group, the maximum of the hole for running fits only is basic. The shaft diameter is established to produce a running fit, using the hole size as basic to under, after which the hole sizes for the wring and force fits are determined from the shaft.

In this group the *shaft size is common* to all three kinds of holes, for the running, wring, or force fit; while the hole size from standard size to minimum in our table, the diameter of the bar not to fall below the low limit. Should the stock run to basic which is over our high limit, it would be slightly large, but could easily be reduced.

New Mating Members for Repairs on Old Size Shafts



Part of our old arrangement involved the use of shafts that were made to an oversize standard and with which certain existing machines still in operation are equipped. The repair changes for the wring and force fit only. Both columns for hole sizes under wring and force fits in this table give smaller diameters than the basic to under hole for running fits. Since no holes over standard are permissible and with the shaft fitted to basic to under holes for running fits, it follows that the tighter fits of the wring or force kind require smaller holes.

The tolerances and the resulting clearances and interferences are identical with those established for studs and short length diameters.

With the shaft diameters established in this manner, it is possible to purchase selected stock or commercial ground bars and replacement problem is involved because of this. When furnishing members or parts for repairs for such machines, the holes in the replacement parts according to the new standard would be small and consequently safe, as the shaft, being to the old standard, is large compared to the shaft of this standard. It might therefore be necessary to scrape or resize the hole slightly to produce the desired fit.

Shafts and studs in service do not increase in size through use, and we find it desirable to leave holes in such repair parts this way, as servicing will be favored and the necessity of carrying parts having special holes in stock will be eliminated.

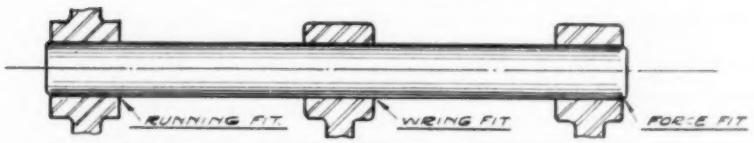


TABLE 2 TOLERANCES AND SIZES FOR FITS

Commercial Cold-Drawn Bars

Table 4 shows sizes and tolerances for commercial cold-drawn or cold-rolled bars from $^1/_4$ to 3 in. diameter. The wide tolerances used by the steel mill will not permit this list to be used where close-fitting members are involved.

The tolerance of the steel mill is set arbitrarily from minus 0.002 in. on the $^1/_4$-in. size up to minus 0.003, 0.004, and 0.005 in. on the larger sizes.

In this tabulation the maximum of the hole for running fits is basic and *the shaft size is common* to all of the three kinds of fits.

Should the hole be to the low limit and the shaft to the high, an interference would be set up for a running fit, which is of course impractical, but it is just as likely that the maximum of the shaft is apt to be under basic.

When the shaft is oversize it is an easy matter to reduce its size slightly by a centerless grinding operation, in which case the tabulations for ground shafts would apply. It is common practice to purchase bars 0.005 to 0.007 in. over standard and centerless-grind them to size.

It will be noted, too, that the clearances for running fits and the interferences for both wring and force fits for this group run into figures that are not at all consistent with those established for the ground and turned parts, and it is anticipated that selective assembly or resizing must be resorted to when the limits under this classification run to the extremes.

Discussion

Luther D. Burlingame.[3] The author cites the Brown & Sharpe practice relative to medium fits, and states that he quotes from a paper by L. D. Burlingame, Trans. A.S.M.E., 1910. As the maximum clearance given by the author is materially more

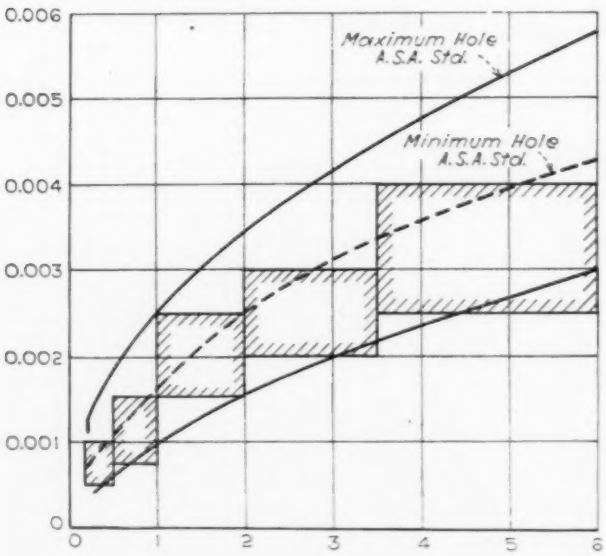

Fig. 16 Brown & Sharpe Present Practice

than is found in the paper presented by Mr. Burlingame at the joint meeting of the Institute of Mechanical Engineers and the A.S.M.E. in Birmingham, England, in 1910, and quoted in W. A. Viall's paper, "Precision Grinding," published in A.S.M.E. Trans., 1910, p. 1328, it is thought that the author has added the same limits for the holes which are used in his other calculations.

The Brown & Sharpe figures were based on standard hole practice and provide for materially closer running conditions than would be indicated by the author's diagram. Even these earlier figures of B. & S. practice have been superseded by closer

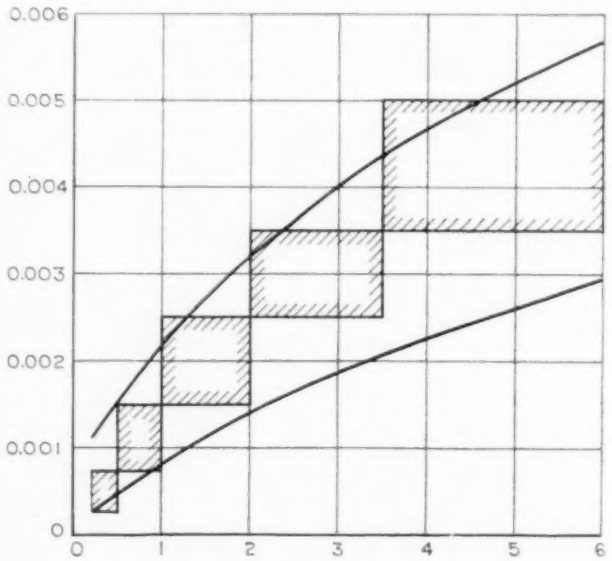

Fig. 17 Brown & Sharpe Early Practice

limits, as shown by the diagram, Fig. 16. These latter figures appear in the reference hand books such as "Machinery's Hand Book" of 1924, p. 980, and the "American Machinist Hand Book" of 1926, p. 540.

Even the earlier figures in the papers presented by Messrs. Viall and Burlingame in 1910, and charted in Fig. 17, follow closely the curves of the tentative American Standard, Class 3, Medium Fit.

That a reduction in the clearance allowed, from these earlier figures, has been possible, is due partly to improved methods of grinding and to improved methods of gaging. Modern grinding machines and processes make it possible to produce a better quality of surface, the advantageous results of which were clearly pointed out and emphasized in a paper, "A Survey of Surface Quality Standards," presented by R. E. W. Harrison at the December, 1930, meeting of the A.S.M.E. This paper clearly shows that by producing high-grade surfaces, which do not have to be worn into place, less clearance is required.

The American Standards Association Committee in its report dated January 2, 1923, presented formulas based on the B. & S. practice, which were adopted. The varying magnitudes of the successive steps of the B. & S. standard are in practically geometric progression, which is believed to be the correct grading.

The following figures represent the adopted B. & S. practice, and the diagram, Fig. 16 shows that they closely accord with the curves of the tentative American Standards, Class 3, Medium Fit:

To $^1/_2$ in. diameter, inclusive, 0.0005 to 0.001 small
To 1 in. diameter, inclusive, 0.00075 to 0.0015 small
To 2 in. diameter, inclusive, 0.0015 to 0.0025 small
To $3^1/_2$ in. diameter, inclusive, 0.0020 to 0.003 small
To 6 in. diameter, inclusive, 0.0025 to 0.004 small

Rowland MacDonald.[4] The question of establishing clearances is a difficult one. The author is to be congratulated on

[3] Legal Technician, Brown & Sharpe Mfg. Co., Providence, R. I., and Vice-Chairman of the A.S.A. Committee on Tolerances, Allowances, and Gages for Metal Fits. Mem. A.S.M.E.

[4] Small Motor Engineer, Westinghouse Elec. & Mfg. Co., East Springfield, Mass.

presenting a very useful paper, which will be of use to all engineers or others interested in bearing problems. The writer will confine his remarks to running fits on small-bore full-journal bearings.

At the Westinghouse plant at East Springfield, considerable experimenting in the laboratory has been done to determine suitable clearances and tolerances used on small motors. Where noise was a factor, it is true that close tolerances minimize vibration and resultant noise, but the lubrication problem then becomes a leading factor.

The replacement of reamed bearings for diamond-bored bearings has given very satisfactory results, and by using a diamond cutting tool, the clearances were reduced. Therefore, we have maximum wear and excellent surface finish. In line with this subject, a paper was presented by Mr. C. L. Bausch on diamond cutting tools at the Rochester meeting of the A.S.M.E. in May, 1929, which may be of interest.

The use of reamers at assembly to correct misalignment is an indication of failure in standardization. Clearance is dependent upon the materials used and ratio of L/D and the surface irregularities and lubrication.

Under controlling influences, the writer believes that two other factors should be considered, i.e., the nature of the finish on the journal and in the bearing, and the problem of lubrication using closer tolerances.

Under the nature of finish, the cutting tool should be considered. Since a reamer is a scraping tool in cutting, the chip breaks and the reamer undercuts and produces surface irregularities that elude measurement, but tend to break the oil film in the bearing. A reamed hole is seldom concentric. There is a tendency for the reamer to lift over the hard spots in the bearing and also toward making a bearing bell-mouthed. If there is an opening in the bearing for lubrication purposes, the reamer tends to cut an egg-shaped hole. The use of a diamond for cutting purposes does not have any of these disadvantages and produces a hard, smooth surface.

The clearances to be used seem dependent upon the method of lubrication, for example:

A waste-packed bearing requires close tolerances, good alignment, and polished surfaces due to partial lubrication.

A ring oil bearing usually will operate with less accurate alignment and greater tolerances due to fluid lubrication.

Close tolerances, very good alignment, and polished surfaces are necessary for pressure-feed lubrication due to the high pressures carried.

Care must be exercised in holding too close on clearances where green castings are used or warpage due to heat is possible. In the latter case, close tolerances would be extremely dangerous. In all cases, close tolerances affect the power required due to added friction. The writer believes that the lack of lubrication has been responsible for many bearing failures. A little consideration of the lubrication problem at the time of design will eliminate trouble due to this source.

In a comparison of clearance with other standards, the writer would make the following comments:

Fig. 1: The upper curve here tends toward a loose fit and removes potential wear. The writer would suggest that a maximum clearance of zero to $^1/_2$ in. diameter not to exceed 0.0010 in. and a maximum clearance $^1/_2$ in. to 1 in. in diameter not to exceed 0.0015 in. be used.

Fig. 2: In the first step, the nature of the surface would appear to be the controlling factor, as would alignment on most running fits. This tolerance seems to be too close.

Table 1: The Brown & Sharpe clearances are very close and require great accuracy and finish in their application, especially on diameters up to 1 in., in order to obtain satisfactory results.

The General Electric clearances do not seem logical and are out of proportion. The writer doubts if such clearances are specified on the small-bore bearings.

The American Machine & Foundry: The steps here seem well arranged and for ordinary reamed holes should be a satisfactory standard.

A.S.A.: The clearances here on the minimum scale are desirable while the maximum scale might be revised and brought in closer, so that there will be more potential wear on the bearing.

Fig. 3: In the experience of the writer, the tendency toward greater tightness under $1^1/_2$ in. diameter is sound and the leaning toward greater looseness above $1^3/_4$ in. is logical.

The practice of "running in" as a means of correcting an imperfect job does not seem reasonable. It is here that the minute surface irregularities wear off and one does not have a nice fitting job, and this is the beginning of trouble as these particles result in excessive wear, regardless of lubrication. The solution here would be surface finish.

Figs. 4 and 5: The running fits here are well arranged and within the desirable range. The writer could suggest only that there be three steps between zero and $1^1/_2$ instead of two as indicated in the graph.

The writer would like to ask the author to what extent the deflection of the journal will affect the film thickness of the lubricant in a bearing using standard practice running fits for the Kelly Press Division, and also his remarks on the effect of misalignment, nature of surface finish, and whether or not proper lubrication can be had with clearance established by the formula given in Fig. 5.

JOHN GAILLARD.[5] One of the merits of this interesting paper is that the author has given a clear picture of the character of the fits required by his industry. The needs of the Kelly Press Division appear to be covered by three classes of fits, called a "running," a "wring," and a "force" fit by this organization. The contents of the paper are the more interesting, as a reorganization meeting has just been held of a technical committee appointed under the auspices of the American Standards Association (A.S.A.) by the A.S.M.E. as the sponsor body, whose purpose it is to review and probably to revise and to supplement the present American standard on fits between cylindrical parts. This standard set up by the original committee, appointed in 1920, under the title "Tolerances, Allowances, and Gages for Metal Fits" (B4a-1925), was approved in 1925 by the A.S.A. as an American Tentative Standard. It has not been very widely introduced into practice, and it is believed that there are three main reasons for this lack of general adoption. First, it can safely be stated that the use of a system of limit gaging is still too rare. Besides a number of manufacturing concerns that have an effective and in some cases even a refined system of fits, there are numerous organizations that could adopt a standard system of fits with great benefits to their engineering, production, and inspection departments, but nevertheless still follow methods of trial and error in establishing fits as a function of the assembly work. Second, some organizations had a system of fits of their own when a national standard was established in 1925. As the maintenance of a system of fits requires a certain investment in tools and gages, this condition is apt to retard change to a new system. Also the replacement of parts of machines delivered and in operation is an important factor from the viewpoint of interchangeability. It is therefore reasonably to be expected that the adoption of a new system of fits will take some time under these circumstances. Third, criticism has been voiced against the American standard on the basis of the reamer situa-

[5] Mechanical Engineer, American Standards Association, New York, N. Y. Mem. A.S.M.E.

tion. Commercial stock reamers are commonly made with a small plus tolerance on nominal size. Consequently, they are not suitable for producing in an economical manner the basic to oversize holes required by the American standard. In fact, they soon wear down to the point where they begin to produce undersize holes and must then be rejected although they have still more wear left. Some systems of fits have therefore been proposed in which the holes are given minus tolerances on the nominal size, instead of plus tolerances, as specified in the American standard. In the opinion of the writer, it is not logical thus to adapt the system of holes to the existing tools, the more so if it is realized that the manufacturing limits of these tools were adopted before the present standard holes were established. On the contrary, the production tools—in this case reamers—should be adapted to the essential requirements of the standard fits, such as simplicity, flexibility, and facility in use by the designer, and maximum amount of interchangeability of parts. The possibility of this adaptability is no mere theory; it has been shown abroad that matters actually develop in this way. For example, in Germany, where a national standard system of fits has been generally adopted by all branches of industry (involving at least 1000 concerns), stock reamers have become adapted to the limits of standard holes and produce the latter economically by being used consecutively for different grades of holes, starting with the coarser and proceeding with the finer grades. Maximum wear life of the reamers is thus obtained.

Another criticism to which the American standard on fits has been subjected refers to the limited choice between fits of different character. The paper shows that still other fits than those specified in the standard may be needed by an industry—in this case, the printing-press manufacturers—whose requirements certainly are not too special to be disregarded by a national standard. Two fits are given as applied by the Kelly Press Division, one of which, the "running" fit, lies between the American Standard, Class 3 and Class 4, fits, while the other, the "force" fit, lies between the American Standard, Class 7 and Class 8, fits. In revising the existing American standard, the new committee should therefore consider an increase in the number of standard shafts and in the number of allowances so as to give the system as a whole greater flexibility in the hands of the designer.

Another deficiency of the present standard which has been brought to the attention of the A.S.A. before, is the lack of a series of fits in the basic shaft system; that is a series of fits in which the maximum size of the shaft is kept constant, the hole being varied to get the desired fit. The need for such fits is also felt by the Kelly Press Division, according to the author. A concern which by the nature of its product can use exclusively, or to a large extent, bar stock, supplied in cold-finished or centerless-ground condition, without giving such stock a machine finish, can in principle make good use of a basic shaft system.

The unification of standard fits, nationally (and also internationally) is a matter of primary importance to the mechanical and other industries. If individual organizations, however important they may be, adopt their own system of fits, all of these systems differing from each other, industry as a whole will not get the maximum benefit that may be derived from unity in tools and gages and in manufacturing practice. Only real cooperation resulting in a nation-wide compromise can establish a unified system, and complete success furthermore requires adoption of the national standard, both by organizations that have not yet used a standard system of fits and by those who have to make some change from their existing system.

It is quite interesting to note, for example, how at present the several fits of the Kelly Press Division actually belong to three sub-systems used according to whether ground studs or other internal parts, ground shafts with uniform diameter throughout their length, or cold-drawn (and not ground) shafts are used. The diversity has evidently grown up in the course of time on the basis of workshop practice not yet coordinated by a unified system. A graphical analysis of the nine fits involved will show that they might be replaced by three, either in the basic hole or the basic shaft system. Such replacement would result in a considerable simplification in tools and gages and in design and manufacturing practice, and although the changes involved may cause some difficulty, or may to some extent even be impracticable with regard to product already sold and in operation, consideration might well be given to such a scheme for new product.

It is very gratifying to know that Mr. Reiman, who has given the subject such thorough consideration, has been appointed a member of the reorganized A.S.A. technical committee on "Fits between cylindrical parts and limit gages," as the representative of the Printing Press Manufacturers' Association. Only such cooperation of the different industries, based on expert knowledge of their particular needs, combined with willingness to view the national problem as a whole, can result in a standard serving the needs of all.

In concluding, it may be said that also the international unification of standard fits has been given a great deal of attention. There are now altogether twelve countries, including the United States, where a national system has been adopted, and when some years ago an International Standards Association (I.S.A.) was founded, of which the A.S.A. is a member, the question naturally arose whether international agreement could be reached. A proposal for a unified system is now being developed under the auspices of the I.S.A., and the new A.S.A. committee has just declared its willingness to cooperate in this effort.

Forces in Connection With the Reciprocating Beds of Flat-Bed Cylinder Printing Presses

By B. D. STEVENS[1] and H. E. GOLBER,[2] CHICAGO, ILL.

This article deals with printing-press beds, their mechanisms, and forces. The mechanisms of some well-known presses are described sufficiently to show that the dynamic problems are identical for all. The forces are examined as to their effect upon the motor, the machine, and the building. Reference is made to certain methods which have been tried for reducing or counterbalancing them, and some criticisms and suggestions are made.

THE purpose of this paper is to arouse interest in the forces exerted and the mechanism used to reciprocate the beds of flat-bed printing presses. The scope is an analysis of the bed motions used on presses on the American market.

B. D. Stevens

These bed motions have either (1) a simple, roughly harmonic motion or (2) a compound motion, treated more fully below. Among the first class are the Miehle Vertical, the Autopress, the Miller High Speed, etc. These presses have their beds reciprocated by means of cranks and connecting rods or their equivalent. The motion of the bed is thus roughly harmonic. As the problems that arise with these presses of the first class also arise with the presses of the second class, the discussion will go directly to the latter, to which belong all the Miehles (except the Vertical), the Babcocks, the Whitlock-Premiers, the Kellys, the Miller Simplex, etc.

A typical compound motion of a flat bed may be visualized thus: Imagine (Fig. 1) a circuit *ABCDEF*, where *BC* and *EF* are straight-line segments and the curves *CDE* and *FAB* are semicircles. Imagine a point *P* traveling around the circuits at constant speed. Let *M* be a projection of *P* on the line *AD*, so that *M* and *P* always have the same velocity horizontally. As *P* travels around the circuit, *M* will reciprocate along *AD*.

Now consider the point *M* to be a part of a flat bed, being fastened thereto in some manner. The motion of the bed is thus the motion of *M*, and the bed movement is easily followed.

It thus is seen that, for the period *BC*, the bed travels at uniform velocity from *Q* to *O*. For the period *CDE*, *P* travels in a semicircle, and therefore *M* and the bed slow down and speed up harmonically from *O* to *D* and back to *O*. For the period *EF*, the motion is uniform, and for the period *FAB*, it is again harmonic.

H. E. Golber

While the relation between the length of the segment *BC* and the length of the arc *CDE* may be varied, some of the presses aforementioned, for instance, the Miehles and the Babcocks, make the length of *CDE* equal to one-half the length of *BC*. The Miller Simplex, however, makes the length *CDE* equal to *BC*. This immediately determines the timing of the forces occurring, for instance in the Miehle:

Period *AB* = 1/12 of cycle = harmonic acceleration
Period *BC* = 1/6 of cycle = no force
Period *CD* = 1/12 of cycle = harmonic deceleration
Period *DE* = 1/12 of cycle = harmonic acceleration in reverse direction
Period *EF* = 1/6 of cycle = no force
Period *FA* = 1/12 of cycle = harmonic deceleration.

Attention is called to the fact that, although during the periods *CD* and *DE* the bed moves first to the left and then to the right, thus reversing its direction, nevertheless the force acts always in the same direction, namely, to the right; similarly for the periods *FA* and *AB*, the force acts to the left.

Above, for the period *BC*, is stated "no force." Frictional forces of course do occur during this period, but in this paper frictional forces are not taken into account.

When it comes to the actual kinematics for producing the motion of *M*, it is found that the various presses have different mechanisms.

For the uniform motion parts, namely, *BC* and *EF*, some presses (some Miehles) have (see Fig. 2) a driving gear *G*, always rotating in the same direction, and meshing first with an upper rack R_1, and second with a lower rack R_2, both racks being fastened to the bed. The two racks face toward each other, and are apart approximately the diameter of the gear. The gear meshes with one rack at a time, and is moved slightly axially or vertically to unmesh from one rack and to mesh with the other.

In other presses, for instance, the Babcock, the construction is inverted. Here the two racks R_1 and R_2 are placed in the center while the gear *G* is moved from above the racks to below the racks to engage first with one rack and then with the other rack.

In still other presses reversing gears are used. The variations are numerous, and will not be further entered upon.

When it comes to the mechanism for accomplishing the harmonic part of the movement *CD* during the periods *CDE* or *FAB*

---

[1] First Vice-President, Miehle Printing Press & Mfg. Co. Mem. A.S.M.E. Mr. Stevens was born in Tuscola County, Michigan, on March 25, 1874. After high school in Vassar, Mich., he attended Michigan Agricultural College, now Michigan State College, Mechanical Department. He was Chief Draftsman, W. B. Mershon & Co., Saginaw, Mich., 1895 to 1903; Chief Draftsman, Berlin Machine Works, Beloit, Wis., 1903 to 1911; Mechanical Engineer, Miehle Printing Press & Mfg. Co., 1911 to 1916; Vice-President and Mechanical Engineer, 1916 to 1928; and elected First Vice-President in 1928.

[2] Research Engineer, Miehle Printing Press & Mfg. Co. Mr. Golber was born in Kalwary, Lithuania, on May 26, 1873. He arrived in Chicago in 1884. He attended grammar school, high school, and was graduated from the University of Chicago in 1896. His background of experience includes chemist, Standard Oil Company, one year; Golber Calculating Machine Company until 1905; Wahl Company, 1905 to 1918; Rite-rite Company, 1918 to 1923; and since then Research Engineer, Miehle Printing Press & Mfg. Co.

Contributed by the Printing Industries Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers, 29 West 39th Street, New York, N. Y.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

(Fig. 1), there again is found a great variety. Generally the mechanism is a special means which is not connected to the bed during the periods BC and EF, but does become connected at, say, C, remains connected during the period CDE, and becomes disconnected at E. The particular kind of mechanism varies, and some will be indicated below.

There are some presses whose harmonic mechanism consists of a harmonically reciprocating gear, making three reciprocations

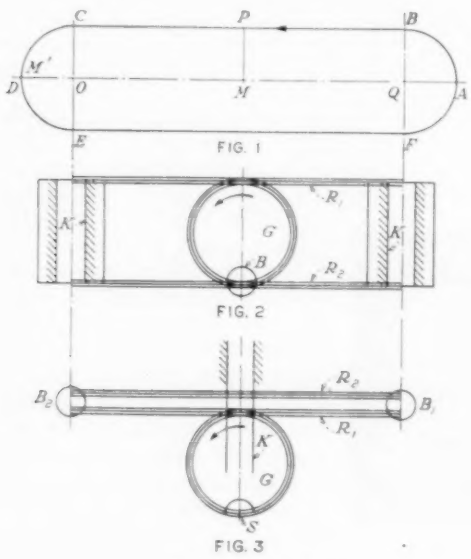

FIG. 1

FIG. 2

FIG. 3

FIGS. 1, 2, AND 3

per impression. Among them are the Kelly and the Miehle Horizontal. The reciprocating gear is given its harmonic reciprocation by a crank and a connecting rod or its equivalent. The reciprocating gear meshes with the bed at, say, C, and during the period CDE imparts its motion to the bed, until at point E the bed becomes unmeshed, ordinarily because it runs off beyond the range of the gear.

The Babcock press has a mechanism that at first view seems radically different, but on analysis is found to be a kinematic equivalent. Referring to Fig. 3, it will be seen that at each end of the double rack there is a roller ball B_1 and B_2. Cooperating with the roller is a socket S on the gear G. As the gear rotates, and drives the rack and bed, the socket S comes nearer and finally embraces the roller B_1. At that moment (see C, Fig. 1), the gear runs out of the rack, but the socket connects with the roller ball and drives the same. The motion is such that the gear center always keeps at a constant distance from the roller center, and the gear center moves straight up and down in a groove K. Upon analysis this is found to give the roller a harmonic motion, and thus the bed itself receives a harmonic motion.

The Miehle press has a mechanically different construction, but one which is again a kinematic equivalent. Referring to Fig. 2, there is a roller B, but here it is attached to the gear shaft and thus operates as a crank. The roller has a circular motion, which may be decomposed into a vertical component and into a horizontal one. The roller B rolls in vertical grooves K, which are attached to the bed. The bed is thus given a harmonic motion while the crank moves through a semicircle bounded by a vertical diameter.

Other variations are introduced in other presses. For instance, the Miller Simplex, departing from the vertical groove K and vertical diameter, employs a groove oblique at 45 deg. The bed still moves horizontally.

To make the mechanism operate, the operating diameter of the crank semicircle is changed from vertical to oblique. While the roller moves in the direction of the arrow, from the position B_1 to B_2, the inclined slot moves from the diametral to the tangential position. While the roller moves from B_2 through B_3 to B_4, the inclined slot moves back to the diametral position. On account of the inclination, the lower portion of the inclined slot is run over twice, once for the travel B_2 to B_3 and again for the travel B_3 to B_4. But the motion of the slot measured perpendicularly to the diameter B_1B_4 is obviously harmonic, and since every parallel-line projection of a harmonic motion is also a harmonic motion, the horizontal movement of the bed of the Miller Simplex is a harmonic motion.

So it is seen that the forces of the flat beds of cylinder presses, whether Whitlock-Premiers, Babcocks, Miehles, or Millers, are those arising from uniform travel and harmonic acceleration. They are all in the same class and may thus be treated together.

It is well known that in all machinery, going through any motion, the forces that occur are a function of both the mass of the moving parts and the speed of the machines. The forces vary directly as the mass and directly as the square of the speed. Also it is known that in harmonic motion the force varies directly as the distance from the center (see O, Fig. 1). So, given the weight of the bed W, the speed or number of impressions per hour, and the length of the radius OD (Fig. 1), the forces can be completely calculated.

The forces, as outlined in the foregoing, while of interest as an academic problem only, manifest themselves pragmatically as well. These forces manifest themselves in three different aspects:

(1) The effect on the motor
(2) The effect on the structure of the machine
(3) The effect on the building.

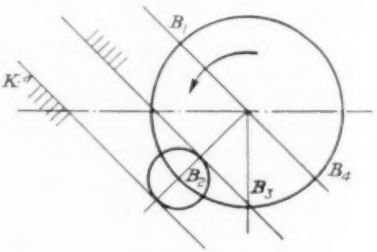

FIG. 4

These will be treated in order.

The effect on the motor is not very important. The flywheel is a storehouse of energy and carries enough to smooth out the inequalities due to the reversal of the bed sufficiently for commercial purposes. Should speeds be increased or other conditions make it desirable, perhaps something like the kinetic energy reservoir (U. S. patent 1,126,750) might be considered.

The effect on the structure of the machine is very noticeable. The reversing roller B must endure the forces necessary to reverse the bed. These are quite considerable. For instance, in a Miehle No. 4 press, the bed and moving associated parts weigh approximately 1500 lb. At a speed of 3300 impressions per hour, the maximum force on the roller would be about 7000 lb. This pressure is great enough to warrant means for counteracting it, and these means have been of various kinds.

Many attempted to reduce the weight of the bed. Thus, instead of cast iron, welded steel has been used. Aluminum and its alloys have been considered. Now that beryllium is suggested for commercial use, with great strength and lightness, it also might be considered. Thus far, however, cast iron is the standard.

Others have reduced the length of the stroke. However, as the motion of the bed relative to the impression cylinder depends on the length of the maximum sheet, that relative stroke must be preserved. What was taken off the stroke of the bed was there-

fore added to the cylinder. Nevertheless, by this means something might be gained, as the total kinetic energy of both bed and cylinder might be decreased. This has been done in the Autopress, the Miller High Speed, and the Miehle Vertical, where the bed and cylinders each move one-half the distance in opposite directions.

Attempts have been made along other lines. Some time ago spring bumpers were tried to help in stopping the bed at the end of its stroke. These springs theoretically operate according to Hooke's law that the force is directly proportional to the distance the spring is compressed. As the force of a harmonic movement is also directly proportional to the distance OM^1 (see Fig. 1), the spring could be made to theoretically balance the bed force. However, the difficulties encountered in making the spring bumper shockless, and to adapt it to various speeds and to prevent the springs from breaking under the rather large forces, kept that solution from coming into general use.

Instead of metal springs, air springs were proposed. Air buffers are quite generally used, and any one who wishes to convince himself of their value may easily do so by comparing the operation of a press with the air spring functioning and again not functioning.

The air spring is generally composed of a cylinder and a piston for compressing the air during the stopping of the bed. This compressed air helps to start the bed in the opposite direction. There are certain laws in connection with air springs that will

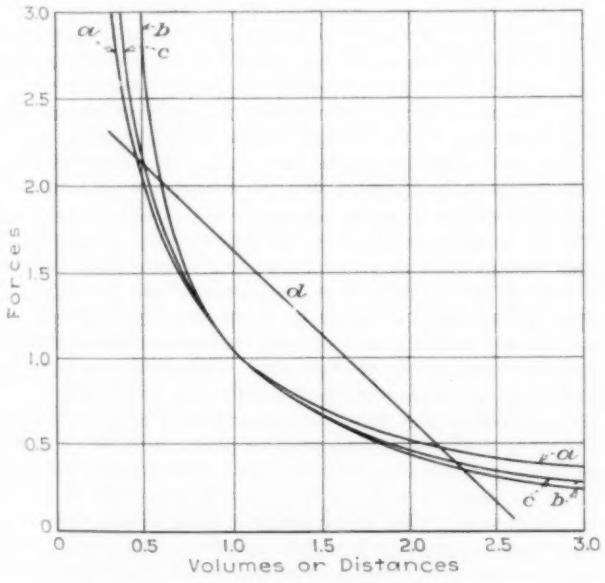

FIG. 5

now be considered. The law of compressing air isothermically is Boyle's Law $PV = C$, or pressure $\times$ volume = constant. In the rapid operation of a modern flat-bed printing press, the air might be considered to be compressed adiabatically with the law $PV^{1.41} = C$. However, in practice a modified law is found better and is assumed to be $PV^{1.3} = C$.

It has been stated in the foregoing that the change of volume occurs by the motion of a piston in a cylinder. The volume may therefore be considered a cylindrical volume, and thus proportional to the length of the cylinder. The law might therefore be changed to $PL^{1.3} = C$, where L is the length of the column of compressed air in the cylinder.

If we lay out a graph, Fig. 5, making the ordinates represent the forces and the abscissas represent the lengths, we find that Boyle's Law $PV = C$ gives a rectangular hyperbola a. The adiabatic curve $PV^{1.4} = C$ is shown as b, while the accepted curve $PV^{1.3} = C$ is shown as c between the other two curves. The three curves cross each other at the point $P = 1$ $V = 1$. They are all hyperbolas of various kinds, and their properties are described in many books, for instance, Steinmetz's "Engineering Mathematics."

If we make a similar graph for the harmonic forces of the flat bed, we find the curve to be an inclined straight line d. The problem of balancing the bed forces by the air spring thus reduces to the superposing of the straight line d upon the hyperbola c. It is manifest that this is impossible. The straight line at best can be made to intersect the hyperbola in only two points, and the best that can be done is to make the differential ordinates (or forces) as small as possible.

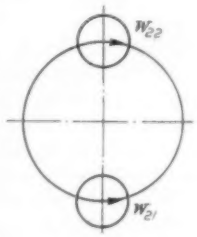

FIG. 6

Moreover, another consideration must be taken into account. The bed forces vary as the square of the speed of the machine. The tangent of the angle of d or its slope therefore varies as the square of the speed of the press. But the formula for air compression $PL^{1.3} = C$ is not varied with the speed. A best match for one speed therefore becomes a poor match for another speed, and it very readily happens that a poor match will introduce differential forces larger than the ones attempted to be matched. It is therefore desirable to introduce mechanism for changing the adaptation of the air spring to the bed forces depending on the speed of the press.

On the larger Miehle presses, this has been done in two ways. Recalling that the Miehle air spring consists of a moving piston trapping air in a stationary cylinder. it is easily seen that one variation might be introduced by the piston trapping the air earlier or later. This is accomplished in practice by keeping a valve open to allow the trapped air to escape until the desired time when the valve is shut—earlier for high speed, later for low speed. This is done by means of a centrifugal governor and cooperating mechanism.

Another method is by enlarging or diminishing the dead volume at the end of the compression stroke.

The foregoing very general treatment of the air spring shows how far-reaching a discussion of it may become, so we will halt here and return to the general problem.

Referring again to Fig. 1, it was stated that in most presses the arcs CDE and FAB were semicircles. The semicircle has been adopted, however, for machining reasons, not for dynamic reasons. Its harmonic motion can be produced on standard machine tools, whereas other motions cannot be so readily produced.

A good deal of thought has been given to the foregoing question, and it was noticed that a parabolic curve no doubt has some advantages. It is the curve of a body falling under gravity, and gravity operates without shock. Upon making the comparison, it is found that the parabolic curve produces a constant force like gravity, while the semicircle produces a varying force, directly proportional to the distance from O, and therefore having a maximum at D. Moreover, calculation shows that

$$\frac{\text{Constant Parabolic Force}}{\text{Maximum Harmonic Force}} = \frac{2}{\pi}$$

or roughly $^2/_3$. Since the force increases as the square of the speed of the press, it is seen that a press with parabolic mechanism could be run $\sqrt{\pi/2} = 1.25$ times as fast as the press with the harmonic mechanism before the constant force of the first press would equal the maximum force of the second press.

There will now be taken up the effect of the bed forces on the building. They manifest themselves, particularly with big presses and weak buildings, by shaking the building, so much so that in some cases the operation of the press has to be stopped.

It has been pointed out previously that the heavy bed runs at a uniform velocity during the period (*BC*, Fig. 1), and is stopped and reversed during the period *CDE*. The kinetic energy of the bed must therefore be somehow absorbed. Generally it is absorbed by the building. True, there has been a discussion of air springs, etc. to balance the forces of the bed, and the air spring is somewhat successful in doing so. But when the bed force goes into the compressed air in the cylinder, the air pushes on the bottom of the cylinder, which pushes on the frame, and which in turn pushes on the building to an amount just the same as if the air springs were not there at all. The effect on the building remains totally unchanged.

Several suggestions have been made, and some of them are in use. Thus since buildings are generally built to withstand vertical stresses better than horizontal ones, the bed motion has been made vertical in some presses. But this is practical in small presses only, where but little trouble would be encountered.

It has been suggested that the press be allowed to move somewhat on the floor, and allow the heavy press base to absorb the kinetic energy of the bed. This suggestion has been tried out, but has not found favor.

Another suggestion is that the bed energy be balanced internally in the machine by making the framing very much heavier. This may help, but has objections of its own.

Still another suggestion is to balance the bed forces internally in the machine. Many years ago a patent was issued showing a balancing weight moving in the direction opposite to the bed. This method would balance the effect on the building, but would double the forces on the crankpin, air spring, etc.

Some variants of the preceding were made. Thus, as mentioned before, in the Miehle Vertical the bed and cylinder move in opposite directions, thus balancing each other and eliminating the effect on the building.

The question has been asked, Could not the bed motion be completely balanced by bodies rotating at uniform velocity about fixed axes? Upon further consideration, this was seen to be equivalent to the decomposition of the bed motion of Fig. 1 into a Fourier series.

This has been accomplished, and it was found that the bed motion forces can be completely balanced by a set of eccentric weights W_1, W_3, W_5, located at crank radii of respectively r_1, r_3, r_5, and having the following values:

$W_1r_1 = 3.72\ WR$ one revolution per impression
$W_3r_3 = 0.333\ WR$ three revolutions per impression
$W_5r_5 = 0.074\ WR$ five revolutions per impression
$W_7r_7 = 0.015\ WR$ seven revolutions per impression, etc.

where W is the weight of the bed and $R = OD$ (Fig. 1).

Of course, these rotating balancing weights were calculated to completely balance the horizontal bed forces on the building, but might themselves introduce unbalanced vertical forces. These vertical forces, however, may be completely balanced by replacing each one of the foregoing rotating weights, say W_3, by a couple of rotating weights W_{21} and W_{22} (Fig. 6), the two weights in each couple rotating at the same speed in opposite directions, and so arranged as to have one weight move up while the other moves down, and while both weights move horizontally together (Fig. 6).

The problem can thus be considered to be dynamically solved, but when it comes to reducing it to practice, the question of distribution of the weights and the mechanism to drive them is a problem in itself.

Discussion

W. S. Huson.[3] This paper, which contributes in a technical manner to the problems of forces at work in the reversal of reciprocating bodies, as in printing presses, brings out some factors that seem to be hard for the average mind to grasp—first, that the work of stopping and starting a body is hardest on the driving mechanism and not keeping the moving body in motion; second, that the positive space in which retardation and acceleration must take place compels positive control that proper synchronism be maintained with other parts of the machine. In a steam engine the reciprocating piston is cushioned at the ends of the stroke by the compression and expansion of a residuum of steam in the cylinder and by the absorption of some of the work by the crank and heavy flywheel. In designing a press, however, where in the main there is no opportunity for a heavy foundation and provisions to suitably adapt the reciprocating parts to theoretical requirements, the endeavor is to find a solution that will give in the best possible way a practical cushioning device that will better absorb the momentum, relieve the strain on the driving mechanism, and which, in the endeavor to counteract the overwork on it, transmits it to the press as a whole; hence the tendency to move on the floor, and the need for better control is accentuated by the increased speed at which presses are run.

That the need for something to stop and start the bed was early recognized is shown by the variety of adaptations of coil springs—in some foreign presses by leaf springs—the endeavor being to meet the oncoming body by an absorbing element that was adjusted to meet the load by presenting a reacting load in which one would dissipate the other. The ability to preset a nest of springs to an initial load was the dominant feature, and while the coil springs have been abandoned, they had that feature which the later air springs do not have, for in the air spring the initial pressure must be built up to several atmospheres before it becomes effective and that done at each stroke of the reciprocating bed. That presses could be made heavier or moving parts lighter seems to be beside the question. The problem is to adequately overcome the impetus imparted to the moving body and return it to its previous state, and this without shock or undue stress on the parts. To this end the paper is a helpful one in the manner in which it sets forth the complex nature of the problem and portrays a deep study of it.

Progress in Railroad Mechanical Engineering

Contributed by the Railroad Division

Executive Committee: R. S. McConnell, *Chairman*, M. B. Richardson, *Secretary*, A. F. Stuebing, Eliot Sumner, A. G. Trumbull, and J. B. Ennis

FUNDAMENTAL conditions in the railroad field show little change since last year. Developments in operation and traffic are still following the general trends and tendencies noted in the preceding report of this division. However, the present situation discloses some distinct changes from that of a year ago. The volume of freight traffic in 1929 has been greater than in any previous year; the average weekly car loadings for the first nine months have been 1,051,000, or 7.5 per cent greater than in 1928. While new records for operating efficiency have been established and the ton-miles per freight car have been increased, the surplus of freight cars has declined from the high level of 1928. This apparently has been responsible for renewed activity in the purchase of equipment. For the first nine months the number of freight cars ordered totaled 66,190. Although this number is small compared with record years, it is 169 per cent greater than purchases in the corresponding period of 1928. Locomotives ordered up to October 1 totaled 672, or 170 per cent more than for the first nine months of the preceding year. The tonnage of rails purchased has been large and the major proportion has been of heavy section, indicative of the railroads' purpose to improve their properties and reduce maintenance costs by investments in the most modern facilities.

The continued growth of passenger travel by highway buses has led the railroads to enter this field more extensively and to coordinate train and bus service. The schedules of through trains on trunk-line and western routes have been reduced and more fast trains have been put in service, especially between New York and Chicago. Advocates of the use of inland waterways for freight transportation have been very active, but their arguments have been offset by the reports of independent analysts who have shown that in practically every case the apparent savings in freight rates are more than offset by the fixed charges on the cost of making the routes navigable and providing necessary facilities. A survey of technical developments reveals many innovations in equipment. The variety of designs and types of locomotives is particularly noteworthy.

High-Pressure Locomotives

The interest in locomotives operating at high pressures and the extent to which this means of increasing thermal efficiency is gaining acceptance are evidenced by the numerous designs now being tried. Double-pressure locomotives of the type originated by the Schmidtsche Heissdampf Gesellschaft and described in the paper by R. P. Wagner presented at the 1928 meeting of the Society, have been placed in service on the London Midland and Scottish and the Paris-Lyons-Mediterranean. Similar designs are now being prepared for the New York Central and the Canadian Pacific.

Another high-pressure locomotive built recently in Germany is the Schwartzkopff-Loeffler type, utilizing steam at pressures of approximately 1500 lb. per sq. in., which will be tested on the German State Railways.

The Swiss Locomotive and Machine Works of Winterthur has built a passenger locomotive of novel design with a geared uniflow engine connected to the driving wheels through a geared jackshaft. The boiler pressure is 850 lb. per sq. in. In comparative trials with a locomotive of standard type this design showed a coal saving of 35 per cent.

H. N. Gresley of the London and North Eastern has prepared a design for a high-pressure locomotive to be fitted with a Yarrow-type boiler.

After several years' experience with two locomotives operating at pressures of 350 and 400 lb., the Delaware & Hudson has placed an order for a third which will carry 500 lb. boiler pressure. The engine will be of the cross-compound type.

Turbine Locomotives

Various arrangements for adapting steam turbines to locomotive service are being tried, of which perhaps the most significant is the use of the non-condensing turbine. The Oxelosund-Flen-Westmanlands Railways have ordered two locomotives with back-pressure turbines designed by the Ljungström Steam Turbine Company, which will be built by Nydquist & Holm. The advantages expected are 25 per cent greater starting tractive force than with the reciprocating engine and 20 per cent fuel saving, with a probable reduction in maintenance expenses. The Ljungström Company further proposes the conversion of piston locomotives to non-condensing turbine locomotives by replacing the cylinders with a back-pressure turbine driving through reduction gears and a jackshaft.

Internal-Combustion Locomotives

During the past year the Canadian National Railways placed in service the most powerful oil-electric locomotive ever built. This is especially noteworthy because it is the first of the internal-combustion type which approaches the power output of the modern steam locomotive. Two units make up the complete locomotive, which weighs 650,000 lb., with 480,000 lb. on the driving wheels. The wheel arrangement is of the 4-8-2-2-8-4 type. Motive power is provided by two 12-cylinder Beardmore high-speed solid-injection oil engines of 12 in. bore and 12 in. stroke, rated at 1330 hp. at 800 r.p.m. The fuel consumption of the engines is 0.43 lb. per hp-hr.

A comparison of this locomotive with the latest steam locomotives for passenger service on the same road shows that from 20 m.p.h. to maximum speed the steam locomotive develops slightly greater tractive force, but below 20 m.p.h. the advantage is in favor of the oil-electric which develops a tractive force up to 100,000 lb., whereas the maximum for the steam locomotive is 49,600 lb. Designs have been prepared for a similar locomotive for freight service, which will develop a maximum tractive force of 130,000 lb.

The Baldwin Locomotive Works has recently built an oil-electric locomotive designed for switching service and equipped with a 1000-hp. Krupp Diesel engine. This locomotive, which has a total weight of 270,000 lb., is carried on four pairs of drivers in two articulated four-wheel trucks. The engine is of the four-cycle airless-injection type with six cylinders of 15 in. bore and 15 in. stroke, operating at 250 to 500 r.p.m. A compressor attached to the engine furnishes air for the brakes, for starting, and also for supercharging the engine at about 6 lb. per sq. in. pressure. The generator and four motors operate at 550 volts d.c. The

theoretical tractive force is 67,500 lb. up to 5 m.p.h. The control equipment is arranged so that the locomotive can be operated from either end. A noteworthy innovation is the arrangement for varying the speed of the oil engine as required, which consists of a connection by levers and hydraulic cylinders from the electric controller to a cam on the governor which manipulates the throttle of the engine.

Another noteworthy design is the 900-hp. Diesel-electric passenger locomotive built by the American Locomotive Company for the New York Central. This has four-wheel trucks at each end and eight driving wheels in the main frame. The engine is a 12-cylinder "V" type built by McIntosh & Seymour. The cylinders are 14 in. in diameter by 18 in. stroke, and develop 900 b.hp. at 310 r.p.m., with 10 per cent overload capacity. Air injection is used and fuel pumps are governed by electric regulation which controls the amount of oil supplied to the cylinders and the torque developed. The main generator has 10 main poles and 10 commutating poles, and is connected directly to the engine.

The Krupp Works have built a Diesel locomotive with a mechanical-magnetic transmission for the Boston & Maine, which has not yet been delivered. The total weight is 314,000 lb. and the maximum tractive force 50,000 lb.

The first application of the Still combined internal-combustion and steam engine to railway traction has been embodied in a locomotive built by Kitson & Co., Leeds. The motive power consists of a four-stroke heavy-oil engine of the horizontal opposed type with eight cylinders. The cylinders and crankshaft are in a plane slightly above the top of the locomotive frames. The engine is geared to a jackshaft which drives the wheels through connecting and coupling rods. The water jackets of the internal-combustion cylinders are coupled by pipes to a boiler located above the engine. This boiler supplies steam which can be applied to the inner sides of the pistons for starting or to furnish auxiliary power on steep grades. The boiler carries a pressure of 200 lb. per sq. in. and is fired when needed by an oil burner. Heat is also applied from the exhaust gases of the oil engine.

The locomotive is of the 2-6-2 type with 60-in. drivers and weighs 195,000 lb. The engine is of 13½ in. bore and 15½ in stroke, designed for a maximum speed of 420 r.p.m., corresponding to a locomotive speed of 40 m.p.h. The fuel is injected without air. On trial runs the engine has commenced to fire at 3 m.p.h. and has operated at speeds up to 45 m.p.h. The tractive force developed was 25,000 lb. with steam alone and 7000 lb. at 45 m.p.h. with internal combustion only. Test runs have been made on the London and North Eastern Railway with both freight and passenger trains. The incomplete data now available indicate that the oil-engine consumption was approximately 10 lb. per 1000 gross ton-miles. It is anticipated that the fuel consumption of the boiler will under average conditions approximately equal the engine consumption. While these figures are far below the best records for steam locomotives in similar service, it is thought that the Still locomotive will give its best results on longer runs with fewer stops and less severe grades.

The most noteworthy locomotive of what may be considered the standard type built during the past year was the single-expansion articulated 2-8-8-4 design for the Northern Pacific, the largest and most powerful steam locomotive in the world. The total weight of engine and tender is 1,116,000 lb., of which 715,000 lb. is the weight of the engine alone. The tractive force of the main engines at 70 per cent cut-off is 139,900 lb., and with 13,400 lb. additional tractive force developed by the booster, the combined tractive force is 153,300 lb.

The Northern Pacific locomotive is especially designed to burn eastern Montana sub-bituminous coal which is high in moisture and has relatively low heating value, necessitating the use of a boiler with 182 sq. ft. of grate area to develop the power required. That the problems involved in the design were successfully met is indicated by the fact that the railroad has placed a second order for locomotives of the same type.

Another interesting development in special fuel is the application of pulverized fuel in Germany. Two different designs are being tried. One has burners extending along both sides of the firebox with multiple slots and water-cooled chambers, the jets impinging against one another in the middle of the firebox. The other type has a diffuser burner in the form of a hollow cone, the enlarged front end of which is closed by a plate having numerous nozzle-shaped holes. The small rear end adjoins a mixing device for the coal dust and air mixture. The diffuser plates are flush with the back plate of the firebox, while the burner bodies are outside. The diffuser plate, which is the only part exposed to radiant heat, is cooled by the coal dust and air mixture.

Freight Cars

The most significant development during the year pertaining to car equipment was the report of the draft-gear tests conducted by the Mechanical Division of the American Railway Association. Following extensive laboratory investigations of draft gears now in general use, the committee submitted tentative specifications setting forth requirements for capacity, sturdiness, endurance, and recoil. The work of the committee will be carried still further, and it is expected that important improvements in draft gears will result from their investigation.

Further extension of the use of special refrigerating systems mentioned in previous reports is indicated by the announcement that the company developing the silica-gel system of refrigeration has placed an order for 50 additional refrigerator cars to be so equipped.

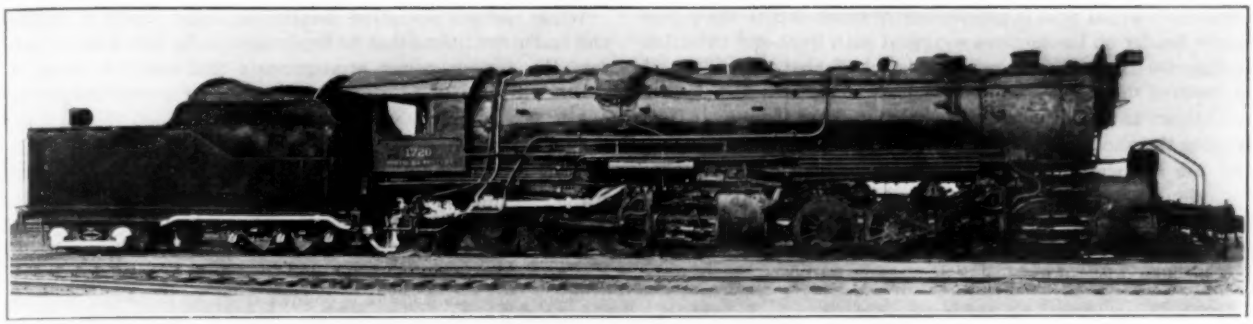

FIG. 1 SINGLE UNIT AUXLOCO APPLICATION TO MALLET HELPER LOCOMOTIVE

Locomotive Auxiliary Power Mediums

BY GEORGE W. ARMSTRONG,[1] BETHLEHEM, PA.

In this paper the author describes the Bethlehem auxiliary locomotive and gives some test results. A self-contained power truck is provided which can replace one of the regular tender trucks, either a front or rear truck of the locomotive, and in some cases to replace both trucks. Ordinarily the rear-truck installation is recommended as it facilitates removal for inspection and maintenance.

EARLY in the development of the steam locomotive efforts were directed toward auxiliary power which would enable the locomotive to handle a more equalized load on gradients and level track without the use of assistant or helper locomotives. The Sturrock locomotive, which consisted of a supplemental locomotive under the tender, is the earliest known application. Some 65 of these locomotives were in use on English railways in 1865. The locomotive under the tender was used only at slow speeds on grades.

The limitations of the small engines of that day in steaming capacity, the excessive steam demand due to condensation with the use of saturated steam, together with the maintenance requirements of a unit always in use, whether operated or not, all combined to sound the death knell for these early attempts.

It is only within recent years, with the extensive use of superheated steam, the development of large power units, and the application of the automatic stoker, eliminating the limitations of firing capacity, that the practical application of auxiliary power for locomotives has been realized.

The concept of railroading, in the meantime, has changed in conformity with the present-day economic necessity, so that this applied auxiliary power is utilized not only as originally considered as a compromise assistant or helper locomotive, but as a starting medium.

Service, the only commodity which the railroad has to sell, demands rapid transportation. Freight trains today are being run at speeds comparable with passenger schedules of not so many years ago. This has brought into existence a locomotive with large driving wheels, 69-in. and 73-in. wheels being common for many recent freight locomotives, as contrasted with 57-in. and 63-in. wheels of 10 or 15 years back.

Along with this trend is the desire to secure the maximum tractive effort permitted by the allowable weight on drivers, which has resulted in a gradual lowering of the factor of adhesion, or ratio of driving-wheel weight to cylinder tractive power. The combination of these two factors has resulted in a locomotive with high sustained power at speed, due to the boiler capacity combined with the lowered piston speeds, and at the same time, an engine of greater tendency toward slipping.

The hauling limitations, consequent upon high-wheel, high sustained power locomotives, without excessive wear and tear of machinery, and undue delay in accelerating frequently become the starting load rather than the road hauling load. An auxiliary power medium permits the locomotive to accelerate promptly and start a train, which is well within the ability of the locomotive to handle after once under way. Early attempts at auxiliary power utilization as previously mentioned, wholly aside from any inherent structural weaknesses, failed due to the limitations of steam production.

The growth in the size and capacity of locomotives has resulted in a boiler of proportions, such that a reserve capacity is available at slow speeds for auxiliary power use. The boiler of a locomotive in its design must be considered in relation to the steam requirements at speed of the cylinders. Generally considered, experience has shown that maximum steam requirements and maximum horsepower for superheated-steam locomotives occur around a piston speed of 1000 ft. per min. Simply stated, this fundamental concept in auxiliary power use is as shown in Fig. 2.

It is this surplus boiler capacity which can be drawn upon, as reflected in road and test-plant results, and utilized in the operation of an auxiliary power medium. The Bethlehem auxiliary locomotive is a self-contained auxiliary power truck, which can replace one of the regular tender trucks. It can be used either as a front or back truck or in some instances to replace both. Ordinarily the rear-truck installation is recommended as this facilitates removal for inspection and maintenance.

A tender-truck installation of an auxiliary power medium results generally in a most satisfactory employment of such additional power. Being gear driven and operated under a wide open throttle, an auxiliary power medium requires a higher factor of adhesion than a locomotive where power output can be graduated by throttle manipulation. The weight of modern tenders is such that a very ample and high factor of adhesion results, giving a unit which permits maximum possible power development and reliable operation, free from slipping.

This advantage is particularly apparent where the auxiliary-

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

locomotive steam pipe is independently connected to the superheater header on locomotives equipped with front-end throttles. In this case the auxiliary power unit is not affected when the main locomotive slips, and since with a high factor of adhesion it is not subject to slippage, it serves a very useful purpose in at least keeping the slack stretched while quieting down the main engine, and has frequently been the means of avoiding stalling under such conditions.

A tender application has the advantage of converting a large, essential non-productive weight into a valuable supplementary power source without sacrificing its primary purpose. At the same

time it permits full utilization of the physical limitations of railroad clearances and rail loads in the development of the maximum boiler capacity and locomotive power.

Utilizing the idle truck axles of the locomotive tender for supplementary power will accomplish the following:

1 It will add to the locomotive drawbar pull from 15 per cent to 35 per cent depending upon the size of the locomotive unit.

2 This added capacity permits a corresponding increase in train tonnage where starting ability governs or where the ruling grade is a somewhat limited portion of the operating division.

3 It provides for increase in train tonnage where bridge and rail limitations restrict locomotive weight and therefore tractive power.

4 It accomplishes the equivalent of grade reduction for purposes of equalizing grades, but with less capital expenditure.

5 Curvature on heavy grades can be compensated by auxiliary power use on all curves.

6 It permits increase in average speed over grades where the added drawbar pull is not wholly utilized for handling tonnage.

7 It provides more prompt and constant acceleration from yard, water station, and enforced signal stops.

8 It reduces locomotive slipping in starting, and therefore tire and rail wear.

9 It provides more uniform drawbar pull which results in a decrease in abnormal starting stresses on draft gears and equipment.

Considering the various features of train operation, it is clear that the use of an auxiliary power unit which can be operated independently so as to be available when required for assisting the locomotive in starting the train, and permitting considerable increase in train tonnage than otherwise could be handled, is closely related to economical train operation.

While railroad operation involves so many kinds of profiles and traffic conditions that no fixed rules can be laid down to indicate the various power arrangements that would be most efficient with respect to utilization of auxiliary power and regular helper service, there are few operations to which the auxiliary locomotive cannot be adapted on a very profitable basis.

Where ruling grades are relatively short (momentum or otherwise), the use of an auxiliary power unit permits increasing the train tonnage an amount over the entire division consistent with that for a locomotive of the tractive power of combined auxiliary and main locomotive tractive power.

Where the ruling grade is compensated by means of assistant or helper-engine service, the next heaviest grade of the district then becomes the ruling grade, and where conditions warrant, tonnage rating can be arranged with reference to the capacity of the main locomotive and auxiliary locomotive on the secondary grade. A condition such as the foregoing would undoubtedly require auxiliary power use in negotiating the primary ruling grade, and might require auxiliary power use on helper locomotives if sufficient differential existed in gradient.

Operating conditions with heavy pusher ruling grades, which do not present long continuous uniform gradients, afford opportunity for increasing train tonnage through use of an auxiliary power medium applied only to the helper locomotives.

Low-grade operating divisions permitting high-speed operation and adaptable to high capacity, large driving-wheel power can, as previously outlined, be negotiated by increased tonnage trains through the use of the auxiliary power unit to start and accelerate the train.

Many locomotives have sufficient boiler capacity to support two auxiliary locomotives where only short periods of operation of the auxiliary units are required. This is especially an important feature in regard to hump engines, so as to permit handling trains with a single locomotive without the necessity of cutting trains for handling.

Dynamometer-car tests were run on the Boston and Maine Railroad during the spring of 1927, which give a very good picture of what can be accomplished under service conditions.

The tests were run between Mechanicsville, N. Y., and East Deerfield, Mass., over the Berkshire division of the Boston and Maine Railroad. In both directions, there is an up grade operation to the Hoosac tunnel piercing the Hoosac Mountains, and through which trains are handled by electric locomotives.

A comparative picture of road operation on the section between Mechanicsville and Hoosick Falls as revealed by these dynamometer tests is shown in the chart Fig. 6. This gives the profile of the section, and at the bottom are figures for the average developed drawbar pull, the speed at the mile posts, and the running time between certain points for east bound operation. This graphic picture serves to show the increased drawbar pull required under varying road conditions, handling an increase in tonnage, justified by the supplementary use of the Bethlehem auxiliary locomotive to handle such tonnage over the ruling grade.

In demonstrating the value of the auxiliary locomotive as well as to answer satisfactorily whether tonnage could be handled, all test trains whether locomotive tonnage only or extra auxloco tonnage trains, were stopped on the ruling grade at the worst operating condition and handled from there. Further, all extra auxloco tonnage trains were started only with the use of the auxiliary locomotive to supplement the locomotive after three stalling starts were made with the locomotive only. Westbound stops were made for signal 1157, just east of mile post 116, and east bound stops for signal 1179, just west of mile post 180.

Regular stops were made at the east and west portal for electric locomotives. Electric locomotives in some east-bound tests were coupled on near mile post 142 at North Adams rather than

at the portal. A stop was also made on all east-bound trips at Eagle Bridge for a non-interlocked crossing. Other extra stops are indicated on the chart.

East-bound traffic is of major importance on tonnage trains, being the prevailing movement. The operation in this direction shows an increase in the gross ton mile per train hour, the average being 60,188 for auxloco-locomotive operation as against 55,718 for engine only, an increase of 8 per cent.

West bound there was a slight loss in gross ton miles per train hour, an average 40,809 being secured under extra tonnage operation compared with 41,690 under regular operation, a loss of 2.2 per cent. Table 1 gives test summaries.

No difficulty was experienced at any time in maintaining the steam pressure on the locomotive during the time the auxiliary locomotive was in operation. The log of boiler, steam-chest, and auxiliary steam-chest pressures as well as water-level, superheat, and reverse-lever position are given in Table 2 for test No. 3 over the section from the start at signal 1157, MP. 116 to MP. 120 with the auxiliary locomotive operating over the entire section. The reason for the drop in pressure at the last reading was to avoid lifting the safety valve after the engine was partly shut off passing MP. 120.

The dynamometer charts which were made but are not included in this paper illustrate the value of an auxiliary locomotive. Entering Soapstone siding, the locomotive ordinarily could handle the train, but in rounding the S curve just beyond the switch entrance, a bad rail condition was encountered owing to water dropping from a ledge of rocks on to the right-hand rail, the

locomotive slipped badly upon reaching this strip. The speed was reduced from 7½ m.p.h. to 3 m.p.h. in 45 sec., and the locomotive would have stalled except for the fact that the auxiliary locomotive was cut in, and within a distance of slightly over 1200 ft. accelerated the train from 3 m.p.h. to 8.4 m.p.h.

A typical use of the auxiliary locomotive to accelerate a train on a grade, and at the same time compensate for curvature on the grade was while a train was being handled on a 0.47 per cent grade. The engine had just started on to a short tangent beyond the last curve, so that the train was being handled around a number of curves. The use of an auxiliary locomotive in handling increased tonnage over a heavy grade is shown in a typical start with a regulation tonnage train from signal 1157, east of MP. 116

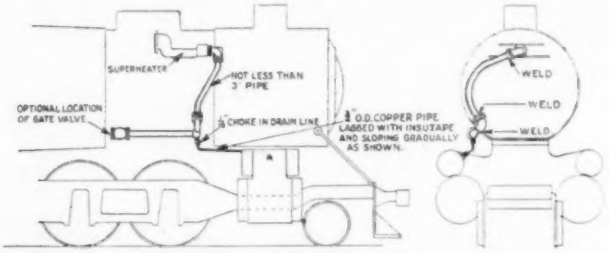

FIG. 3 AUXILIARY LOCOMOTIVE STEAM-PIPE CONNECTIONS TO SUPERHEATER WHERE FRONT-END THROTTLE IS USED

using the locomotive only, and the starting of an auxiliary locomotive extra-tonnage train from the same point. An additional drawbar pull of 10,000 lb. was needed to start this train over that which the locomotive alone developed in a stalling start. A steadier pull was secured through the use of the auxiliary locomotive added to that of the main locomotive, and there was a decreased tendency of the main locomotive to slip.

Use of the auxiliary locomotive is shown in Table 3 which gives the acceleration while handling of regulation tonnage from signal 1798 near MP. 180. These records also serve to show the relative accelerating ability of the locomotive equipped with the auxiliary locomotive where the use of the auxiliary is continued beyond the point absolutely required to handle the extra tonnage train.

The use of an auxiliary locomotive from a bad water-plug stop is presented by the operating conditions at Johnsonville, where the train is on a 0.55 per cent grade, and the engine dips over the crest of the hill and starts down a 0.39 per cent grade.

It is evident in the foregoing that the locomotive boiler fundamentally determines the utility of an auxiliary power medium. While a given locomotive boiler has a definite evaporative capacity, it must be conceded that this capacity cannot under present locomotive design be availed of at all speeds.

Stephenson in the early stages of locomotive development conceived the idea of employing the exhaust steam in a blast for the purpose of drafting the locomotive. This principle is still employed, and with the employment of the most efficient appliances represents a nearly ideal method for ordinary operation.

Draft is a function of combustion rate, and also of steam consumption and therefore exhaust, and the variation in the combination of variables is such that as an increased firing rate becomes necessary, the increased steam consumption and therefore the exhaust increases the draft so as to support the higher firing rate.

It must therefore follow that under certain conditions, the increased boiler capacity required for auxiliary power use must result from forcing the boiler beyond the normal capacity for that

condition of working. Many attempts have been made to develop methods of induced and forced draft which will have the effect of making the boiler independent of engine working, and with the successful development of any such method, a greatly extended field for auxiliary power utility will be opened up.

Having in mind the limitations of boiler output under present conditions and the effect of such on the use of an auxiliary power unit, as well as the complete development of the value of an auxiliary power medium, the use of the Pennsylvania Railroad's locomotive test plant at Altoona was obtained and comprehensive tests were run of the locomotive and Bethlehem auxiliary locomotive, alone and together.

These tests were conducted with the auxiliary locomotive working alone, and also working in operation with a locomotive as it is applied in actual service. Owing to the limited length of the testing plant, it was impossible to test the auxiliary locomotive as one of the tender trucks. It was, therefore, applied in place of the trailer truck to a 2–8–2 type locomotive (Pennsylvania class

FIG. 6

L–1–s). The steam supply pipe to the auxiliary locomotive was connected to both branch pipes of the locomotive. The usual number of bends and Barco joints were placed in the steam line to give the same length of pipe and resistance to steam flow, as if the auxiliary locomotive were placed in its normal location under the tender. The gears were blocked in mesh. The weight supported by the auxiliary locomotive was not ascertained, but it was sufficient to prevent slipping of the wheels.

The first tests were made for the purpose of comparing the results obtained with the locomotive working alone, and when assisted by the auxiliary locomotive. These preliminary tests were made at speeds of 40, 50, and 60 r.p.m., which correspond to 7.3, 9.2, and 11 m.p.h. respectively.

Full gear tests of the locomotive at 80 per cent cutoff were made at all three speeds, while tests at 60 and 70 per cent cutoff were made at speeds of 7.3 and 11 m.p.h. Special tests of the

FIG. 8 BASIC U.S.R.A. LIGHT MIKADO DESIGN WITH INDEPENDENT STEAM-PIPE CONSTRUCTION

locomotive alone were made to show the change in drawbar pull at 7.3 and 11 m.p.h. with various changes in cutoff. Tests were also made to determine the steaming capacity of the locomotive. In addition a series of tests of the auxiliary locomotive were made to determine its characteristics when operated alone.

All the tests, except those conducted on the auxiliary locomotive alone were made in pairs. In other words, a test of the locomotive and the auxiliary locomotive was followed by a test of the locomotive alone, the test of the locomotive alone starting as soon after the auxiliary locomotive was stopped as the firing rate, rate of boiler feed, branch pipe temperature, etc., became adjusted to the new test conditions. The locomotive and auxiliary when operated together were run at the same speed in miles per hour. Tests of the auxiliary locomotive alone were made at speeds lower than when it was operated with the locomotive. Starting tests were not attempted either with the locomotive or auxiliary locomotive on account of the danger of slipping.

The diameters of the driving wheels of the locomotive were 62 in., and that of the auxiliary locomotive driving wheels, 36 in. The gear ratio of the auxiliary locomotive used in these tests was 2.25. The locomotive was hand fired with run-of-mine bituminous coal. The factor of primary importance to the railroad man developed by these tests is "what does it add in hauling capacity?" Table 4 shows the drawbar pull of the locomotive alone and the locomotive and auxiliary locomotive operated together:

TABLE 4 DRAWBAR PULL ABOVE MAXIMUM OF LOCOMOTIVE

	Drawbar pull—pounds			
Speed, m.p.h.	Locomotive alone	Locomotive with auxiliary locomotive	Difference between locomotive with auxiliary and locomotive alone	Cutoff of locomotive per cent
7.3	58,669	69,111	10,442	Full gear
7.3	56,425	68,615	12,190	80
9.2	55,740	66,184	10,444	80
11.0	53,838	63,433	9,595	80
7.3	51,679	63,121	11,442	70
7.3	47,244	57,689	10,445	60

These tests were made at three speeds, 7.3, 9.2, and 11.0 m.p.h. At 7.3 m.p.h. it was possible to operate both the locomotive in full gear, and also the auxiliary locomotive, giving a combined drawbar pull of 69,111 lb. The locomotive blower was required in this test to maintain boiler pressure.

No full-gear tests with the auxiliary locomotive in use were made at speeds above 7.3 m.p.h. As full boiler pressure was maintained in the test in full gear at 7.3 m.p.h. with auxiliary, it is probable that the locomotive could have been worked in full gear with the auxiliary in use at a slightly higher speed.

When operated together, the drawbar pull is less than the sum of the drawbar pulls of each individual unit under the same test conditions due to the greater drop in steamchest pressure. This difference increases as the speed increases. The minimum speed at which the locomotive was run in these tests was 40 r.p.m., or 7.3 m.p.h., and it is probable that at lower speeds the total drawbar pull would approach the sum of the drawbar pulls of the two units, and very nearly if not equal it at starting speeds.

While Table 4 shows the increase in drawbar pull due to the auxiliary locomotive, for various test conditions, it does not show either the maximum pull of the locomotive alone, or the net increase due to the auxiliary locomotive, except at the lower speed of 7.3 m.p.h.

Tests of a class L–1–s locomotive, as recorded in P.R.R. Bulletin 28, show maximum pulls at other speeds, and tests were made of locomotive No. 1306 to confirm the results shown there. These are tests at 50 r.p.m., 9.2 m.p.h., and full gear cutoff, and at 60 r.p.m., 11.0 m.p.h., and full gear. The drawbar pulls obtained are shown in Table 5 which also shows the net increase in pull, due to the auxiliary locomotive.

The pulls of 66,184 lb. and 63,433 lb. at 9.2 and 11.0 m.p.h. were not made with the locomotive in full gear, but at 80 per cent cutoff. It may be that a slightly greater pull is possible at 9.2 m.p.h. In this test, while the blower was used, the boiler pressure was easily maintained. The pull at 11.0 m.p.h. is a maximum as, in this test, the blower was used, and the pressure was not fully maintained throughout the test.

In the plotted results shown on Fig. 9 the drawbar pull of the locomotive and auxiliary at 9.2 m.p.h. falls on the curve and, therefore, it is probable that the net increase shown is the maximum obtainable for not only 7.3 m.p.h., but also for 9.2 and 11.0 m.p.h.

TABLE 5 INCREASED PULL DUE TO AUXILIARY LOCOMOTIVE

	Maximum drawbar pull, lb.		Net increase in pull due to auxiliary locomotive	
Speed m.p.h.	Locomotive alone	Locomotive and auxiliary locomotive	Pounds	Per cent
7.3	58,669	69,111	10,442	17.8
9.2	57,084	66,184	9,100	15.9
11.0	55,964	63,433	7,469	13.4

Tests at Long Cutoff

In addition to the tests of the locomotive at 60, 70, and 80 per cent, and full-gear cutoff, tests were made to determine the effect on the drawbar pull line when the cutoff was decreased by small increments from full gear, the speed remaining constant. This was done for two speeds, 40 and 60 r.p.m. or 7.3 and 11.0 m.p.h.

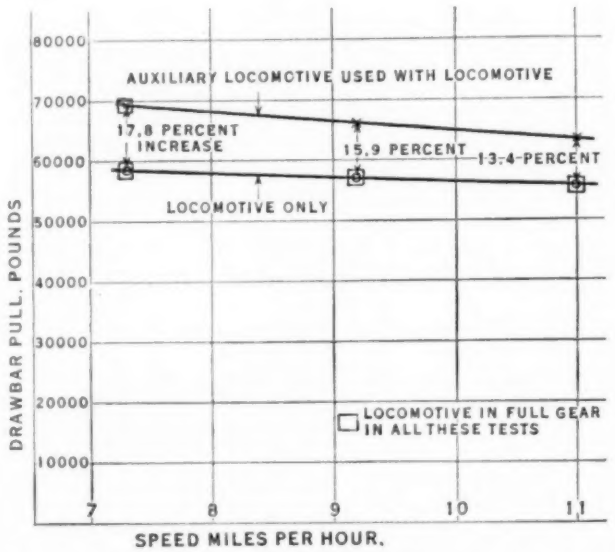

Fig. 9 Maximum Drawbar Pulls With Locomotive Alone and in Combination With Auxiliary Locomotive

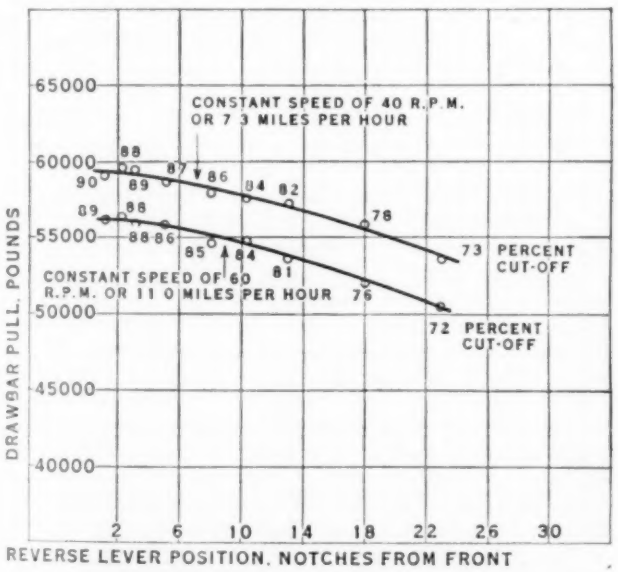

Fig. 10 Drawbar Pull of Locomotive as Effected by Cutoff Adjustment With Constant Speed

The principal data obtained in these tests is shown in Fig. 10. The cutoffs were about evenly spaced in nine notches between 70 per cent and full gear. The drawbar pull falls off as the cutoff is shortened. At 70 per cent cutoff it is about 10 per cent less than in full gear, and at 80 per cent cutoff 4 per cent less for both speeds.

The steam per indicated horsepower-hour was not measured in these tests, as the time of running, in each cutoff, was not long enough. This figure has been calculated from the heat apparently utilized in the cylinders, the quantity of heat being derived from the live- and exhaust-steam pressures and temperatures.

Having learned what is secured by auxiliary locomotive use,

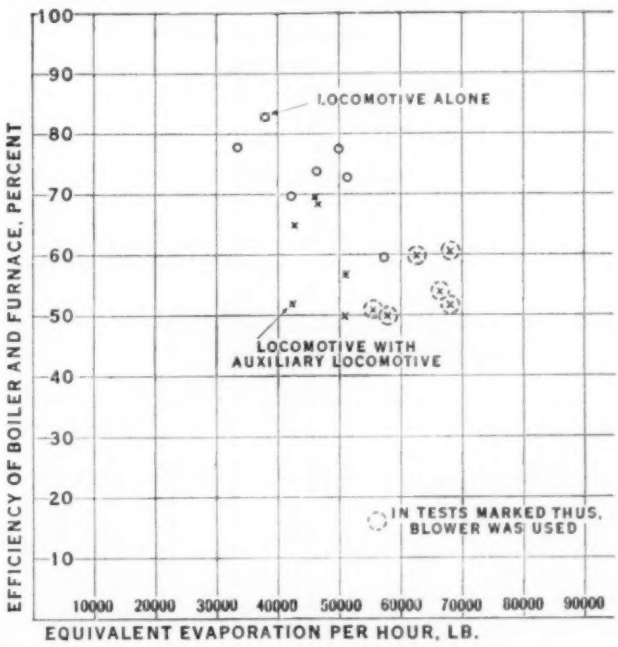

Fig. 11 Boiler Efficiency

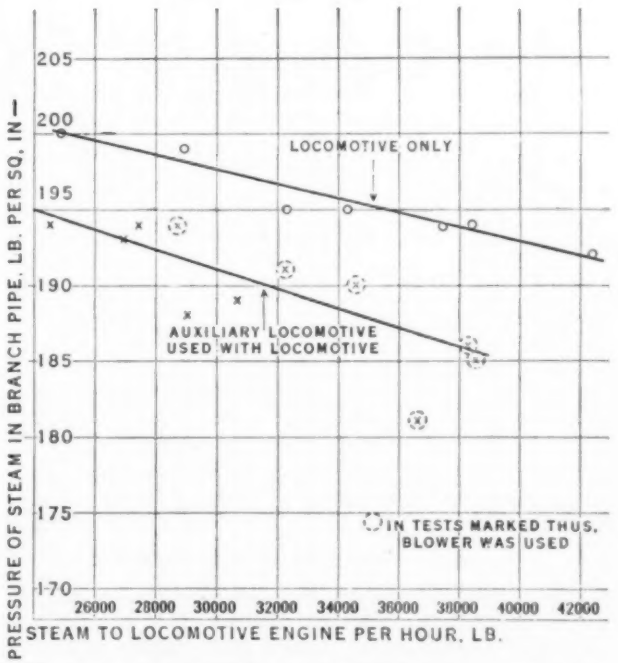

Fig. 12 Branch-Pipe Pressure With Relation to Steam Consumption per Hour

the next natural question is how is it obtained? Full boiler pressure of 200 lb. or above was maintained in all of the tests of the locomotive when operated alone. When the auxiliary locomotive was used in combination with the locomotive, the steam pressure could be maintained up to an equivalent evaporation of 50,000

lb. per hr. Beyond this evaporation rate the blower was necessary. It was not used in test No. 8220, where the evaporation was 56,820 lb. per hour, but this test shows a low boiler pressure,

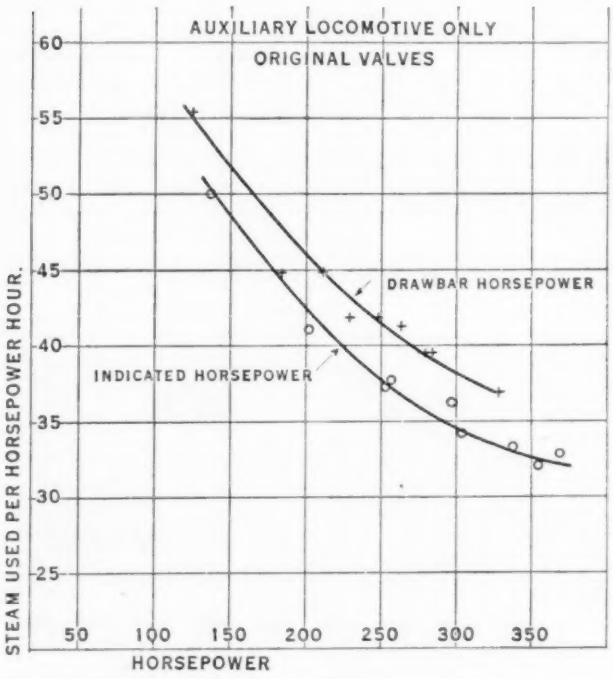

FIG. 13 AUXILIARY LOCOMOTIVE STEAM PER INDICATED HORSE-POWER-HOUR, ORIGINAL VALVES

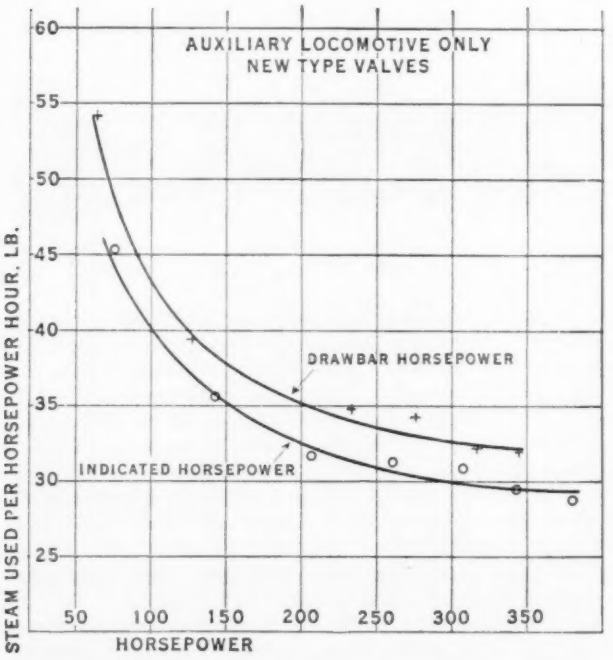

FIG. 14 AUXILIARY LOCOMOTIVE STEAM PER INDICATED HORSE-POWER-HOUR, NEW VALUES

indicating that the blower was needed in a test at this rate of working, with the auxiliary locomotive in use. Because of the low boiler pressure of test No. 8220, the results of this test are omitted on the plotted diagrams.

When operating the locomotive at long cutoffs in conjunction with the auxiliary, the demand for steam exceeds the ability of the boiler to supply it, with the draft available, except at the lower

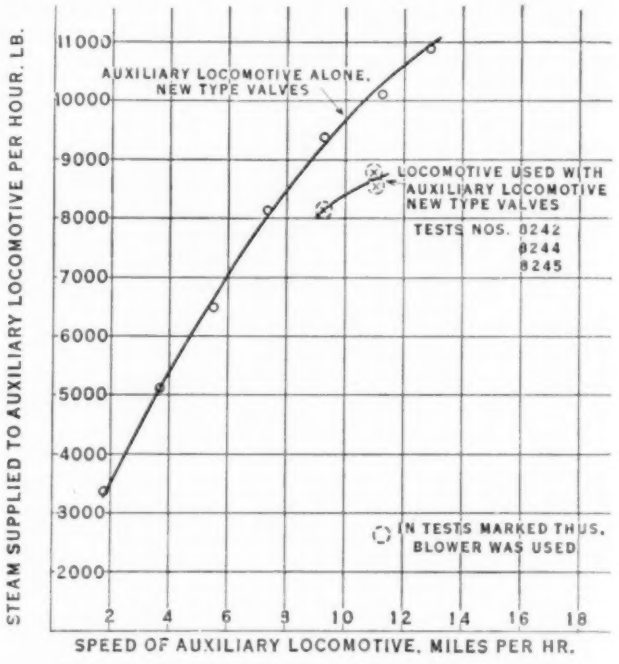

FIG. 15 AUXILIARY LOCOMOTIVE STEAM CONSUMPTION

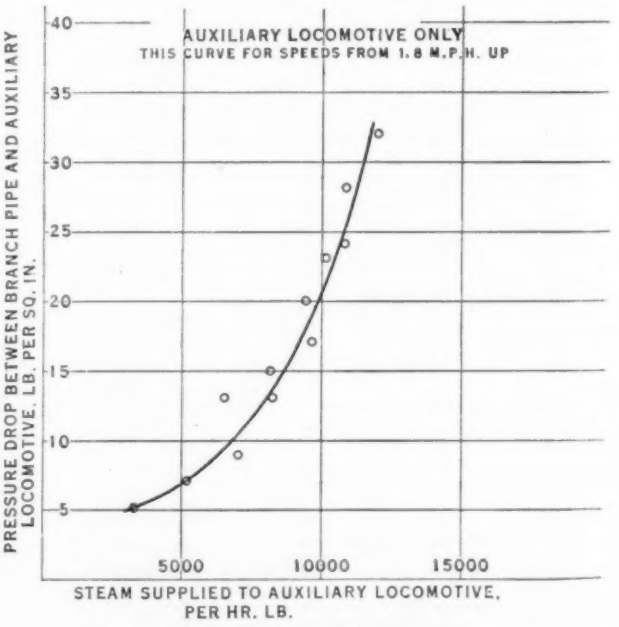

FIG. 16 PRESSURE DROP IN MAIN STEAM PIPE AUXILIARY LOCOMOTIVE

speeds. The available draft can be augmented to some extent by the use of the blower, but not sufficiently to attain the maximum evaporative capacity of the boiler at low speeds.

This forcing of boiler evaporative output naturally results in a lowered thermal efficiency of the whole unit. In full gear at 7.3 m.p.h. the locomotive has an efficiency of 4.9 per cent. When working in full gear in combination with the auxiliary locomotive the efficiency of the unit falls to 3.1 per cent.

When it is realized that the use of an auxiliary poweir unt is required for only a short portion of the operating time for the locomotive, while the benefits of its extra hauling capacity are realized for the whole operating time, this factor becomes of minor importance, except in the general relation of the steam locomotive thermal efficiency.

Boiler Efficiency

The boiler efficiencies at the different rates of evaporation were plotted on Fig. 11, and it was found that the efficiencies are higher for the locomotive alone. With one exception they are above 70 per cent. When the auxiliary is operating with the locomotive and the blower not used, the efficiency is from 50 to 70 per cent, and not in line with the efficiency of the locomotive alone. When the blower is used and normal draft conditions are restored, the efficiency is found to be nearly normal for the output of the boiler, which output, of course, is greater with the auxiliary in use. These tests were of such short duration that figures in regard to coal are not reliable and show scattering points on the diagram when plotted.

Steaming of Locomotive

In order to determine if the locomotive used in the tests was steaming freely, and would develop as high a total evaporation rate per hour as has been found in other class L–1–s locomotives, a test was made at 160 r.p.m. and 65 per cent cutoff. No difficulty was experienced in maintaining a steam pressure of over 200 lb. with an evaporation rate of 61,841 lb. per hour (81,917 lb. equivalent evaporation per hour); a combustion rate of 12,662 lb. of coal per hour, and a steam temperature of 621 deg. fahr. P.R.R. Bulletin No. 28, "Tests of a Class L–1–s Locomotive," shows a test having a maximum evaporation of 57,460 lb. per hour (78,071 lb. equivalent evaporation per hour) with a steam temperature of 618 deg. fahr., using a long superheater, such as the one on locomotive No. 1306. By this comparison, locomotive No. 1306 with a long superheater was shown to be in good steaming condition.

Branch Pipe Pressure and Temperature

Table 6 shows branch-pipe pressures and temperatures for the various test conditions when operating the locomotive alone, and also with the auxiliary locomotive. The pressures are also plotted on Fig. 3. In the table, tests under like conditions are averaged, but the graph shows results for each test separately. It will be noted that the operation of the auxiliary locomotive causes an average reduction in the branch-pipe pressure of five pounds. In this table, averages are shown where there are two tests under like test conditions.

Similarly, the pressure of the steam supplied to the auxiliary locomotive is subject to a greater drop when the locomotive is operated than when the auxiliary is operated alone. When tests are compared under like conditions with and without the auxiliary locomotive, it is found that there is a difference in the average steam temperature of about five degrees, see Table 6. The steam is at a higher temperature with the auxiliary locomotive in operation.

The indicated horsepower of the locomotive, when the auxiliary locomotive is operating, shows the effect of the lower branch-pipe pressure, and is somewhat less at all speeds than when the auxiliary is not used.

The steam per indicated horsepower-hour averages about $1^1/_2$ lb. less when the auxiliary is in use. The reduction in water rate of the main engines when the auxiliary is in use seems rather large for the small increase in steam temperature shown. When the auxiliary is in use the boiler is being worked at a higher rate. The temperature of the steam should, therefore, be higher and consequently a reduction in the water rate of the main locomotive engines is to be expected.

Steam Economy of Auxiliary Locomotive

In Tables 7 and 8 the pressures, temperatures, and weights of steam supplied to the auxiliary locomotive are shown as are also the horsepowers and water rates of the auxiliary when operated alone. Table 7 is for tests in which the original valves were used, and Table 8 is for tests using the new-type valves. There is a very considerable decrease in the steam per indicated horsepower-hour when using the new type of valve, the amount of decrease ranging from 10 to 29 per cent.

The auxiliary with the new-type valves uses steam at rates between 3400 and 11,000 lb. per hr., when operating between about 2 m.p.h. and 13 m.p.h. The steam used per indicated horse-

* In these tests the new type valves were used. In all other tests shown in this table the original valves were used.

power-hour, is from 45.5 lb. at 1.8 m.p.h. to 28.7 lb. at 12.8 m.p.h. The indicated horsepower of the auxiliary was from 75 at 1.8 m.p.h. to 382 at 12.8 m.p.h.

Most of the tests of the auxiliary locomotive operating in combination with the locomotive were made with the original valve in use. It may be assumed that if the new-type valves had been used in all tests, the steam consumption would have been less than is shown.

In Table 9 the steam per indicated horsepower-hour, of the auxiliary locomotive, when used with the locomotive, is less than when tested alone. This is, no doubt, due to the higher steam temperature when the locomotive is operating.

The drawbar horsepower, steam economy, and machine efficiency of the auxiliary are shown in Table 10. The machine efficiency ranged between 84 and 92 per cent.

TABLE 10 AUXILIARY LOCOMOTIVE ALONE—NEW TYPE VALVES

Test no.	Duration of test, minutes	Speed m.p.h.	Drawbar horsepower	Steam supplied per i.hp-hr. lb.	Drawbar pull lb.	Machine efficiency per cent

8240	10	12.8	345	31.8	10,093	90.3

At a speed of 7.3 m.p.h., the machine efficiency of the locomotive in full gear cutoff is 91.3 per cent and that of the auxiliary locomotive at this speed, as shown in Table 10, is 89.7 per cent.

Heat Transfer in the Locomotive Superheater

By LAWFORD H. FRY,[1] BURNHAM, PA.

The author's method for calculating heat transfer in locomotive flues is applied to determine the heat transfer in the superheater flues and tubes. It is applied to three sets of experimental data obtained from two locomotives on the Altoona locomotive test plant. In each case the firebox temperature and the rate of flow of the gases of combustion through the flues are taken as points of departure. The Fry method is used to calculate the temperature drop along the evaporative flues and along the superheater flues, and the transfer of heat to the evaporative surface of the flues containing the superheater pipes and to the superheater pipes. The results of the calculations indicated are shown in tabular form in comparison with the observed results.

THE present paper extends the author's method for calculating heat transfer in locomotive flues and shows how it can be applied to determine the heat transfer in the superheater flues and tubes.

To illustrate the scope and accuracy of the method, it is applied to three sets of experimental data obtained from two locomotives on the Altoona locomotive test plant. For one locomotive, Class K2sa, No. 877, with a type A superheater, the test represents a high rate of operation with 50,000 lb. of water evaporated per hour, while for the other locomotive, Class M1s, No. 4700, the two tests with 65,000 and 35,000 lb. of water per hour represent, respectively, high and low power. In each of these cases the firebox temperature and the rate of flow of the gases of combustion through the flues are taken as points of departure. The Fry method is used to calculate:

(*a*) The temperature drop along the evaporative flues

(*b*) The temperature drop along the superheater flues

(These together enable the average smokebox temperatures to be computed and compared with those found experimentally)

(*c*) The transfer of heat to the evaporative surface of the flues containing the superheater pipes

(*d*) The transfer of heat to the superheater pipes

(The last item represents the heat used to superheat the steam and can be compared with the amount of superheat found experimentally.)

TABLE 1 COMPARISON OF OBSERVED AND COMPUTED TEMPERATURES

Locomotive, Class	K2sa	M1s	
Locomotive, No.	877	4700	
Rate of evaporation, lb. of steam per hour	50,000	65,000	35,000
Temperatures of gas in degrees fahrenheit:			
Observed at back flue sheet	2,080	2,000	1,200
Computed for front flue sheet, evaporative flues	614	648	512
Computed for front flue sheet, superheater flues	643	532	470
Computed smokebox temperature	625	578	485
Observed smokebox temperature	620	570	510

The results of the calculations indicated are shown in tabular form in comparison with the observed results. Table 1 shows the computed temperature drop in the evaporative and superheater flues and the resulting smokebox temperatures. These are seen to agree very satisfactorily with the observed smokebox temperatures. It is of interest to note the difference in computed temperatures for the evaporative and for the superheater flues. In locomotive No. 877, with the type A superheater, the temperature of the gases at the front flue sheet is found to be 614 deg. fahr. for the $2^1/_4$-in. evaporative and 643 deg. fahr. for the $5^1/_2$-in. superheater flues. That is, the evaporative flues are slightly more effective in taking up heat. The reverse is, however, the case for locomotive No. 4700, with the type E superheater. In this case the gases, in the high-power test, reach the front flue sheet at temperatures of 648 deg. fahr. for the $2^1/_4$-in. evaporative and 532 deg. fahr. for the $3^1/_2$-in. superheater flues. At first sight it may seem inconsistent to find the gases emerging at the lower temperature from the superheater flues in which the heat-receiving surfaces are at a higher temperature. This result is, however, confirmed, at least qualitatively, by such experimental data as are available, and the reasons for it become apparent when the laws governing the transfer of heat are examined. As will be seen from the formulas given later, the rate at which a gas gives up heat to the flue through which it passes varies for a given rate of gas flow, with the ratio p/a where p is the gas-swept perimeter of the flue and a is the cross-sectional area of the flue. It also varies inversely with the temperature of the flue wall. In locomotive No. 877, with the type A superheater, the $2^1/_4$-in. evaporative flues with a p/a ratio of 2.00 would, other things being equal, be slightly less efficient than the $5^1/_2$-in. superheater flues with a p/a ratio of 2.28, but the higher flue-wall temperature of the superheater flues, 505 deg. against 435 deg., more than offsets the effect of the p/a ratio, and consequently the final temperature of the gases is 614 deg. for the evaporative and 643 deg. for the superheater flues. In locomotive No. 4700, on the other hand, the wall temperatures of the two sets of flues are not so far apart, being 485 deg. for the superheater and 431 deg. for the evaporative flues, while the p/a ratio is 3.30 for the superheater and only 2.00 for the evaporative flues. The effective heat transfer due to the high p/a ratio brings the gas temperature at the front flue sheet down to 532 deg. in the $3^1/_2$-in. superheater flues, while the drop in the $2^1/_4$-in. evaporative flues is only to 648 deg. In this connection it may be noted that in the type E superheater the high p/a ratio causes the temperature drop along the flue to be so rapid that the gases fall below the temperature of the superheated steam long before the front flue sheet is reached. From inspection of Table 2, which shows the progressive drop in temperature along the superheater flues, it can be seen that the gases have reached the branch-pipe temperature while still more than 7 ft. from the front flue sheet. That is to say, the last 7 ft., which is more than 35 per cent of the flue length, is not effective in increasing the superheat of the steam in the outgoing superheater pipe.

Table 2, as already indicated, shows the progressive drop of temperature along the superheater flues for the three cases considered. It also shows for each increment of length of the flue the amount of heat taken up by the superheater pipes and by the evaporative surface. By summing up the heat shown to be taken up by all sections, it is possible to compute the total amount of heat taken up by the superheater pipes. This is compared in Table 3 with the amount of heat shown by the tests to be present as superheat. The heat taken up by the superheater expressed as a percentage of the total heat taken up by boiler and superheater is shown in Table 3 to 8.9 per cent by computation and 11.2 per cent by measurement for locomotive No. 877, while for locomotive No. 4700 it is 10.0 per cent as com-

[1] Metallurgical Engineer, Standard Steel Works Company.

puted and 9.8 per cent as measured. This agreement between computation and measurement is, considering the circumstances, extremely satisfactory, and taken in conjunction with the excellent agreement between computed and measured smokebox temperatures gives considerable confidence in the method of computation.

Equations

The fundamental equations used by the author to determine the transfer of heat from a gas to a flue through which it flows derive from the suggestion made by Hedrick and Fessenden[2] that the rate of heat transfer is proportional at any moment to the total amount of heat carried by the gas. This leads to the conclusion that if the flue has a mean wall temperature of t, and if the gas in flowing a distance of x feet drops from a temperature of T_1 to a temperature of T_2, the relation between these temperatures is

$$\text{lolog } T_1/t - Mx = \text{lolog } T_2/t \quad \ldots\ldots [1]$$

where "lolog" means "the logarithm of the logarithm," M is a coefficient derived from the Equation [2], and all temperatures are measured in absolute units.

The author has shown[3] that this equation is widely applicable and that the coefficient M is dependent only on the rate of flow of the gas through the flue, on the perimeter of the flue in contact with the gas, and on the cross-sectional area through which the gas flows. The relation is given by the equation

$$\log M = B - m \log W/p \quad \ldots\ldots [2]$$

where

W = the rate of gas flow in pounds per hour
p = the flue perimeter in inches
B and m = constants for any flue, being determined by the ratio between the perimeter and the area of the flue as shown in Table 4.

These two equations have a somewhat formidable appearance, but are, as a matter of fact, by no means difficult to apply.

Total	684	100.0	820	100.0
Observed amount of heat required to superheat the steam (this is item 3(*b*) above)	76.5	11.2	80.3	9.8

From Equation [1] it follows that for any given set of operating conditions (that is to say, for a flue of given dimensions, with a fixed initial temperature, and with a given rate of flow of gas through the flue) the temperature at any point along the flue is dependent only on the main coefficient M. This main coefficient, as shown by Equation [2], is determined by the flue dimensions and by the rate at which the gas is flowing through the flue. Its value in any particular case can be found easily by using Table 4, which gives the values for the auxiliary coefficients B and m when the p/a ratio of the flue is known. For example, a 2-in. circular flue with a perimeter $p = 6.28$ in. and an area $a = 3.14$ sq. in., the p/a ratio is 2.00, and from Table 4, $B = 9.053$ and $m = 0.296$ for this ratio. Then from W, the weight of gas flowing through the flue, and p, the flue perimeter, the value of log W/p is found. By inserting this and the values

[2] Trans. A.S.M.E., vol. 38, p. 407.

[3] Trans. A.S.M.E., vol. 39, p. 709; also, "A Study of the Locomotive Boiler," 1924, Simmons-Boardman Co.

of B and m in Equation [2], the value of the main coefficient M is found. Again, by inserting this in Equation [1] the temperature at any point along the length of the flue can be found. If the rate of flow of gas is changed, it is necessary to find the corresponding change in the value of log W/p, and to find from Equation [2] a new value of the main coefficient M. So long, however, as the dimensions of the flue remain unchanged the coefficients B and m remain the same.

The whole process of finding the drop in temperature along a flue may be summed up as follows: From the dimensions of the flue, its p/a ratio (that is, the ratio of perimeter to area) is found, and from Table 4 the corresponding values of the coefficients B and m are taken, either directly or by interpolation. These values and the value of W/p (that is, the weight of gas flowing per hour per inch of perimeter of the flue) are used in Equation [2] to find the value of its main coefficient M. Having this and knowing t, the temperature of the flue wall, and T_1, the gas temperature at a point along the flue, Equation [1] enables one to find the gas temperature T_2 at any desired distance, say x feet further along the flue.

When the equations are applied in practice, it will be found that the relation between the coefficients B and m derived from the perimeter-area ratio is such that if the rate of gas flow remains constant, an increase in the p/a ratio increases the rate at which heat is transferred. Also, if the p/a ratio remains constant, an increase in the rate of gas flow tends to reduce the temperature drop over a given length of the flue. It will be found, however, that the reduction in temperature drop is less in proportion than the increase in the rate of flow of the gas. That is, at the increased rate of flow the flue takes less out of each pound of gas, but the increase in the number of pounds of gas is proportionately greater, so that the total amount of gas taken up by the flue is increased.

TABLE 5 DIMENSIONS OF LOCOMOTIVES

Methods of Calculation

Having described in general terms the results obtained, consideration is now given to the calculations involved in applying the Fry method to specific conditions. For present purposes two different locomotives are considered. Both belong to the Pennsylvania Railroad and have been tested on the locomotive testing plant at Altoona. Information regarding the results of these tests given to the author by Mr. J. T. Wallis, assistant vice-president, is the source of the experimental data used in the calculations. The dimensions of the locomotives pertinent to the present purpose are collected in Table 5, while the necessary experimental data are given in Table 6. These data are taken from smooth curves drawn for a complete series of tests for each locomotive. In this way the effect of irregularities in individual tests is eliminated. The two locomotives dealt with are a 4–6–2 Pacific type, Class K4s, No. 877, fitted with a type A superheater, and a 4–8–2 Mountain type, Class M1s, No. 4700, with a type E superheater. Locomotive No. 877 is studied when evaporating 50,000 lb. of water per hour, which represents a high rate of operation, while locomotive No. 4700 is taken at both high and low rates, the evaporation in the two cases being, respectively, 65,000 and 35,000 lb. of water per hour.

Dimensional Coefficients for Flues

In order to deal with heat transfer in the flues it is necessary to obtain values for the coefficients of Equations [1] and [2]. The coefficients B and m used in Equation [2] depend only on the dimensions of the flues. The dimensions required are set out in Table 6. Using these dimensions, the coefficients can be obtained from Table 4. With the evaporative flues this is a very simple matter. The area divided into the inside perimeter gives the p/a ratio, and the values of B and m can then be taken from Table 4, either directly or by interpolation.

Thus for locomotive No. 877 the first line in column 13, Table

7, shows that the $2^1/_2$-in. evaporative flues have a p/a ratio of 2.00, and for this value of p/a Table 4 gives $B = 9.053$ and $m = 0.296$. For the flues which carry the superheater pipes four sets of coefficients are needed, one for the back end before the superheater pipes are reached and three sets so that the heat transfer may be dealt with for the evaporative and the superheater surfaces separately and also for the combined surfaces.

The method followed is shown in Table 7. Taking locomotive No. 877 as an example:

(*a*) Before the superheater pipes are reached, there is, neglecting the swaging at the flue sheet, a plain flue of $5^1/_2$-in. inside diameter for which the p/a ratio is 0.760. The corresponding values for B and m taken from Table 4 are set down in columns 14 and 15.

Flow of Gas in Flues—Temperature of Flue Wall

In order to use the dimensional coefficients B and m in Equation [2], it is necessary to know the rate at which the gas flows through the various flues. The experimental data show the total amount of gas passing per hour through the boiler for a given rate of operation, but there is no direct experimental evidence as to the distribution of this gas between the evaporative and superheater flues. This distribution is estimated for the present purposes by a method which appears to be justified by the results it gives. It is assumed that the gas carried by each of the two groups of flues is proportional to the total area of the group and is inversely proportional to the p/a ratio of the group. The latter half of this assumption implies that the resistance of the flues to the flow of gas is inversely proportional to the p/a ratio. Until definite experimental information is available, this approximate method for distributing the gas between the two groups of flues seems to be satisfactory. Computation of the gas distribution can be followed in columns 5 to 10 of Table 8. Column 7 gives the total area of each group of flues, and column 8 the resistance factor which is the reciprocal of the p/a ratio. The product of these two columns gives the relative gas-carrying capacity of each group. This is expressed as a percentage in column 10, and these percentages of the total rate give the amount of gas carried by each group. Table 9 continues the computation, showing the weight of gas in each flue, column 4, and the weight of gas per inch of perimeter per hour, W/p, column 5. With this figure and the coefficients B and m, Equation [2] is used to find the values of the main coefficient M, column 9.

To complete the data necessary for the use of Equation [1] to determine the temperature drop along the flue, information is needed as to the mean temperature of the flue wall in contact with the gas. This must be estimated from the known tem-

		(*c*) Superheater surface only	178	7.068	25.2	8.992	0.336	0.0332
		(*d*) Evap. & suph. surface combined	178	16.552	10.76	9.163	0.246	0.0813

When the superheater pipes are reached they reduce the fire area available for the passage of the gases, so that the net area becomes 15.156 sq. in. instead of 21.648 sq. in. The gases passing through this area may be considered as giving up heat in one of three ways:

(*b*) By transfer to the evaporative surface of the outer flue only. The receiving perimeter in this case is 16.493 in. and the p/a ratio 1.088

(*c*) By transfer to the surface of the superheater pipes only. In this case the receiving perimeter is 18.064 in. and the p/a ratio is 1.200.

(*d*) By transfer to the evaporative and superheater surfaces simultaneously. In this case the combined receiving perimeter is 34.557 in. and the p/a ratio is 2.280.

The values of the coefficients B and m taken from Table 4 for all three values of p/a are tabulated in columns 14 and 15 of Table 7.

heat from the gases on their inside surface and transmit it through their outside surface to water at a temperature corresponding to the boiler pressure, while the superheater pipes receive heat on their outside surface and transmit it from their inside surface to steam which has a temperature ranging from that of the saturated steam up to the temperature observed in the branch pipe. The temperature gradient due to the heat flow through the flue wall establishes a temperature differential between the transmitting and receiving surfaces. This differential will be greater the greater the rate of heat received and transmitted through the flue wall. It will therefore be greater at the firebox end than it is at the smokebox end of the flue, and at any given point in the flue will be greater for a high rate of evaporation than for a low. It has been found that for calculations of the temperature drop over the full length of the flues of a locomotive boiler, satisfactory results are obtained if the mean receiving flue-wall temperature is taken to differ from the transmitting-wall temperature by the differential indicated in Fig. 1, where the differential is made to vary with the heat carried into the flues measured in B.t.u. per hour per inch of total perimeter. The heat in the gases entering the flues is found from the total weight of gas, the temperatures, and the heat content for that temperature as given in Table 10. This is divided by the total perimeter of the flues, including evaporative and superheater surface. The values in Fig. 1 have been arrived at by computing smokebox temperatures from test data and comparing the results with the observed smokebox temperatures. No information is available which would enable the differential to be determined separately for the evaporative and superheater surfaces. In the absence of more complete and better-established information, the curve of Fig. 1 is put forward as a reasonably accurate basis for calculation.[4]

[4] The author is indebted to Mr. Robert Rennie for suggesting the use of a differential of this sort.

Table 11 shows the flue-wall temperatures which have been used in the three series of computations covered by the present paper. It will be seen that for dealing with short flue sections the differential is given a high value for sections near the firebox and a low value for sections near the flue sheet. The temperature of the transmitting surface of the flue is assumed to be that of the saturated steam for the evaporative surfaces. For the superheater surfaces the transmitting-surface temperature is taken to be the mean between that of the saturated steam and that of the steam in the branch pipe. When the evaporative and superheater surfaces of the superheater are combined in a single calculation, this mean steam temperature is averaged with the saturated steam temperature.

Determination of Temperature Drop Along Flues

The foregoing calculations and considerations provide all the elements necessary for the application of Equation [1] to compute the temperature drop along the flues for any operating condition. Take, for example, Locomotive No. 877 evaporating 50,000 lb. of water per hour, and consider first the $2^1/_4$-in.

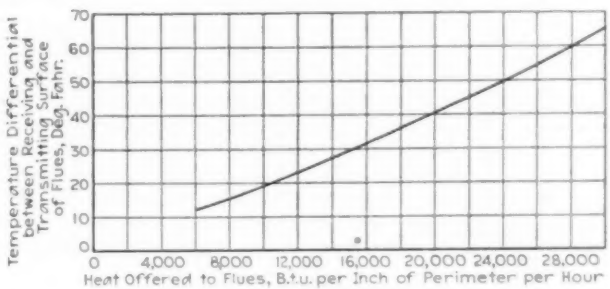

Fig. 1 Assumed Temperature Differential for Full-Length Flues

evaporative flues. Having values for T_1, t, M, and x, it is required to find T_2 from the equation

$$\text{lolog } T_1/t - Mx = \text{lolog } T_2/t \quad \ldots\ldots\ldots\ldots [1]$$

The sequence of calculations shown on the work sheet, Table 13, shows a simple and direct method of procedure. First is set down log T_1, the logarithm of the absolute temperature at which the gases enter the flue. Below this is log t, the logarithm of the absolute temperature of the receiving flue wall. The difference gives log T_1/t, and the logarithm of this is lolog T_1/t. Alongside of this is the value of the main coefficient M which has been determined previously and set down in Table 9. This coefficient is multiplied by the length of the flue over which the temperature drop is to be computed; in the present case, the

[1] This "differential" is the figure to be added to the temperature of the receiving surface to find the flue-wall temperature to be used in Equation [1].

whole length of the flue or 20.8 ft. This product Mx deducted from lolog T_1/t gives according to Equation [1] the value of lolog T_2/t. By finding the antilog of this (that is to say, the number of which it is the log) log T_2/t is obtained. The addition of log t gives log T_2, from which T_2, the end temperature in absolute units, is found.

For the superheater flues a similar calculation is carried out, but in two steps. The first deals with the back 2 ft. of the $5^1/_2$-in. flue which does not contain any superheater pipes. For this portion of the calculation the main coefficient M has the value given under (a) in Table 7. For the remainder of the flues the gas is taken to lose heat to the evaporative surface of the $5^1/_2$-in. being used for the evaporative surface and the (c) value for the superheater pipes. Equation [1] is applied just as before, except that the calculation must, for reasons which follow, be restricted to short sections of the flue length. Consider, for example, the section of superheater flue lying between 2 and 3 ft. measured from the back flue sheet. This is the first foot of flue containing the superheater pipes. The temperature of the gases entering this section is, as shown in Table 2, 1938 deg. fahr. Now if the temperature drop be computed for heat transfer to the *evaporative* surface only, the temperature at the 3-ft. point will be found to be 1840 deg. fahr., a temperature drop which will be seen from Table 12 to correspond to a transfer of 30 B.t.u. from each pound of gas. Computed for heat transfer to the *superheater* surface only, the temperature at the 3-ft. point will be found to be 1845 deg. fahr., corresponding to a loss of 27 B.t.u. per pound of gas. Now if the heat transfers to evaporative and to superheater surfaces, which have been computed as though acting separately, are assumed to take at the same time, the gas, which has a temperature of 1938 deg. fahr. at the 2-ft. point, would lose 30 + 27 = 57 B.t.u. by the 3-ft. point. This from Table 12 would give a temperature of 1745 deg. fahr. at the 3-ft. point, which is the same temperature as would be found for this point by computing the temperature drop for the combined evaporative and superheating surfaces. The same thing is found for other short lengths of the flues. It is therefore concluded that by dividing the flue into short sections, in which the temperature drop is not great compared with the initial temperature, the method of calculation can be used to find the amount of heat taken up by the superheater. In doing this, though, the initial temperature for each section must be that found by computing the heat transfer to the combined superheater and evaporative surfaces. Thus, in Table 2, column 2 shows the temperature drop along the flue computed for heat transfer to both superheater and evaporative surfaces—that is, with the coefficient M having the value given under (d) in Table 9. Then if for each of the sections the temperature of column 2 is taken as the initial gas temperature and the value of M given under (b) in Table 9 is used to compute the heat transfer, the values given in column 5 of Table 2 are obtained for the heat given up per pound of gas in each section. By summing the heat given up in the successive sections and expressing this in terms of the heat in the total weight of gas passing through all flues, the figures in Table 3 are obtained. These show that the computed heat transfer to the superheater agrees quite closely with the amount of superheat as measured in the experiments.

The table is computed from the values of the mean specific heat given by the equation $Cp = 0.235 + 0.000014\ t$ where t is the gas temperature in deg. fahr.

This does not include the latent heat of the water vapor.

TABLE 13 WORK SHEET

(Locomotive No. 877 at an evaporation of 50,000 lb. of water per hour, $2^1/_4$-in. flues, temperature drop firebox to smokebox)

Temperature at back flue sheet,	2080° F.	T_1 = 2540° absolute
Temperature of water surface of flues	388° F.	
Differential (Table 10),	45° F.	
	433° F.	t = 893° absolute
log T_1 = log 2540	= 3.405	M = 0.0363 (Table 9)
log t = log 893	= 2.954	x = 20.8 flue length
log T_1/t	= 0.454	Mx = 0.755
lolog T_1/t = log 0.454	= 9.657	
Mx	= 0.755	
lolog T_2/t = lolog T_1/t − Mx	= 8.902	
log T_2/t = antilog 8.902	= 0.080	
log t	2.951	
log T_2	3.031

Temperature at front flue sheet	= 614 deg. fahr.	

and to the superheater pipes simultaneously, and the coefficient M has the value given under (d) in Table 9.

When carried out, these calculations show that at the front flue sheet the gas comes out of the $2^1/_4$-in. evaporative flues at 614 deg. fahr., and out of the $5^1/_2$-in. superheater flues at 643 deg. fahr. To find the corresponding average smokebox temperature it is necessary to take into account the weight of gas from each set of flues, column 11, Table 8, and the specific heat of the gases, Table 12. As shown in Table 1, the average smokebox temperature thus computed is 625 deg. fahr., while the observed temperature corresponding to the same conditions was 620 deg. fahr. This agreement is very satisfactory.

In addition to computing the total drop of temperature from back flue sheet to front flue sheet, the method can be used to compute the drop from foot to foot along the flues, and also to determine for the superheater flues the amount of heat taken up by the evaporative surface and the amount taken up by the superheater pipes. For this latter purpose the coefficient M has the values given under (b) and (c) in Table 9, the (b) value

Discussion

H. B. OATLEY.[5] The paper is of keen interest to all those who are engaged in the design and construction of locomotive boilers. The great heat-absorbing capacity of the flue and the superheater pipe used therewith is an object continuously striven for in designing. The conditions attending locomotive development have made necessary a more intensive study of this matter. Among the causes which have made this subject of ever greater importance are:

(1) Increasing demand for boiler output
(2) Demand for still higher steam temperatures
(3) A decrease in the percentage of the total heat liberated from the fuel available for use in the fire-tube type of superheater
(4) An increased duty on the superheater as a result of a larger moisture content in the steam to be superheated
(5) Increasing steam pressures.

The type E superheater, with which engine No. 4700 was fitted, has come into widespread use as a means of meeting the conditions itemized. It has been necessary to provide greater superheating capacity within limits of boiler diameter and length, which cannot be increased to any great extent due naturally to the limitations of height, width, and weight, within which the locomotive can be built. It is naturally gratifying to find that in applying the theory and formulas which the author has developed, the proportions of flue and superheater unit used in the type E superheater show a greater heat-absorbing capacity and a noticeably lower gas-exit temperature than with the type A superheater.

These conditions have been pronounced during the past ten or fifteen years and have brought about changes in superheater proportion which are used in the paper. The problem of modifying the superheater design to keep pace with the trend of locomotive development is assisted by such studies as the author has made.

It may, however, not be out of place to point out some of the difficulties which are encountered when we come to apply theory to practice. These conditions, resulting from the changes in locomotive requirements enumerated, are of course well known to students of this problem. To follow the theoretically correct values determined on a heat-absorption basis may bring practical difficulties of a magnitude which will offset the theoretical advantages. In this, as in most other problems, a compromise to get the best all-around results must be made.

We know, and calculations using the formula set forth in the paper confirm, that a larger value for p/a will give greater heat absorption. Increasing p or decreasing a will have this result, but other factors must be taken into account.

For example, if the flue diameter is increased, p/a is thus decreased, the total number of flues in a given sized boiler will be decreased, the total amount of evaporating surface in the boiler decreased, the total steam area through the superheater decreased, and the smokebox temperature increased, thus causing some decrease in boiler efficiency which the higher degree of superheat and the increased cylinder efficiency resulting therefrom may not cancel. From the practical side it must be considered that, so long as fire tubes are used and boiler pressures continue to increase, an increase in the tube diameter means a thicker tube wall, entailing greater attention to and possibly trouble in tube setting.

If we now increase the diameter of the superheater pipe, we will decrease a and at the same time increase p; the ratio p/a changing also. The effect here is to increase superheating surface, but to decrease the total gas area through a given size of boiler; hence, an increase in the draft requirement for any given quantity of gas and a decrease in the mean effective pressure in the cylinders as a result of the higher back pressure needed for the greater draft required. We also increase the total steam area through the superheater and decrease the steam velocity through the units. While this increased steam area is advantageous from the standpoint of smaller pressure drop through the superheater, it does not so well contribute to a lower metal temperature in the superheater units subjected to the higher gas temperatures and therefore must be regarded as less desirable.

Reference has been made in the paper to the fact that the gas temperatures through the last 7 ft. of the flues is not high enough to impart additional heat to the steam in the outgoing pipe. That statement is true for the type E equipped engine at the rate of 65,000 lb. per hour. It is quite probable that this distance varies with the rating, and perhaps through a considerable range. It must not be forgotten, however, that there is heat imparted to the steam in the ingoing pipe and, furthermore, that the temperature head for heat to flow from the superheater pipe is relatively small throughout the distance stated. The conditions, however, with the type E superheater do point to the fact that tube lengths may easily be unduly great if we solely consider flue-gas temperatures. On the other hand, it must not be forgotten that the demand for great boiler-evaporation capacity necessitates full advantage being taken of all the available length.

These illustrations are given merely to indicate some of the problems involved in what may at first appear to be changes in unimportant details. They do show, however, that the locomotive and its details compose the "linked triangle of fire, water, and air" which the author has used so appropriately in his book on the locomotive boiler.

They show, it is believed, that it is almost impossible to modify one part without, adversely or otherwise, affecting the performance of other portions, and hence the performance of the locomotive as a whole.

C. W. BENICA.[6] The author has proposed a method of calculating the superheat temperature from the amount of heat absorbed by the steam in passing through the superheater pipes. This paper, in connection with the author's paper delivered before the Society in 1917, the summary of an article in *Mechanical Engineering* for November, 1920, and his book entitled, "A Study of the Locomotive Boiler," provides the designer with the necessary data for connecting test-plant results to anticipated performance. The author deals mostly with known values for the gas analysis, combustion conditions, temperatures in the firebox and smokebox, and the necessary data covering the extent of actual heating surfaces, etc., of an existing locomotive.

In order to obtain the temperature drop through the flues the author again uses his log-log equation, starting with a known value for the gas temperature t_1 at the tube entrance. The superheater designer, however, does not have this very important figure; and a survey of much of the printed matter extant and of the great variation in tube- and flue-temperature-drop curves that have been given to us through the publication of papers and test reports by C. A. Brandt, C. A. Seley, J. T. Anthony, the Pennsylvania Railroad locomotive builders, and the foreign technical press, as well as by the author himself, shows that this temperature must be calculated or assumed only after a careful analysis has been made of firebox radiation and the combustion conditions before the gases enter the tubes. Since the value of t_1 is the starting point and in a way determines what can be expected from the tube and flue section of the boiler, the writer has assembled the foregoing data and has worked out a formula that,

[5] Vice-president, Charge of Engineering, Superheater Company, New York, N. Y. Mem. A.S.M.E.

[6] Sales Engineer, Millard F. Smith Company, New York, N. Y. Assoc-Mem. A.S.M.E.

while it is to a large extent empirical, seems to fit the data very well.

The firebox temperature, as measured, follows closely the formula $t_1 = a + b\sqrt{G}$ where t_1 = temperature in firebox in deg. fahr., G = combustion rate in pounds of coal fired per square foot of grate area per hour, and where a = 1660 and 1100 and b = 70 and 120 for passenger and freight locomotives, respectively. These constants seem wide apart, but they are characteristic for locomotives in the two respective classes of service, and even though wide apart, they give a comparatively close agreement with the test data. At a combustion rate of about 125 lb. of coal per square foot of grate area, the formulas give equal temperatures for freight and passenger locomotives. Values for t_1, firebox temperature, and t_2, temperature at tube entrance, must not be confused.

Two variables enter into the calculation of firebox temperature not considered in the foregoing, but which are important to the superheater designer—air supply and the ratio of firebox volume to firebox heating surface. The author usually deals with test data from which the firebox gas composition and air supply can be determined, but the designer, not having this data, must take an average figure for weight of gases per pounds of coal burned at about 16.3 to 0.032 G. One must however, consider the fact that the ratio of coal burned to coal fired depends considerably on the particular firebox or boiler design, but is approximately represented by $1.00 - aG^2$ where a = 0.000020 and 0.000016 for freight and passenger locomotives, respectively. Combined with the t_1 formula, we get $t_1 = 2000 + 60\sqrt{G} - 16.7\,(16.3 - 0.032\,G)$ approximately.

The other variable, ratio of firebox volume to heating surface, seems to be more regular in its effect on firebox temperature because these dimensions are directly involved in extracting the heat in the firebox, reducing its temperature in some ratio to their extent. Tests of twenty locomotives where this ratio varied from 0.75 to 1.50 showed remarkable adherence to the formula $t_1 = (2400 - 533\ R) + 75\ \sqrt{G}$, where R = firebox volume ÷ firebox heating surface, the extent of these dimensions being capable of accurate estimation from the designer's drawings.

The temperature of the firebox at the tube sheet bears a direct relation to the temperature of the firebox in all data investigated except in one series of tests where the relation was inverse; viz., a higher firebox temperature occurred with an increase in combustion rate, but the relation of tube-entrance temperature to firebox temperature decreased with an increased combustion rate. The reduction of the gas temperature at the tube sheet has been compared to the reduction in temperature just above a gauze placed over a bunsen burner where the conductivity of the gauze reduces the temperature above it to a point where the gases do not burn in a flame; the evaporation in pounds of water per square foot of surface per hour is probably greater at the back tube sheet than anywhere else in the boiler because the temperature drop and gas flow are greatest at this location.

Due to the discrepancies usually found in collecting and arranging considerable data from various sources it was found that the most regular results would be obtained by representing the various temperature drops as a percentage of the firebox temperature, where the firebox temperature = 1.0. Thus, the temperature at the tube entrance, the quantity T_1 of the paper, is found to be $t_2 = ct_1$ where $c = 0.654 + 0.00143\ G$ for 2 in. or $2^1/_4$ in. tubes, $c = 0.600 + 0.00176\ G$ for $5^1/_2$-in. flues, and t_1 = the firebox temperature as estimated by one of the three formulas given. Having this value for t_2, the calculation can progress according to the author's method, using the log-log Formulas [1] and [2]. The writer has found that fairly reliable results for design or estimates for the temperature drop through the tubes and flues can be represented by the equation $t_x = t_1\,(1.00 + KL)$, where C is the value of C as already determined and k = 0.110 for 2 in. and $2^1/_4$-in. tubes and 0.0980 for $5^1/_2$-in. flues, L being the length of the tube or flue up to the point where t_x is to be determined. It is not expected that this formula is to be taken in place of the author's more accurate and scientific expression, but in the absence of coal and gas analysis, of quantity of gases per square inch of tube and flue perimeters, and of the important relation of coal burned to coal fired, the foregoing expression fairly well represents test data in as simple a form as can be expected over ordinary ranges.

It has been found that the degree of superheat obtained in a type A superheater can be fairly well represented by $S^\circ = K_1\sqrt{E}$, where K_1 = 6.25 and 6.00 for passenger and freight locomotives, respectively, and E = equivalent evaporation in pounds per hour per square inch of pipe cross-sectional area. (One pipe is considered to each flue and must not be confused with four passes going to make up one pipe.) This simple expression does not give accurate results for the half-return bend, extra length, or short superheater. It must not be overlooked that the difference in specific heat of superheated steam is 13 times as great from saturated steam to 100 deg. superheat as it is from 200 deg. to 300 deg. superheat and that the superheater acts as a steam drier through a fraction of its surface. It has often occurred to the writer that the superheater design and heat transfer data should start at the smokebox end where the temperature of the saturated steam and combustion gases vary through a much smaller range than close to the rear tube sheet.

Mr. Oatley's discussion of the paper stresses the difficulties of designing a superheater to get the desired results within space limitations and physical specifications. The average weight of 30 type A superheaters was determined to be 9.3 lb. per sq. ft. of superheater heating surface. The practical difficulty in designing modern locomotive boilers and superheaters and providing for sufficient transfer of heat through their surfaces is closely wrapped up with the limitations of weight that can be given to the various heating surfaces. The weight analysis of a larger number of locomotive boilers shows that there is a very small difference in the ratio of boiler weight to total locomotive weight; viz., if we let W_L = approximate estimated total weight of a proposed locomotive and W_b = weight of the bare boiler, shell, tubes, and firebox, including water, then $W_b = wW_L$, where w = 0.341, 0.342, and 0.337 for passenger, freight, and Mallet locomotives, respectively. The variation in w is small, the maximum and minimum values for 35 standard-gage locomotives being 0.321 and 0.368 over a range in locomotive weights from a 200,000-lb. Atlantic type to a 680,000-lb. Mallet type. The relation existing between the weight and extent of the boiler heating surfaces is represented by the equation $W_b = 22.0\ A_t + 167\ A_f - C$, where A_f is the firebox heating surface (syphons, arches, etc. excluded), A_t = tube plus flue heating surface, and C = a constant and equals $18{,}500 + 2.5\ (A_t + A_f)$. For ordinary ratios of tube and flue heating surface to firebox heating surface the weight of the boiler can be taken to be $W_b = 32.5\ (A_t + A_f) - 18{,}500$.

It would be a valuable contribution to the Society and to the railroad engineering fraternity in general if the author would give a few rules or formulas connecting his heat-balance theory to the proportioning of heating surfaces and cylinder performance. If the heat-unit basis of design could be established for preparing designs and proportioning locomotives along the conventional lines of the present machine, it would not be so difficult to introduce such locomotives as have been described in Mr. Stuebing's paper and whose appearance, operation, and heat performance are exceptional. For an example of the application of the foregoing analysis, take the data presented in the paper, as follows:

The temperature at the back tube sheet = 2080 = $t_2 = ct_1$. For the small tubes the value for $c = 0.654 + 0.00143\,G$. Since the value of G (combustion rate) is not given, it must be determined as $2080 = (0.654 + 0.00143\,G)(1660 + 70\sqrt{G})$, whence $G = 133$ lb. coal per square foot of grate area per hour. Then, using the first equation, the firebox temperature is found to be $t_1 = 1660 + 70\sqrt{133} = 2470$ deg. fahr. (All temperatures in this discussion are on the Fahrenheit scale instead of on the absolute scale.) If the value for the combustion rate (133) is substituted in the foregoing equation, the value of c becomes 0.844 and $t_2 = 0.844 \times 2470 = 2080$. Notice that as the combustion rate increases the value of c increases, which produces the same increase in the temperature and heat transfer in the tubes as an increase in the W/p ratio of the paper. Substituting the length of the tubes, 20.8 ft., in the t_x equation, the temperature at the end of the tubes is found to be $t_x = 2470\left(\frac{0.654 + 0.00143 \times 133}{1.00 + 0.110 \times 20.8}\right)$ = 635 deg. fahr., and changing the length factor from 0.11 to 0.098 and the c factor from 0.654 to 0.600, the temperature at the end of the superheater flues is found to be 680 deg. fahr. The final temperature in the smokebox depends upon the relative gas-carrying capacity of the two sets of tubes, which, according to the paper, is in the ratio of 0.598 to 0.402, making the gas temperature in the smokebox about 655 deg. fahr. The registered smokebox temperature at a combustion rate of 133 lb. for this locomotive was 659 deg. fahr., as reported in the Bulletin of the Franklin Institute on superheater tests of this locomotive. The paper gives this temperature 620 deg. fahr., which is a difference of 1.55 per cent expressed in heat units.

Using the $S°$ equation with a factor of evaporation of 1.23 for a feedwater temperature of 50 deg. fahr. and a pipe cross-sectional area of 32.64 sq. in., the temperature of the superheated steam is found to be 663 deg. fahr. instead of 670 deg. fahr., as given in the data.

Design and Application of Rail Motor Cars

By CHARLES O. GUERNSEY,[1] PHILADELPHIA, PA.

The rail car is capable of performing certain services to better advantage than motive power of any other current type. It is not a competitor of the locomotive in the locomotive's proper field. It is capable of performing services within its scope at a cost and with an availability and reliability at least equal to other railroad equipment.

Satisfactory operation depends on correct design, correct application, proper handling by the operators, and intelligent and thorough maintenance. The maintenance should be in the hands of an intelligent, properly trained supervisor, who has sufficient authority to handle his work without clearing details through other officials. The design must be such that all wearing parts are renewable, at the minimum of expense, and with a minimum of time out of service. The exhaust valves are apt to require attention more frequently than other features of the engine, therefore the design should be such as to give maximum exhaust-valve life. Twin exhaust valves have been found desirable for this purpose.

Cooling systems must be designed to operate effectively regardless of car speed or direction. Transmission equipment should be capable of delivering to the rails the maximum possible percentage of engine power throughout the range of car speeds, at least to 60 m.p.h. The parasites and accessories can be handled to best advantage by the use of a small separate power plant. Cars of current designs are proving their worth in millions of miles of service annually on many different railroads in various parts of the world. The rail car is generally accepted as a proved tool for the reduction of operating costs and improvement of service within its field.

This paper gives the field for application of motor cars, some problems of design and use, and conclusions as to design, operation, and maintenance.

WHILE the rail motor car is not new, having been commercially introduced during the early part of the present century, it was not accepted as an important unit in the economics of rail transportation until very recently. During the past seven years the development has been extremely rapid. Designs have been improved, sizes have been increased, the scope of application has materially broadened, and it has come to be recognized as having a definite field wherein it is superior to other forms of motive power.

Scope of Application

Rail motor cars are at the present time in daily service in sizes ranging from single cars developing about 70 hp. and weighing about 15 tons, to 800-hp. cars, capable of handling a number of trailing cars. Even larger sizes are being discussed at the present time. Cars now in successful service cover a field broader than any advocate would have dared predict as recently as five years ago. The sizes using power plants of 200 hp. and less are generally arranged with mechanical transmission. Usually they are limited to use as single cars, or at most, with one comparatively light trailing car, and are produced at the present time principally for export. Cars ranging from 250 hp. upward are practically all of the gas-electric type. A great majority of the cars being produced for the American market at the present time are of this type.

It will be readily seen that the range of sizes is adequate to cover a wide variety of conditions, as a result of which rail motor cars are now being successfully used in at least the following classes of service:

1 Branch-line passenger, baggage, express, and mail service.
2 Local main-line service requiring trains of from one to four or five standard cars.
3 De luxe express service where trains are limited to three or four cars.
4 Milk train service.
5 Local freight service on light lines.
6 Mixed train service on light lines.
7 Both light and medium switching service.

Typical successful applications have demonstrated the practicability of this service in the respective fields.

Why Use of the Rail Motor Car Is Justified

Among the more important considerations which have led to the use of rail motor cars, are the following:

1 Low cost of operation. In practically all applications of rail motor cars, savings in operating cost have been effected.
2 Properly maintained, the motor car is capable of performing an exceptionally high percentage of its scheduled mileage. This class of equipment can be kept available for service a higher percentage of time than steam equipment. Averages from a number of different properties indicate an availability of about 93 per cent, with many individual cases above 95 per cent.
3 Again assuming proper design and maintenance, the motor car is thoroughly reliable, and can be depended upon to complete its schedules.
4 The maintenance cost is comparatively low.
5 Stand-by losses are much less than with steam equipment as it is not necessary to maintain hostling service or burn fuel during a layover.
6 Due to the absence of cinders and smoke, the equipment can be kept clean and attractive to the public.
7 A given equipment properly designed can be adapted to a considerable variety of service.
8 Under some conditions, as for instance the complete motorization of a branch line, the expense of dock and terminal facilities can be eliminated.

Relative Responsibilities of Manufacturer and Operator

The success of the rail motor car in performing any service depends upon satisfactory design, satisfactory application, proper operation, and proper maintenance. Satisfactory design is the problem of the manufacturer. The manufacturer can assist in the proper application of the equipment. The correct operation and satisfactory maintenance of the cars is a problem entirely in the hands of the railroad, although the manufacturers are glad to assist in any way possible.

The design is and properly should be the function of the manufacturer. By reason of the engineering, sales, and servicing staff which he maintains, he is constantly in touch with rail-motor equipment throughout the world, and is in a position to profit from experience gained in all sorts of applications. Furthermore since the manufacturer is selling his product to many different railroads to meet many different conditions, he is compelled to spend sums in development far beyond what any given railroad might reasonably spend for the same development. Also by reason of the time and care which the manufacturer can and does necessarily take in the development of new apparatus, he is able to turn out a properly coordinated, well-balanced unit,

[1] Chief Engineer, Automotive Car Division, The J. G. Brill Co.

Contributed by the Railroad Division and presented at the Annual Meeting, New York, N. Y., Dec. 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

which would hardly be possible for any railroad to do without undue expense, test, and experimentation.

A great deal of emphasis could profitably be placed on the importance of proper balance and coordination between the various units which enter into the make-up of a complete self-propelled car. It would seem reasonable to expect that a better product, more thoroughly adapted to its purpose, can be had when purchased as a complete, trademarked, predesigned, and pretested equipment, than is possible where an attempt is made by the railroads to specify certain features, which obviously upset the balance of the whole. It is felt certain that no one would purchase an automobile or a motor truck, and attempt to specify special features in the engine. True enough, the purchaser will and rightly should determine the arrangement of body that is wanted for his work. The same should follow in rail-car design, but in the essentials, the design as offered by the manufacturer, both as to power equipment and general car design, should be used, and he should in turn be held responsible for the proper performance of such an equipment, when operated in accordance with the conditions agreed upon. Obviously also, if the manufacturer is able to manufacture parts in quantities, carry them in stock, and build to an existing design, which has been proved and with which his engineers, workmen, and service men are familiar, the product can be delivered at a far lower price than where special designs are attempted. The purchaser will get a better product at a lower price, and with less chance of trouble in service, if a complete, trademarked, manufacturer's design is accepted.

On the question of proper application, the manufacturer can be of considerable assistance to the railroads in selecting proper equipment for a given service; in fact, when the railroads so desire, the manufacturer is entirely willing to select and guarantee the proper equipment to meet a specified service. However, it is entirely within the province of the railroad to see that the actual application is reasonably in accord with the recommendations of the manufacturer. Proper application has a great deal to do with the success of this class of equipment. If the equipment is grossly overloaded, obviously failures in service and maintenance expense will be all out of proportion to the service rendered. There is, however, another side of the picture, in that if too large for a given service, the equipment will be running at such a low load factor that economy of operation will be lost. It is not the desire to convey the impression that the application of any given equipment must be within very narrow limits. Quite the contrary is the case in fact. Any given equipment can acceptably cover a rather broad field.

Satisfactory operation of rail motor cars is not at all difficult, in fact modern designs are so arranged and functions are so interlocked one with the other, as to make the equipment more or less fool-proof. Nevertheless, the operators should be thoroughly instructed and properly qualified, just as is the practice for steam-locomotive engineers.

The fourth, and in the long run probably the most important of the factors entering into successful operation, is maintenance. It is not necessary to say to a group of engineers that any mechanical equipment requires a certain amount of maintenance. There are many cases of cars in service which have averaged 95 per cent availability over a period of several years, whereas other cars of identical design have had a far lower factor of availability primarily because of the difference in maintenance. In this field, the manufacturer attempts, by offering technical advice, by maintaining a proper field staff, and by the preparation of voluminous instruction books, to assist the mechanical departments of the railroads, but after all he can only assist. The burden of the job is and properly should be carried by the mechanical officials of the railroad. It is not the purpose to dwell on this phase at any length, but it does seem advisable to point out that on an internal-combustion engine, and for that matter on the transmission equipment as well, if the proper thing is done at the proper time, maintenance expense can be kept surprisingly low, whereas if some minor adjustment is neglected, heavy expense may follow. In this respect this equipment differs rather widely from steam equipment. The steam engine can be operated, inefficiently it is true, but nevertheless without failure, even though much needed repairs are postponed. If some very minor inspection functions on an internal-combustion equipment are neglected, comparatively heavy repairs may be required, otherwise, a road failure may result. This point can be well illustrated by mentioning cleaning of gasoline-line filters and oil filters, checking and setting of magneto points and spark-plug points, and the correct setting of valve clearances.

Experience shows that when cars are first introduced on any property or division, troubles are far greater than after some months of service, in spite of depreciation of the equipment.

The railroads which have had the best results in the use of motor cars recognize that the maintenance of this class of equipment requires the services of men who are specialists in this work. They must have had sufficient experience with the internal-combustion engine, and know enough about the electric-transmission equipment to handle adjustments and repairs intelligently. These men should be under the supervision, direct or otherwise, of a thoroughly qualified supervisor. Satisfactory operation in all its phases probably depends more upon intelligent supervision and maintenance than any other one thing. This supervisor should have authority to direct engine-house and shop personnel, pass on qualifications of operators, place minor orders for repair parts, and in general be permitted to handle the routine of maintenance without delay, interference, or the necessity of clearing through a number of officials or departments. It will be found that when so set up, assuming the men to be properly qualified, the total maintenance expense can be kept to a minimum, and a large portion of such expense will be expended in minor adjustments, inspection, etc.

Design Requirements

The designer should bear in mind the following requirements: (1) As near absolute reliability as possible, (2) maximum availability for service, (3) long life, (4) performance, (5) ease of adjustment and repair, (6) simplicity, (7) low maintenance cost, (8) low first cost, and (9) light weight.

In view of the very rapid progress which has been made in the past few years, one would be rash indeed to attempt to set out an arbitrary specification, and insist that it covers the last word in rail-car design, either as to power-plant or transmission equipment. Nevertheless, the experience which has been accumulated indicates certain trends, which should be given serious consideration in determining good design.

Obviously, no one size or type of equipment will meet all varying conditions of service any more than a given type of steam locomotive meets all types of steam service. The equipment must continue to vary in size, also in the relation between tractive effort on the one hand and speed on the other, depending upon the particular service in which it is to be used. It would be very desirable if a given railroad could standardize on one type and size of equipment, maintaining interchangeability of parts, etc., but that will not be possible if the equipment is to be used throughout the full field to which it is adapted.

Various kinds of power equipment have been built for rail-car work, including steam plants of various types, and a number of Diesel equipments. The experience with steam plants has been limited to one or two cars. A considerable amount of pioneering work has been done with Diesel-electric power plants, particularly on the Canadian National Railroad. It seems that for con-

ditions within the United States, the Diesel cannot as yet be classed as a competitor with the carburetor-type engine for rail-car work. Due to the extremely high pressure involved in Diesel operation, either the weight per horsepower must be higher, or the maintenance more expensive, and the reliability less than for a corresponding gasoline engine. For the present at least it has not been accepted for our conditions. In this paper, therefore, only the carburetor-type internal-combustion engine will be considered.

General Design

While the weights of rail motor-car equipments are constantly being increased, because of the higher horsepower of the new models, and the heavier trains in which they will run, it is, nevertheless, important that the weights of these trains be kept to the minimum. A given power plant can meet a given schedule with a fixed gross tonnage. Obviously the lower the weight of the train itself the more net load can be carried, or conversely, if the train weight can be kept lighter, the requirements, and consequently cost of operation, are reduced. Surplus weight costs approximately one-half cent per ton per mile to handle.

When considering the relation of engine horsepower to train weight, the efficiency and factor of utilization of the transmission equipment must, of course, be taken into account. Generally speaking, fast schedules can be made with weights of from 400 to 600 lb. per horsepower, and average schedules with weights as high as 1000 lb. per horsepower.

The conditions under which rail-car engines operate are in many respects very favorable. The engine can be kept at desired operating temperature while in service; it can be kept at least reasonably warm during layover by means of the car heater, thus avoiding the ills incident to frequent cold starting; the oil temperature can be maintained substantially constant; the intake air for the carburetor is reasonably clean and at a moderate temperature; the engine need only run wide open at its designed speed; and finally, when using the electric transmission, the connection between the engine and the ultimate load is elastic, thus preventing transmission of shock.

In some other respects the conditions to be met are far more severe. The engines are expected to operate more miles before the valves are ground than many automobile engines will run during their life. The engines should also be capable of operating the maximum length of time between overhaul periods. A fair figure for recent designs is about 6000 hr., or 150,000 miles. The engines operate with a comparatively high load factor, and with comparatively high water-jacket temperatures, making necessary careful attention to cooling details. When all of these things are taken into account it is evident that engines to give the best results must be specially designed with the conditions of this service definitely in mind.

Engine Ratings

It is undesirable, at the present time at least, to attempt any arbitrary formula for rating engines for this class of service. The designs offered by different manufacturers vary so widely that any formula based on bore, stroke, number of cylinders, and piston speed is very apt to be misleading. Too many factors which must be taken into account, are omitted in any such arbitrary formula. Naturally the railroads would like some yardstick whereby the power plants which they buy for this class of service can be checked as to rating. No engine can be expected to develop throughout its life in normal service, the maximum horsepower which it is capable of developing under laboratory conditions. It seems, therefore, that a service rating should be given these power plants somewhat below the power actually developed on test, because of the depreciation in power which may be expected in service. The following is suggested as a simple and reliable means of rating:

For rail-car service, engines are to be rated at a speed which the manufacturer is willing to guarantee for continuous duty, and at 90 per cent of the actual power developed on test when operating at that speed. This practice has been followed by one prominent producer for several years, and has given uniformly satisfactory results; in fact engines tested after 150,000 miles in service and previous to any overhauling have developed power somewhat in excess of the rating thus determined.

Engine Speeds

There has been a trend during the past several years toward increased operating speeds on internal-combustion engines of all kinds, particularly for automobiles, trucks, and bus service. This same trend should logically be followed in rail-car work. Considering that other things are equal, the power output of a given engine is more or less directly proportional to speed, it is obvious that the engine should be used and rated at the maximum speed consistent with satisfactory life and reliability. Increase in power from a given engine secured in this way does not materially increase the first cost, either of the engine or the generator to which it is attached. It may be true that to operate at these higher speeds, the bearing loads are somewhat increased, but this is considered in bearing design, and is partly offset by careful balance and the use of aluminum pistons, thereby reducing reciprocating weight; in fact when light-weight reciprocating parts are used and considering centrifugal, inertia, and gas-pressure loads, the net load on the bearings is frequently less at higher speeds. In any case it is only necessary to provide adequate bearings. At the present time the limitation as to speed seems to rest more in satisfactory life and functioning of exhaust valves, than in bearing loads or piston speeds. The engines on the present market for this class of service, vary in average piston speed from about 1200 to 1800 ft. per min. Engines using twin exhaust valves, thereby improving valve conditions, are ordinarily rated at about 1650 ft. per min.

Engine Life

It has been the practice of railroads using motor cars, to depreciate the engines on the basis of a life of eight to twelve years, while depreciating the car and trucks on the usual basis as determined by I.C.C. rulings. In view of the progress which is being made in this field, this basis may be fair from the standpoint of obsolescence; however, all modern engines used in this class of service are designed for the ready renewal of bearings, pistons, rings, cylinder liners, valves, and other wearing parts, so that there is apparently no reason why these engines should not last more or less indefinitely, if proper renewals are made from time to time.

Fuels

The vast majority of all rail motor-car engines in service are designed for and operate with gasoline as the fuel. At the present time there is no power plant which can compete with the gasoline engine from the standpoints of weight, first cost, maintenance cost, reliability, and ease and flexibility of operation and control. Certain Western roads have adapted the carburetor engine to the burning of less volatile fuel, commonly known as distillate, by the use of special carburetors. This fuel can ordinarily be purchased at the refineries, under proper specifications as to sulphur, etc., at a price of some 4 cents per gallon less than gasoline. In addition to this saving in the cost of the fuel itself, the highway tax on gasoline widens the differential to as much as 8 or 10 cents per gallon in such states as do not rebate the tax when used for other than highway purposes. Obviously the saving in

fuel cost becomes quite attractive, particularly where the tax is involved. The use of distillate as a fuel introduces additional complication in the carbureting equipment, and requires additional skill in the handling and maintenance of the apparatus. It also results in a considerably more rapid dilution and deterioration of the lubricating oil, necessitating changing of oil at frequent intervals. It is also necessary in burning the heavier fuel to reduce the compression of the engine, thus somewhat lessening the horsepower, which in turn increases the per-horsepower

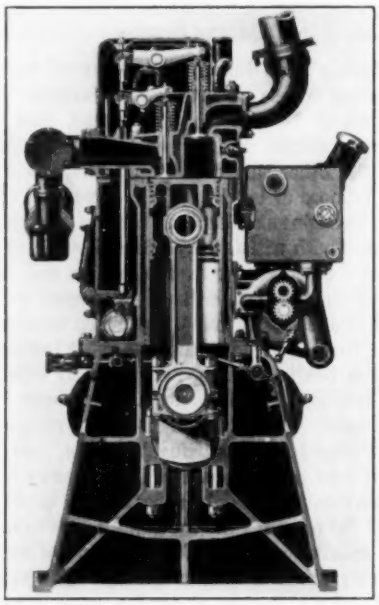

FIG. 1 CROSS-SECTION THROUGH SIX-CYLINDER BRILL MODEL 660, OR EIGHT-CYLINDER MODEL 860 ENGINE

cost of the power plant. It seems probable that distillate will be used where the railroad has a sufficient number of cars and a sufficiently well-trained personnel properly to handle the additional complications and servicing required. This will be especially true of the Midwestern roads, where distillate can be secured from refineries on their own lines. Apparently, however, unless these conditions obtain, the moderate saving in fuel cost is not sufficient to justify the additional maintenance expense and supervision which may be required.

A considerable effort is being put forth at the present time to improve methods of burning distillate as a fuel, and it is possible that some of the present objections may eventually be eliminated, in which case the use of this heavier fuel may become more general.

CYLINDER HEADS AND VALVES

In a rail car, as well as other internal combustion engines, the need for regrinding exhaust valves is usually the first thing that makes it necessary to remove an engine from service, therefore anything that can be done to increase the life of exhaust valves, materially increases the availability of the engine. Furthermore, the temperatures of the exhaust valves and exhaust-valve seats are largely responsible for limiting the compression which can be used, and consequently the power output and economy. The cooler the exhaust valves can be kept, the longer will be the time between regrinding periods. The heat of the valve head is dissipated primarily through the seat, and the greater the distance from the center of the head to the seat, the hotter will be the center of the valve head. Further, the area of the valve head exposed to heat increases with the square of valve diameter, whereas the cooling surface increases only in direct proportion to the diameter. Therefore, the smaller the valve, the more will be the cooling surface on the seat in proportion to total exposed area. These considerations have led to the use of twin exhaust valves in preference to one large valve, in most engines of more than 5-in. bore. In addition to securing longer valve life, considerably more power can be taken from the engine without undesirable results.

Twin intake valves are generally used, partly because they permit a higher volumetric efficiency due to more complete filling, but also because it makes possible interchangeability between intake and exhaust valves.

The majority of engines used in rail-car work are of the overhead-valve design, with the combustion chamber contained in the head. On most designs in general use at the present time this combustion chamber is of a generally cylindrical shape. In modern automobile engines the combustion chamber is designed so as to give a high turbulence to the charge during the compression and firing strokes. This arrangement has certain decided advantages in decreasing detonation and insuring complete mixture, vaporization, and burning of the charge, and consequently in further increasing exhaust-valve life. A recent design of rail-car engine, as shown in Fig. 1, uses four overhead valves per cylinder, but locates the intake and exhaust valves at different levels, thereby achieving the high turbulence design generally used on automobiles, but without sacrificing the advantages of four overhead valves per cylinder. It is expected that this design will permit higher horsepower output, smoother operation, longer exhaust-valve life, and in the case of slow-burning fuels, will materially improve fuel consumption. This arrangement also makes possible a very convenient arrangement for camshaft and rocker arms, also insures a thorough distribution of cooling water around exhaust valves, exhaust ports, and spark plugs. Also due to

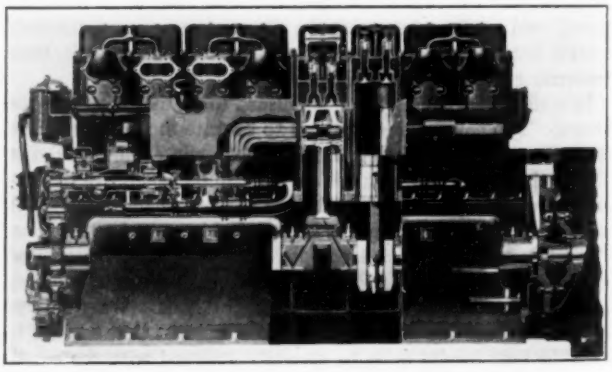

FIG. 2 LONGITUDINAL SECTION BRILL MODEL 860-535 HP. RAIL-CAR ENGINE

the compact arrangement of the combustion chamber and the thorough mixing of the fuel with the air, only two spark plugs are required. Three or four spark plugs are required even in engines of smaller size when using the conventional combustion chamber. In this same design the two exhaust ports have been kept entirely separate, which represents a distinct improvement from the standpoint of cooling. (See Figs. 1 and 2.)

CRANKSHAFT, BEARINGS, AND OILING SYSTEM

Generally speaking, all engines on the present market are satisfactory from this standpoint. It has been observed, however, that bearing replacements, when finally required (usually after 60,000 to 150,000 miles), are made necessary not by reason of excess wear, but rather because of the babbitt cracking loose from

its support. This cracking almost invariably starts where anchoring dowels, screws, or rivets go through the bearing. Dowels and similar locating devices are also undesirable, particularly in the crankcase half of the main bearing, because it is impossible to remove the dowels, and hence a bearing for replacement without removing the shaft from the engine. In the new design illustrated, therefore, the cap half of both main and connecting-rod bearings has a thin layer of babbitt cast into the cap itself. The crankcase half of the main bearings, and the rod half of the connecting rod bearings are heavy bronze backed, babbitt lined, removable shells. Due to the thickness of these shells the cap abuts the ends of these at the joint, thereby securing the loose half of the bearing without any dowels. This makes possible a smooth unbroken bearing surface without reliefs of any kind, which should not only improve the condition as to cracking, but also, due to the absence of reliefs, insures longer bearing life because the oil cannot as readily be squeezed out of the bearing under shock loads. Also the case half of the main bearing can be readily removed without disturbing the shaft.

All modern engines in rail cars carry high-pressure lubricating systems. They vary in several essential details, however. In the new design to which reference is made, a hole is drilled longitudinally through the crank-pin bearings, thus reducing adjacent main-bearing loads by as much as 1300 lb. per bearing, at the same time providing an oil reservoir. The oil is introduced into the main bearings, and thence into the crankshaft through the bearing caps, i.e., on the low-pressure side of the main bearing. A considerable quantity of oil beyond actual lubricating requirements is circulated through the crankshaft, and allowed to escape through a pressure-regulating valve, thus materially assisting in the cooling of bearings. The crankshaft is drilled from end to end so that even though one or more of the supply lines be obstructed, oil to all bearings is assured.

A suitable inter-cooler, or other provision, should be made for maintaining the oil temperature high enough to boil off as much dilution as possible, but low enough to prevent excessive oxidation of the oil. Satisfactory results have been had when the oil temperature is maintained between 150 and 170 deg. fahr. The use of a satisfactory oil filter is important. If good oil at the proper temperature is used, the matter of changing oil when using gasoline as a fuel is practically a question of contamination or dirt. With a filter consisting of a series of felt stacks, through which the oil is passed edgewise through felt washers, all dirt but the finest particles in suspension can be removed. With such a filter oil has been used for as much as 4000 miles between changes with entirely satisfactory results.

If the temperatures are not correctly maintained within a reasonable range, or if the filter is inadequate, or in any case when burning distillate without heat, more frequent changes are necessary, sometimes as frequently as once in 500 miles.

Cooling Systems

The cooling system should be designed so that the car will cool equally well when running in either direction and at any car speed, and should be such that the correct temperature can be maintained regardless of atmospheric temperature. This can be accomplished best by using forced-draft circulation of the cooling air through the engine radiators with electrically driven fans arranged for a variable-speed control so that the cooling capacity can be set to suit the conditions. The cooling system should be arranged so that all water automatically drains inside the car whenever the engine is shut down. This makes it unnecessary to drain the system to prevent freezing, as cooling water inside the car can be kept warm during layover periods by means of the car heater.

The air from the radiators should be discharged upward adjacent to the exhaust discharge, in this way carrying any obnoxious exhaust gases into the air, and preventing their being drawn into the car windows. (See Fig. 3.)

Exhaust Systems

Due to the intense heat developed in exhaust manifolds and pipes when the engine is running for long periods at a high power

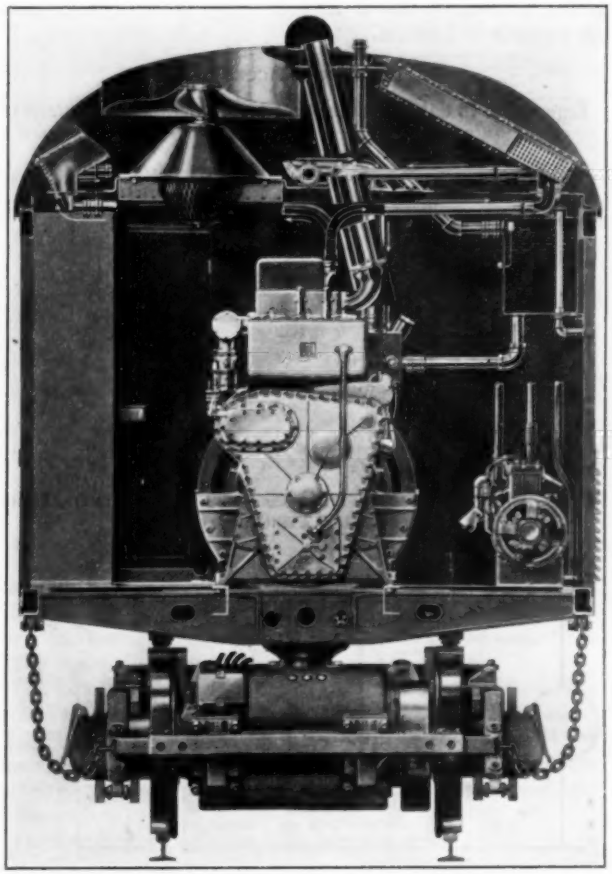

Fig. 3 Section Through Brill Model 860 Car, Showing Cooling System, Exhaust System, Front View of Main Engine, Location and Arrangement of Auxiliary Power Plant

factor, discharge should be as direct as possible. The exhaust manifold should be made as simple as possible, as experience has indicated that intricate castings are certain to make trouble. This has been satisfactorily overcome in some cases by using a high chrome-content cast steel. The simplest method seems to be the use of a separate exhaust manifold for each port, entirely eliminating any chances of cracks. For use in congested areas, at least a partial muffling of exhaust is necessary.

Fuel-Feeding Systems

Various fuel-feeding systems have been used. None of them have been entirely satisfactory. With pressure or gravity systems there is always danger of flooding the engine room in case of a leaky or dirty float valve in the carburetor. Vacuum feeding systems working off of the intake manifold, as commonly used in the automobile, are not satisfactory as the source of vacuum when the engine is running wide open is inadequate. A separate pump on the engine as a source of vacuum has been used with fair success, but is open to the criticism that loose connections or other

disturbances in the system may render it inoperative. Mechanical pumps driven from the engine have not been entirely satisfactory due to difficulty of maintaining stuffing boxes on plunger types, and the short life of diaphragms or bellows in those types. Considerable work is being done at the present time to render the vacuum system less susceptible to derangement. If these shortcomings can be corrected it represents the ideal system. There is also the possibility of using a series of small electrically driven pumps, so arranged that if one goes out of order the remainder will continue to function.

Duplication of Accessories

Experience to date indicates that a considerable percentage of failures in service result from the failure of minor accessories, rather than failures of the basic parts of the equipment. For that reason good practice provides for duplication of such accessories as fuel-feeding devices, magnetos, spark plugs, carburetors, and similar parts, so that even though one part may fail the car can at least complete its run.

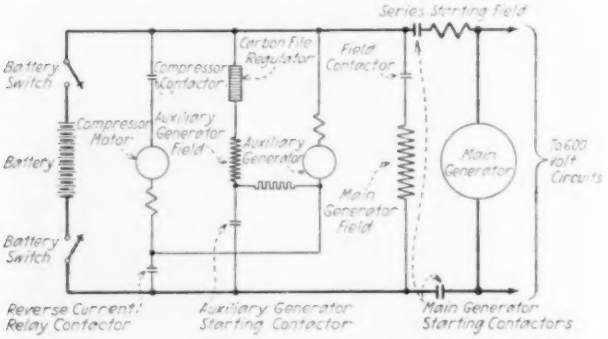

Fig. 4 Schematic Wiring Diagram of 32-Volt Circuits, Brill Model 660 and 860 Cars

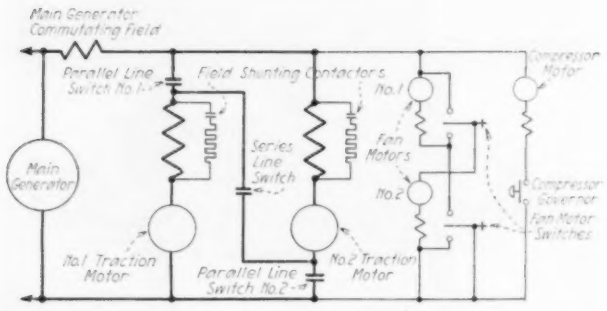

Fig. 5 Schematic Wiring Diagram of High-Voltage Circuits, Brill Model 660 and 860 Cars

Furthermore, apparatus should be arranged, if possible, so that a failure of one part will not affect another. As an illustration, when cranking the main engine under unfavorable conditions the battery voltage may drop considerably, thus making battery ignition somewhat difficult. The use of magnetos prevents trouble from this cause.

Electrical Equipment—Loading Characteristics and Accessories

In the essentials, electric transmissions are all alike. In each case the engine drives a direct-current generator, which in turn transmits power to one or more series motors. The variation between different systems comes in the means of handling the accessories, the generator control, and the switch gear for properly connecting the traction motors, i.e., to say, reverse or forward and series, parallel or shunted-field connections of the traction motors. In the matter of motor connections, the simplest scheme is the so-called "K" control, in which the operator manually operates a controller, setting up power circuits in the proper fashion directly. This has been used particularly where low first cost was a serious factor. In the other system the motor connections are handled by contactors remotely controlled from the operator's position. This type of control is universally used where heavy currents are to be handled, as for instance in electric-locomotive applications. It has the disadvantage of somewhat higher first cost and somewhat more complicated wiring, but has advantages in that 600-volt potential can be kept entirely away from the operator, and further in that contacts are made or broken at high speed and are maintained under high pressure, thus reducing the tendency to burn. Both systems have given good results. With the trend to constantly increasing horsepower, the contactor or remote type will undoubtedly gain favor for the reasons given. This arrangement has a further advantage in case of double-end control or double power-plant cars, in that the heavy current-

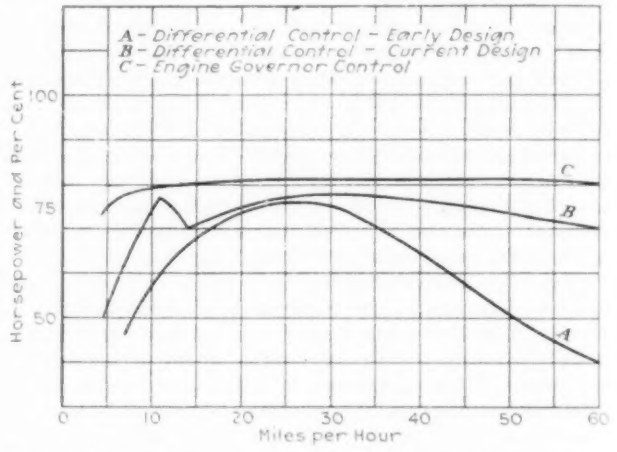

Fig. 6 Graphs Showing Progress in Electric Transmission Design From the Standpoint of Power Utilization

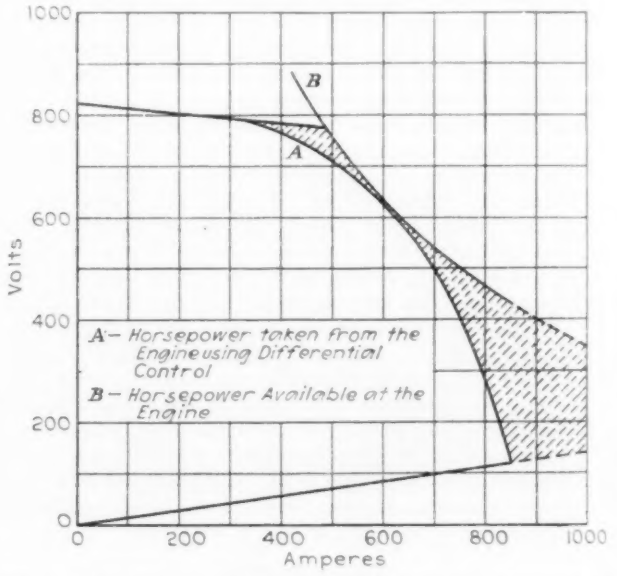

Fig. 7 The Principal Additional Performance Secured by Governor Control Is the Result of Increased Utilization, Rather Than Increased Efficiency

carrying cables need not be carried throughout the length of the car as is the case with "K" control. This equipment has the further advantage that transition can be made from series to parallel connections of the motors without closing the engine throttle. This can also be done with "K" control if skillfully handled, but it is general practice to close the throttle when making such transition with "K" control.

The function of the electrical transmission is obviously to transmit the full power of the engine to the wheels at all times, regardless of car speed, motor connections, or other conditions outside the engine. With differential control of the generator field, such as has been generally used by all builders in the present market, the inherent characteristics of the generator and of the traction motors prevent full utilization of the engine horsepower at all times, although it does approximate it.

Marked progress in electric-transmission design has been made during the past five years. Fig. 6 shows graphically engine horsepower in percentage against miles per hour. The engine is capable of developing 100 per cent of its power rating at all car speeds. In early designs a comparatively small percentage of the power thus developed reached the wheels, as shown on graph "A." The equipment in general use at the present time delivers to the wheels power approximately in accordance with graph "B." The equipment designed for engines shown in Figs. 1 and

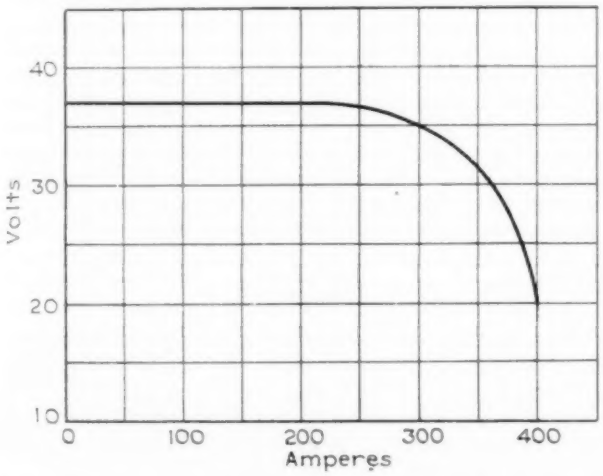

Fig. 8 The Auxiliary Power Plant Can Be Set at a Desired Voltage to Maintain Correct Battery Charge, and Will Operate Accessories Without Change in Voltage, Within the Limits of Its Output

2 will deliver power to the wheels in accordance with graph "C." This is brought about partly by increased efficiency in the electric generator and traction motors, but primarily in the improved design of the generator control, such that the generator utilizes the full power of the engine throughout the full range of car speeds. It is primarily a question of complete utilization, rather than a question of improved efficiency. In this design the generator is a simple, separately excited, shunt-wound machine, the current for this shunt field being supplied from the low-voltage system, to which reference is made later, through a rheostat or controller, which varies the field strength. This rheostat is in turn actuated by the engine governor, so that if the engine tends to run above its rated speed the load is increased, or vice versa. In a conventional equipment as generally used heretofore, the engine drives a main generator and an exciter. In these two machines there are at least five fields, all of which must be properly coordinated and balanced. When so coordinated and balanced they take a power output from the engine as shown in graph "A" of Fig. 7, assuming the power of the engine to be represented by graph "B." With the control system mentioned, additional power can be delivered as indicated by the shaded areas, and limited only by the commutating limit of the generator on the one hand and voltage limit on the other. Power delivered to the rail, shown as tractive effort at various speeds for engines il-

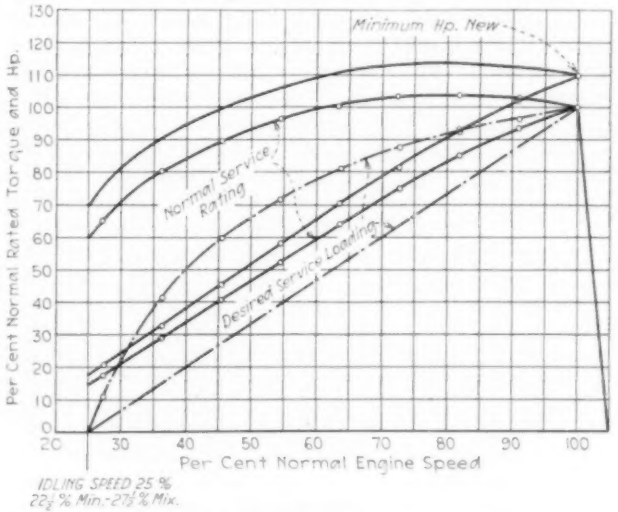

Fig. 9 The Most Desirable Loading Characteristic Extends in a Straight Line From No Load at Idling Speed to Full Load at Rated Speed

lustrated, is shown in Fig. 10. Further, in the conventional equipment the amount of load imposed varies as between hot and cold equipment, in this way preventing uniform loading of the engine under all conditions.

The power available from a given engine varies, depending upon its condition. With the governor-operated control arrangement the engine will be called upon to develop whatever power it is capable of delivering at its rated speed, and it is not necessary to reset the electrical load to suit changed conditions of the engine.

The carburetor engine is most efficient when running at or near wide-open throttle. Its efficiency is reasonably independent of speed. The fuel consumption per horsepower increases rapidly as closed throttle operation is approached. On the majority of runs the full maximum power of the engine is not required as an average condition, the average power factor probably being in the neighborhood of 60 to 80 per cent. The ideal condition, when reduced power is required purely from the standpoint of economy, would be to overload the engine, thereby reducing its speed and power; however this would be detrimental to the life of the engine, as operating at wide-open throttle and reduced speed would increase the maintenance. A happy medium between high fuel consumption on the one hand and excess maintenance on the other, is as indicated on Fig. 9. The desirable load extends from zero at idling speed to a maximum at rated speed, in a straight line. The use of an equipment which will give a loading characteristic of this nature will insure good economy when operating at less than full power, in that way representing a distinct advance over the conventional differential control equipment, without overloading the engine at reduced speeds to the detriment of the engine, in this respect having an advantage over any control arrangement which maintains a fixed torque. The best application is that which, at any given engine speed, loads the engine to the maximum torque which it can carry smoothly and without detonation or other unsatisfactory performance at that speed.

The steam locomotive is essentially a comparatively simple machine. In recent years, however, locomotives have been fitted with superheaters, feedwater heaters, boosters, and numerous other accessories to increase their effectiveness. Rail cars must necessarily follow the same general line of development particularly if the added efficiency can be obtained without added complication. In the case of the equipment given, a 550-hp. engine will perform the same schedule, with full utilization per graph "C," Fig. 6, as a 600-hp. engine with the utilization as indicated by graph "B." Power in the engine is of no use unless it be transmitted to the rail. Further and also important, since

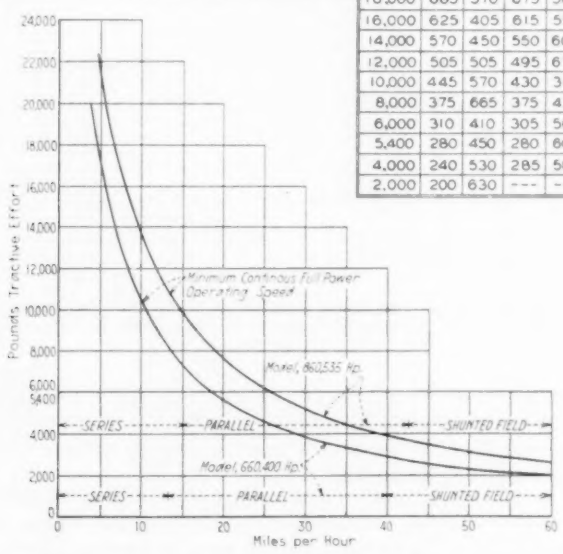

FIG. 10 BY REASON OF COMPLETE UTILIZATION OF ENGINE POWER, RELATIVELY HIGH TRACTIVE EFFORT IS AVAILABLE AT ALL CAR SPEEDS

the engine is working somewhere near its point of maximum efficiency, the fuel consumption will be less.

Ordinarily various accessory devices, such as battery, exciter fields, car fans, car lights, air compressor, etc., must be supplied with current at 32 volts. With equipment as generally used heretofore, this has been supplied, although rather imperfectly, either from the main generator or from the exciter. By reason of the characteristics of the differential control machine, the exciter is inherently a variable-voltage machine, and therefore, scarcely suited as an ideal source of 32-volt current for accessory purposes. If, on the other hand, the exciter is made a constant-voltage machine, it is capable of delivering only its full voltage when operating at two-thirds of rated speed or higher, unless it be made extremely large, which introduces prohibitive costs.

It is extremely important that the battery be kept in good condition, as the whole performance of the car depends upon it. In spite of auxiliary starting devices such as compressed air, the engine must after all be started, as for instance, after an overnight layover, by using the battery as a source of power.

Also there are many conditions where it is necessary to maintain air pressure for braking purposes, where otherwise the engine would not be needed. With the typical differential control it is necessary in such cases to disconnect the traction motors from the circuit and speed up the engine for the purpose of supplying five or six horsepower necessary to operate the air compressor. This obviously is objectionable from the standpoint of wear and tear, to say nothing of fuel economy, but the most serious objection is that the operator must willfully perform certain functions to insure an adequate supply of air for the safety of his train.

In view of the above requirements as to battery-charging and air-compressor operation, arrangements have been made whereby these functions can be handled from the main engine while idling. A number of such equipments are in service, and represent a distinct improvement in respect to these accessories over previous practice. These equipments, however, require elaborate control apparatus.

In the new design to which reference is made, a small industrial-type four-cylinder vertical engine, direct connected to a 32 to 40-volt generator, is used for battery charging, and the handling of such parasite loads as air compressor, lights, train control, excitation, etc., thus entirely segregating the low voltage system from the main plant and the high voltage system. In this way a small generator thus driven can be maintained at constant voltage, giving ideal battery-charge conditions, in addition to handling such accessories as may be required. Obviously the main engine can be shut down under many conditions where it would not otherwise be possible. Further, the small engine can be used as an additional source of power for starting the main engine. In case it is desired to supply a limited amount of current to trailing equipment, this can also be supplied from this small power plant. It will be seen, therefore, that the segregation of the low-voltage and high-voltage circuits, generally as shown schematically in Figs. 4 and 5, considerably simplifies the apparatus, and at the same time improves the functioning of both plants. While this, of course, adds to the cost of the equipment, the results in safety, decreased complication of the main transmission, less wear and tear on the main engine, added assurance of an additional source of power for starting the main engine, and numerous other incidental advantages, seem to justify this added expense.

Discussion

HUGO MOREN.[2] As the author pointed out, the Midwestern roads are burning distillates, which they obtain from refineries on their own lines. Their gasoline engines are fitted with special carbureters and vaporization devices. This way of burning fuel oil is inefficient and costly to service and maintenance, and consequently the savings, if any, are small.

Due to the necessarily lowered compression ratio, the power output and flexibility are less than with ordinary gasoline engines. As the combustion is incomplete, the engine smokes and the fuel consumption is excessive.

An oil-burning engine of the low-compression type has been developed recently in Europe. It has a considerably lower compression ratio than a Diesel engine, but slightly higher than a good gasoline engine. It starts on gasoline and retains the electric ignition not only for the start but for continuous running. It has a solid-injection fuel system, which distributes the fuel with great uniformity. This European engine has the advantage of a remarkably low fuel consumption under load, but at low speed and at idling the combustion is rather incomplete. It has to use gasoline for the start.

Properly developed, an engine of this kind could be made to start without using gasoline, and after a few minutes' running the first inevitable smoke would disappear, even when the engine is idling. In order to facilitate idling and avoid crankcase-oil dilution, the injection-fuel pump will be so designed as to cut out a variable number of cylinders, whereby the others will

[2] High-Speed Diesel Engineer, American Machine and Foundry Company, Brooklyn, N. Y. Mem. A.S.M.E.

have to pull hard enough to keep up the temperature in the combustion chamber.

An engine of this kind will have as good a flexibility as any internal-combustion engine. It will develop more power than a corresponding gasoline engine. It will have as good fuel consumption as a good Diesel engine (0.42 lb.). There would be no limit as to size of the cylinder; a 12-in. cylinder will not present greater difficulties than an 8-in. cylinder. Finally, this engine would be lighter and cheaper to build than a corresponding Diesel engine. It can easily be imagined what an immense field of application there would be for an engine of this kind.

The combustion system need not be confined to the four-cycle principle.

HERMANN LEMP.[3] The paper is a valuable contribution to the application of internal-combustion engines to railroad service in connection with electric drive.

Years ago, in discussing with Mr. Henry Chatain the control situation, he was eager that some way could be found to produce automatically the electrical energy required by the traction motors in a rail car or locomotive in the form demanded by the service, and which automatic method would remove the skill necessary in the operator to obtain the same results by hand manipulation.

My patent No. 1,216,237, issued on February 13, 1927, was for a control intended for an internal-combustion engine using a carbureter, although it also could be used in connection with an oil engine supplied with fuel by a pump. This patent broadly covers an engine-driven speed governor, the range of which would be controlled by the car operator. In other words, by increasing the speed of the engine through the governor control greater horsepower would be developed or less, as the occasion demanded. The speed governor, in its turn, would operate a set of valves acting on a fluid piston, containing either oil or air, and the traveling piston would then first increase the fuel supply to the engine from a minimum to a maximum, while maintaining all the time full field excitation on the generator. Once the full fuel admission is reached, it would then be maintained constant through the rest of the stroke, while the field excitation would be gradually reduced to a minimum.

In other words, between the two extremes of the piston travel somewhere a balance would be found between the fuel furnished to the engine and the field excitation which would give the amount of energy called for by the governor setting in that particular form the service demanded.

My patent No. 1,313,097, issued on August 12, 1919, showed another application of the same principle to an oil-electric locomotive in which, in addition to strengthening and weakening of the field, the grouping of the motors in series and parallel was also automatically performed.

This patent disclosed also a method of controlling the engine speed by the car operator by means of varying the relative speed between the engine crankshaft and the governor, which has the advantage of always utilizing the governor at its most efficient range, which usually runs over about 10 per cent speed variation.

These patents are cited to show the principal reason why, later on, when the time was ripe, I preferred to use what is known as a "drooping characteristic" or "differential control," reference to which has been made by the author.

This method of control, which has found wide application in the United States, in Canada, and abroad, I termed an "inherent automatic control," meaning thereby that it did not depend upon a mechanically directing mind through relays, valves, and contacts and moving members to achieve the results desired, but that the service demands from the traction motor, opposing a separately exciting force, drew automatically a substantial constant energy from the generator over a wide range.

It was never contended that this control would cover exactly the ideal power hyperbola furnished by the engine, but near enough for all practical purposes, and having as its chief advantage great simplicity. All practical railroad men have laid great stress at all times upon as simple equipment possible to give reliability of operation, even if by doing so some of the last 5 or 10 per cent of power utilization had to be sacrified.

The oil-electric locomotives produced jointly by the General Electric, American Locomotive, and Ingersoll-Rand companies have used this "drooping characteristic control" for the past four years successfully, because it is particularly suitable for switching operations, where the accelerations and decelerations are continuously called upon.

I have dreamed that some day the big main-line transportation now done by steam would be supplanted by oil-electric equipment where the great saving of fuel and relatively continuous operation would be brought to its full accomplishment. For this main-line service I anticipated that what is now termed the "speed control," and which is disclosed in the two patents cited, would be employed. As a matter of fact, one of the locomotives now being built at Erie is being so provided.

The graph shown by the author, Fig. 6, is somewhat misleading. In the first place, these curves are developed under the assumption that the engine speed is constant through the whole range, which is not a fact. As soon as the engine tries to unload, its speed will go up. This will take place on both ends of the curve. Hence, the curve *A* is different, and not nearly approaching ideal curve *B*. (See Fig. 11.)

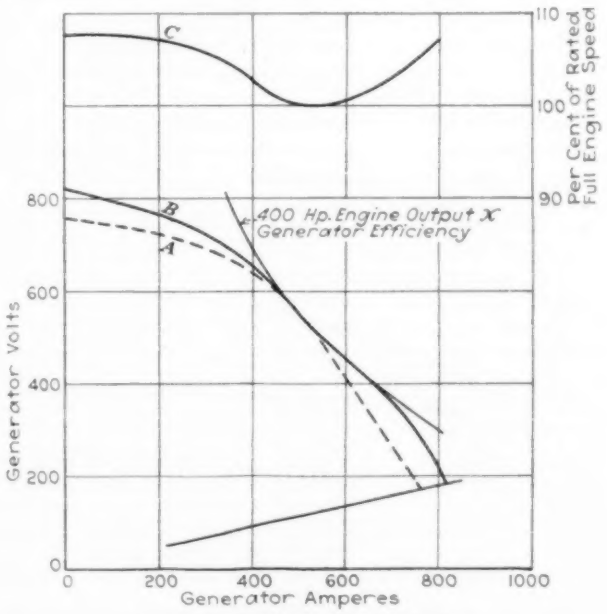

FIG. 11 GENERATOR CHARACTERISTICS

(*A*, test at 100 per cent full engine speed; results on four machines. *B*, test with 400-hp. engine. *C*, per cent rated full speed of engine.)

Second, when the curve *A* is then corrected for the speed variation of the engine, and transferred to the tractive effort curve obtainable with the car or locomotive, it will be found that the variations do not amount to as much as would be implied by the graph diagram of the author. (See Fig. 12.)

Third, when finally a curve is prepared showing the speed variations caused by lack of power, as applied to a car running on

[3] Consulting Engineer, Locomotive Department, Ingersoll-Rand Company, New York, N. Y.

the level and on a grade, it will be found that the maximum variation may amount only to about 5 per cent in the case of the level and less than 2 per cent on a grade. (See Fig. 13.)

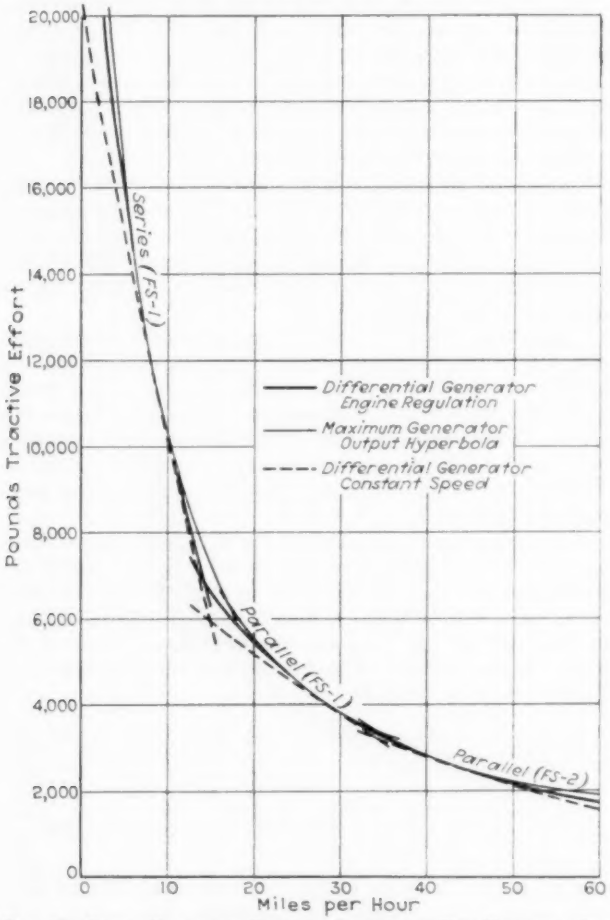

FIG. 12 SPEED-TRACTIVE EFFORT CURVE FOR GAS-ELECTRIC CAR

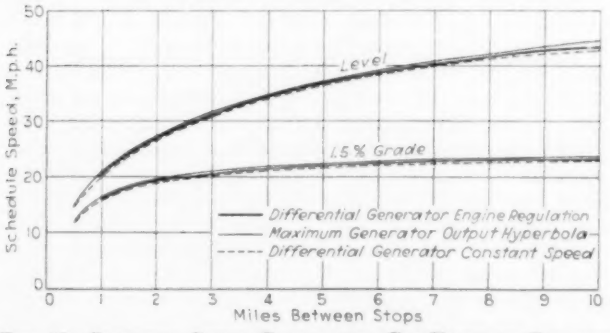

FIG. 13 SCHEDULE SPEED CURVES FOR GAS-ELECTRIC CAR AND TRAILER

(Curves show practical operating schedule speed for continuous operation with normal motor ventilation. Based on 110 per cent of minimum theoretical time in motion without coasting. Duration of stop, 30 sec.; rate of braking, 1.5 m.p.h.p.s.; car friction G E T-3-F; motor car, loaded and equipped, 65 tons; trailer loaded, 50 tons; total train weight, 115 tons.)

Free running speeds	M.p.h.
Maximum output hyperbola, level	57.1
Maximum output hyperbola, 1.5%	25.9
Differential generator engine regulation, level	55.4
Differential generator engine regulation, 1.5%	25.7
Differential generator constant speed, level	54.2
Differential generator constant speed, 1.5%	25.5

Now the question arises if it is necessary to go to the complication of a robot-controlled method with the admitted added complication and possible unreliability, when the inherent control produces only a loss in operating schedule of 5 per cent.

Referring to the author's proposition of using a separate engine set for operating the auxiliaries independent of the main engine, operating the traction motors, the writer is fully in accord with that viewpoint. The General Electric Company used such a unit in their first two-unit locomotive furnished to the Dan Patch Railroad before the war, and in fact used such a unit in most of their rail cars.

With gasoline as a fuel, and particularly with bigger units, this is the right course to pursue. The Brill Company has adopted it. When, however, the same plan is proposed for an oil-electric locomotive, the first cost and the matter of the reliability of a small oil engine for the auxiliaries furnish a real problem.

The General Electric Company has straddled the proposition by using a gasoline engine for the small unit in connection with the traction engine operating on oil, but this is not looked upon favorably by railway officials, because of having to supply two classes of fuel.

However, with the advent of big locomotives, say of 1600 hp., where the auxiliary unit will amount to about 160 hp., such an oil unit is in sight and ought to be used.

F. H. HATCH.[4] The author has presented valuable data on present-day rail-motor-car design technicalities. In a broader sense, however, perhaps a few remarks concerning application and design may not be amiss. Suppose that a given railroad is operating a branch line by steam. Due to competition by bus lines or private automobiles, passenger traffic has fallen off or disappeared altogether; the only reason for operation of the line is mail and express business, or else because abandonment is forbidden by the State authorities. The railroad has decided to give ear to the many claims of economy advanced for the rail motor car and to try one out on this branch line in place of steam passenger service. There are, then, three courses open:

(1) Substitute a small rail car that either is too small or is barely large enough for the service, with the idea that diminution of business is inevitable.

(2) Substitute a single passenger-and-baggage car with sufficient capacity for present-day traffic and with leeway for growth.

(3) Substitute rail-motor equipment of ample capacity for present and future service, but fitted throughout with the latest devices and apparatus for the comfort and convenience of the riding public. Gas-electric drive is arbitrarily assumed.

The first course probably will lead where it is expected to—i.e., ultimate drying up of the service entirely. The second course should hold present business, and if schedules and running times are attractive, might add some seasonal business at least. The third course, provided there are any business potentialities in the territory, should begin, after a short time, to show increasing signs of a traffic comeback.

In the gasoline-electric car, for instance, the gasoline engine is the only part of the equipment that is not electric in its operation and design. Why not definitely set out to make this engine as unnoticeable as possible through the elimination of noise, vibration, fumes, and smoke nuisance, and concentrate on the power plant as a whole to profit fully from the advantages of electrification, including such features as smooth and rapid acceleration, absence of smoke and cinders, quietness of operation, decrease in property damage due to fires started by steam locomotives, etc.? In other words, gas-electric cars (or in fact self-propelled cars in general) have the inherent advantages of electrification which can be realized for branch-line service at costs which are less than for existing steam equipment.

[4] Engineer of Automotive Equipment, N.Y., N.H. & H. R.R. Co., New Haven, Conn.

Such advantages as outlined, together with a superior class of rolling stock, convenient and fast schedules, and reasonable fares, cannot help but attract and hold business in any but the most barren territories. Railroads and manufacturers, in the writer's opinion, would do well to cooperate on their design and application of rail-motor-car equipment, not only that an economical stop-gap for diminishing traffic may be obtained, but that all the latent possibilities for popular and attractive travel may be realized in automotive rolling stock.

So much for the design of the rail motor car as it may relate to attractiveness to the riding public. From the purely railroad viewpoint two features are paramount in the selection of any equipment. These two items are standardization and simplicity. They are important particularly from the maintenance standpoint. A reasonable economy of operation as regards the fuel bill, crew wages, etc., may be entirely wiped out by excessive maintenance.

If all manufacturers had the same ideas or if they should standardize generally in their products, design could properly be left in the hands of such manufacturers, but with the rapid change in the art, coupled with the wide divergence of designs and products on the part of the manufacturers, the railroads are forced to take a hand in design. The ideal solution would seem to lie in cooperation between railroads and manufacturers by means of committees, where free interchange of ideas might take place to the end that rail motor cars could be produced with a reasonable degree of standardization of apparatus and arrangement.

Simplicity is likewise important, particularly where the personnel involved must be trained anew.

Another feature, related to standardization, that is far from helpful to the railroads is the sudden and radical change in design. No management desires to embark on a program of rail motor cars only to find them superseded by other designs before realization on the investment begins. Active cooperation on the part of both railroads and manufacturers should go far to prevent such occurrences.

In conclusion, the rail-motor-car equipment (motor cars and trailers) should be designed as a separate service, which by its very nature can be made attractive to the riding public. At the same time both manufacturers and railroads should cooperate fully on design, to the end that rail-car equipment will prove of greatest use and benefit to the railroad concerned.

In this manner branch-line traffic can be handled in an efficient, economical way and its comforts and attractiveness increased to main-line standards.

O. A. Garber.[5] The problem of rail-motor-car maintenance has been a factor to which every railroad that is operating motor cars has been forced to give serious consideration. Maintenance problems seem more difficult where only a few motor cars are being operated and where frequent changes are made in assignment of cars to operate on divisions where enginemen and mechanics have not become familiar with this type of equipment.

Records indicate that the best performances of motor cars are on divisions where the greatest number of cars are operated or where cars have been operating the greatest length of time.

Many so-called motor-car failures, after investigation, are found to be due to an inexperienced engineman having been called to operate the car or are traceable to an inexperienced mechanic attempting to service the car.

The successful operation of motor cars depends upon three factors—namely: competent and careful operators, proper service and maintenance at terminals, and a suitable repair department with competent and careful mechanics to make general repairs to both mechanical and electrical equipment.

[5] Chief Mechanical Officer, Missouri Pacific Lines, St. Louis, Mo.

A well-designed power plant for rail-motor-car use should endure 200,000 miles of service before renewal of bearings or general repair becomes necessary. The best performance is secured from motor cars that are assigned to trains making from 250 to 350 miles per day.

To maintain and service motor cars requires the skill of a good mechanic. At each terminal where motor cars lay over, a competent mechanic accustomed to close tolerance should be selected for the work.

A form indicating stated periods when service of the various kinds is to be performed, such as oiling, cleaning, adjusting, etc., of the various appliances, should be kept for each car, which will assist in securing regular service and provide a means for supervisors to check work performed. Enginemen or motor-car operators should be required to give a general inspection of all mechanical and electrical equipment at the end of the run, and they should indicate on a suitable work-report form any defects noted and also any unusual performance.

When renewal of broken or worn parts becomes necessary, they should be replaced in kind, so that service parts will always be interchangeable. Emergency makeshift repairs should always be corrected promptly.

In designing power-plant equipment for rail motor cars, manufacturers can assist in reducing maintenance costs materially by giving consideration to accessibility and simplicity as well as to stability.

In power plants of 200 hp. and above operating on gasoline or distillate the engine-cooling system presents a problem for careful study. Circulating a maximum quantity of water through the cooling system in a given time does not always accomplish the desired results. Slime and mud will frequently accumulate in the water passages of cylinder heads and cylinder water boxes or jackets and are difficult to remove unless a plug or a removable plate is provided at the bottom section of water passages for occasional flushing or washing out.

Various types of radiators have been developed, but much has yet to be accomplished in providing a radiator that will withstand the severe stress and strain encountered in rail-motor-car service.

The importance of the engine-cooling system can be more readily understood when considering the fact that the limited dissipation of heat through the cooling system has made it very difficult to develop and operate engines of greater than 450 to 500 hp. successfully with gasoline or distillate fuel.

Proper lubrication is also a vital factor, and it does seem that much would be gained if the circulating oil could be filtered and be maintained at lower temperatures through some method of cooling.

The development of rail motor cars is advancing very rapidly, and any attempt toward standardization at this stage of development may retard progress.

The writer feels that, with the cooperation between the railroads and the manufacturers, the rail motor car will soon be developed to a point of efficiency and in sizes suitable to handle almost any class of service.

W. J. Wilson.[6] These comments are offered by the Union Pacific as an addition to some details of the paper and not in disagreement thereto.

(1) While generally true that the rail car was not accepted as an important unit of transportation until recently, there are some exceptions, such as for example the Union Pacific System, upon which rail-car service was started in 1905 with the first McKeen-type car. Thirty-two of these cars are still in service, all of them over 15 years old and several over 20 years; the latter having

[6] Charge of Rail-Motor-Car Design, Union Pacific System, Omaha, Neb.

considerably more than a million miles of service to their credit. Twenty-three gas-electrics have been added in recent years, making a total of 55 cars in service, which number will be increased progressively.

(2) It is desirable from the manufacturer's viewpoint to adhere to a standard or predesigned car in so far as possible. Operating conditions, fixed policies or programs, and ideas based on experience vary to such an extent that some flexibility is necessary in any design. (Some changes usually are required when distillate is used.)

(3) The Union Pacific is in full accord with all efforts to eliminate unnecessary weight, having persistently advocated and practiced such a policy for years. In the semitubular structure of the McKeen car body great strength was attained with the use of a relatively small amount of material.

(4) In connection with depreciation, the Union Pacific makes no distinction between the car body and power apparatus. The experience with the McKeen car seems to justify this policy. (The Union Pacific depreciation rate is $4^1/_2$ per cent.)

(5) Relative to the use of distillate as fuel, the Union Pacific believes that it competes in practically all respects with gasoline, except in first cost of equipment, which is approximately $1200 more, and in ease of handling. These conclusions are based on 15 years' experience with this fuel, during which time a number of gasoline cars also have been used for limited periods. A certain skill, easily acquired, is necessary on the part of operators for best operation with distillate fuel. So far as we are able to determine no more servicing is required than with gasoline and repair bills are no higher. The distillate used by the Union Pacific has an end-point of about 620 deg. and is considered only a medium-grade fuel. Higher grades are available in large quantities in some districts. (The average price of distillate in 1928 was $4^3/_4$ cents. The average price of gasoline in 1928 was $9^1/_4$ cents. The gasoline tax of 3 and 4 cents applied to rail cars.)

(6) No systematic tests to develop comparative output of distillate and gasoline cars have been made, but actual service indicates a superior performance with distillate. The low resistance of the short gas path through the distillate carbureters makes the volumetric efficiency high, which offsets the effect of lower compression.

(7) Proper cooling of exhaust valves is vital, but less trouble is experienced with valves in distillate engines than in gasoline. The water used for detonation control reduces the temperature of the valves and checks carbon deposits. The distillate also provides top lubrication. Grinding valves is an infrequent operation.

(8) The combustion chamber design presented appears well suited to distillate fuel, and it is believed that a higher compression may be feasible. (The compression for distillate is now 65 to 70 lb.)

(9) Dowels and screws are ineffective for retaining bearing shells in engine beds or bearing boxes. The cap described by the author should hold them securely and prove satisfactory, provided there is no difficulty in the application of babbitt direct to the steel cap.

(10) For use in distillate engines it is advantageous to cool the lubricating oil as much as practicable to improve the operating viscosity. But little distillate dilution can be boiled off at the usual operating temperatures, this dilution being composed of heavy ends requiring high temperatures for evaporation. Crankcase ventilation is effective for removal of vapors which otherwise might condense.

(11) Electrically driven rotary fuel pumps, one for each kind of fuel, have proved very satisfactory on the Union Pacific. Fuel is delivered to the engine at a constant rate, that in excess of the requirements overflowing back to the tanks. No floats or float valves are used in the carbureters.

(12) The small auxiliary engine described would make an undesirable increase in the gasoline consumption of a distillate car. It would no doubt be feasible, however, to arrange for the use of distillate on this small unit.

Author's Closure

Referring first to Mr. Lemp's contribution, the author makes no claim for the discovery of the speed-control principle nor does he mean in any way to imply that the speed-control principle cannot be worked out satisfactorily by methods other than that used. He was not previously aware of the patents issued to Mr. Lemp, to which reference was made, but through the courtesy of Mr. Lemp has been supplied with copies of the patents cited, explaining his method of speed control. Other satisfactory methods have been developed by Mr. McNary of the General Electric Company and by the engineers of the Westinghouse Electric & Manufacturing Company, these being embodied in their so-called "engine torque control." Mr. Lemp's objections to speed control as originally proposed—i.e., the undesirability of relays, valves, contacts, etc.—are of course valid. Since the control described in the subject article avoids the use of such apparatus, however, and is a very simple and entirely straightforward mechanical device, involving no new principles and no added complications, it is felt that these objections have now been eliminated. Mr. Lemp dwells at some length upon the fact that by using a "broad tuning" governor the differentially controlled generator will more nearly approximate the engine-horsepower hyperbola than is indicated in the author's sketches. This is quite true. If, on the other hand, it is considered permissible to operate the engine at these higher speeds and if, then, the speed control is set for such higher speeds, the advantage of utilization is in favor of the speed control; or if, for example, the differential-control equipment and its governor are so set that the average speed is equivalent to the speed when using speed control, then again the advantage is in favor of the latter device. If, therefore, any predetermined speed is considered as the correct speed for the engine—no matter what that particular speed may be, whether high or low—improved performance will be obtained with the speed control. The author has found in calculating numerous applications that the gain is usually about 5 per cent.

Mr. Hatch's suggestion as to cooperation between the manufacturers and users of rail cars is, of course, quite right. The manufacturers are desirous of building the best equipment they can to meet general conditions, and inasmuch as there is a general trend in experience which can be embodied in new designs, it can and should be followed. Due to the tremendous development expense which the manufacturer must undertake for his own account, however, it is not desirable or expedient to make detail modifications of an established design to meet the wishes of a particular customer, if it can possibly be avoided—this for the reason that manufacturing such special parts in relatively small quantities as might be required by any particular purchaser and conducting the necessary tests in connection with such special developments will run the cost out of all comparison to a standardized product. Further, the manufacturer can, in some cases, by reason of experience gained on numerous properties, better judge as to what should be done than might be possible from the limited experience of any one operator. The manufacturer can of course draw on experience under all sorts of operating conditions and incorporate the results of such experience with his standard designs.

There is no question as to the undesirability of sudden changes in design, from the standpoint of users. On the other hand, the modern rail motor car as at present built is still comparatively new, and it would seem that for the best interests of all concerned

such changes as are necessary as a result of experience should be made from time to time.

Mr. Hatch also raises one other question, with which the manufacturers are heartily in accord. The rail motor car cannot realize its full potentialities until it is considered on its own merits and applied to its own best advantage, rather than merely being considered as a substitute for the steam locomotive. If the advantages peculiar to the rail motor car are given due consideration in its application, it should, as Mr. Hatch points out, make a very definite niche for itself. Some of the points which should be considered are (1) possibility of light trains with more frequent service, (2) lighter weight car design by reason of the lighter trains, (3) freedom from smoke, cinders, etc., (4) smooth acceleration, and (5) the reduced stand-by losses.

Mr. Garber has touched a very fundamental question in connection with the operation and maintenance of rail motor cars, and his experience coincides with that of other operators, particularly in the following points:

Cars operating moderately long mileage will give best results. Maintenance must be in the hands of a mechanic accustomed to work of the required character. If possible, a particular man should be responsible for the condition of any given car or lot of cars. A definite inspection, maintenance, and adjustment schedule should be established and rigidly adhered to. A competent supervisor should be appointed, having complete charge of all cars on a system.

The accumulation of impurities in the water-circulating system is particularly injurious if a heavy coating of scale is deposited on the cylinder liners and in the cylinder heads. It is necessary that adequate steps be taken to insure that such accumulations are removed before they become heavy enough to cause damage by reason of the lessened heat flow.

Regarding the cooling radiators, it is felt that the modern fan-cooled, roof-type radiator, as developed about four years ago, should give entirely satisfactory service.

In regard to the matter of oil filtration, the author has had entirely satisfactory results with oil filters built into the car, incorporating a series of felt washers under compression, through which the oil is filtered. These have been used as standard equipment for the past several years and should meet Mr. Garber's suggestion.

The author also has found it desirable to maintain the lubricating oil at approximately the same temperature as the cooling water. Running the oil too cool is very undesirable, as it permits higher dilution. On the other hand, the oil must be held at a temperature low enough to prevent oxidation. A temperature of 140 to 170 deg. fahr. has been found quite satisfactory.

It is noted that Mr. Wilson feels the oil temperature should be held somewhat lower, and it is of course possible that when using the heavier fuel conditions may vary.

The rotary fuel pumps to which Mr. Wilson makes reference have been found quite satisfactory on distillate, but it seems doubtful whether their life would be satisfactory when operating continuously on gasoline, due to the absence of lubricating qualities in the gasoline itself.

Symposium on the Maintenance of Rail Motor Cars

Gas Rail Cars on the New Haven Railroad

By E. O. WHITFIELD,[1] NEW HAVEN, CONN.

THIS paper outlines various rail-car problems, pertaining particularly to organization and maintenance, that have been dealt with on the New Haven railroad over a period of approximately eight years. As would naturally be expected, a vast amount of pioneer work has been necessary to bring rail-car internal-combustion and transmission equipment up to its present state of efficiency and reliability.

Brief History

The New Haven railroad today operates 36 rail cars, which vary in life from 2½ to 8 years. Their description is as follows:

No.	Type of car	Age, years	Transmission	Pass. cap.	Engine hp.
3	Mack (9000–02)	8	Mechanical	35	45 at 1200 r.p.m.
1	Wby. hydraulic (9003)	6	Hydraulic	65	160 at 1200 r.p.m.
10	Sykes (9004–13)	5	Mechanical	45	130 at 1600 r.p.m.
10	Brill No. 65 (9014–23)	4½	Mechanical	50	130 at 1600 r.p.m.
12	Brill gas-electric (9100–11)	2½ 3½	Electrical	90	250 at 1100 r.p.m.

Twenty-three of these cars are mechanical drive, one hydraulic transmission, and twelve gas-electric.

It may be noticed from the foregoing that progress in design and size of equipment was rapid, although cars 9004–23 and 9100–11 represent a group of 32 units of definite standards and characteristics.

Organization

Although the New Haven made its "debut" in the gas rail-car field as far back as 1922, it was not until 1925 that a separate maintenance organization was created to specialize on gas rail-car operation. The present automotive maintenance organization consists of a supervisor of rail car maintenance and inspection, reporting direct to the general mechanical superintendent and five specially qualified rail-car inspectors, reporting to the supervisor. The automotive division, as it is called, supervises the entire maintenance program at the outside terminals, also at the main repair shop at New Haven. It was found necessary to create a separate organization, especially in view of the scattered assignment of cars and the necessity for segregating upkeep and other work from steam, as this new work presented many differing problems entirely new to the railroad. The rail-car inspectors qualify operators, inspect cars, instruct and examine maintainers, assist in emergency repairs and trouble shooting, and also take care of general matters pertaining to rail-car maintenance. They must be on hand to assist at any time they may be called upon. An engineer of automotive equipment reports to the mechanical engineer and follows through all engineering revisions, cooperating with the supervisor of rail-car maintenance and inspection in the elimination of design failures. Specifications pertaining to new equipment come under the engineering department for preparation. With the construction of a separate organization, serviceability has improved.

Maintenance

(1) *Decentralization.* On the New Haven the rail-car assignments are scattered, terminals in many cases being at most inaccessible points, which immediately brought up difficult problems, especially regarding maintenance and inspection. The assignment of cars includes Poughkeepsie on the west, Chatham on the east, and Fitchburg and Pittsfield on the north, the territory being bounded by the shore line on the south and with many scattered assignments coming in between.

(2) *Divisional Separation.* In former days, inasmuch as the entire system was operated with steam, it was only necessary to carve up the operating territory into several divisions and assign master mechanics to each portion, who would in turn each have his group of terminals, foremen, and maintainers to take care of. When the rail cars were assigned to their different runs, it frequently occurred that several cars within a radius of a few miles would come under the jurisdiction of several master mechanics. This in turn meant a different group of maintainers for each car, with decentralized control and responsibility.

(3) *Grouped Maintenance.* We have settled on the following principles, which are working satisfactorily. At points where it is possible to bring a group of cars under fully qualified maintainers, it has been the practice to so handle them, even though, as stated, cars operate on two or three different divisions. The result is, therefore, that a group of cars comes under competent and trained mechanics and under one master mechanic, who is responsible for the entire group, such a group of cars being covered by a rail-car inspector at least weekly. At points where it is impossible to group cars it is sometimes found the best and most economical method to assign a mechanic to perhaps only one car. In order to demonstrate this feature, suppose we arrange to maintain an isolated car by intermittent attention from some central point. The time taken going to and from the car is the largest single item of labor, and there is actually little time left for maintenance, and it is found eventually that overtime has to be resorted to in such cases, with incident expenses. Therefore, it has been found desirable to locate a mechanic at points where, due to their inaccessibility, they cannot be reached promptly from a major repair terminal. Cars coming into large terminals present little difficulty from a maintenance standpoint and are assigned certain hours with a fully qualified maintainer.

(4) *Instruction and Education of Maintainers.* One of the chief duties of the rail-car inspectors is to instruct and educate maintainers and to train them to be sufficiently exacting to properly take care of equipment under their charge so that they may by daily check preclude possibility of failure due to defective conditions. Inspectors are therefore instructed to work entire shifts with maintainers, going through each item on the maintenance card. The inspector is called upon to fill out a form, indicating the efficiency of the maintainer in the various branches, such as trouble shooting, card reports, questionnaires, operation, intelligence, and average efficiency rating. In addition to this education, the maintainer is provided with instruction books and also questionnaires covering equipment under his care. In connection with maintenance on gas-electric cars, it is expected that the mechanic in charge will be capable of taking care of both the mechanical and electrical details satisfactorily without its being necessary to divide responsibility, and he is educated on this basis.

(5) *Maintainers' Records.* The maintainer is required to fill in a maintenance card which covers daily, weekly, semi-monthly, and monthly maintenance items for every unit on the cars he is called upon to maintain. This is sent into the master mechanic at the end of the month for signature and then to the supervisor. The inspector's card is filled out weekly covering every car under his jurisdiction, which is also forwarded to the supervisor at the end of the week. The inspector on his weekly visits writes up a report to the maintainer covering defects noted, which are checked again the following week. Fuel and lubrication cards

[1] Supervisor of Rail-Car Maintenance and Inspection, New York, New Haven & Hartford Railroad.

indicate gasoline used on various cars together with the amount of grease, oil, and transmission lubricant, specifying also the brand. These are signed by the master mechanics and sent to the supervisor at the end of each month. Cards also are kept on the condition of batteries, and it is expected that the maintainer will make a report on the gravity reading of each cell daily, sending such a card to the supervisor at the end of each month. The inspector also takes hydrometer readings in his weekly visits. The maintenance and fuel-lubrication cards are kept in a sheet-metal case hanging on the wall of the engine room in order that they may be referred to by the supervisor or inspector at any time, thereby telling at a glance whether maintenance work is being properly taken care of and as prescribed by the management.

Qualification of Operators

Each prospective operator must be instructed by a rail-car inspector and is issued a qualification card, signed by the master mechanic and inspector in charge. Engineers are also instructed in minor trouble shooting. Requirements under this heading are strict, and under no condition is an operator provided with a certificate until he is fully familiar with his duties.

Facilities

The matter of providing adequate facilities broached a difficult program in view of the fact that assignments were frequently changed, but it is sufficient to state that concrete floors are desirable, together with proper greasing and oiling facilities, with material supplies, and correct assortment of tools and wrenches to suit the equipment. Such items as proper capacity-delivery gas pumps and strainers reduce troubles due to the fuel system. Proper provision for the keeping and the segregation of lubricants should be made in order that they may be kept clean and free from grit and foreign matter. The correct brand of lubricant should also be specified. The foregoing touches on facilities at the outside points, but does not cover major shops such as New Haven.

Main Shop

The railroad carries out its major repairs at the New Haven shop. This shop is equipped to take care of both large and small cars and has the proper tools for fitting main and rod bearings accurately, together with engine dynamometer, water rheostat, electrical-instrument and auxiliary testing apparatus, special fuel-system testing benches, etc. All work that passes through the New Haven shop must be passed on by a competent resident inspector, who fills out a report form on every car released from the shop.

Cars are scheduled through the shop to conform with the units available for application to the car such as engines, trucks, air compressors, and transmissions. Although engines are tested on dynamometer before being placed in the car, the completed unit is taken out finally on a standard test run, which includes severe grades and curvature, sufficient to give the car a thorough trial. Each of these test runs is in charge of the resident inspector, who takes note of defects and reports them to the superintendent for attention. On completion of the repairs the work is again inspected. Numerous tools have been developed to take care of this highly specialized work, but when the work of general overhaul on the large sizes of engines was commenced (250 hp.) there was nothing on the market to meet requirements, and it was necessary for our tool designers and shop forces to build up suitable boring bars, special reamers, and fixtures to carry out this work, in addition to special testing apparatus for testing vacuum tanks, oil pumps, vacuum pumps, tachometers, carburetors, etc.

Unit Replacement Program

As far as is possible with the regular scheduling of cars, units are brought into the shop to conform with the unit replacement program. For instance, if it is desired to bring in a mechanical car from the outside, we make sure that complete assemblies, such as engine, transmission, and trucks, are ready, so that when the car arrives at the shop it is stripped of its equipment and the new replacement items are installed. We have acquired spare engines for our gas-electrics, also spare trucks, generators, and motors, and as a consequence have been able to reduce the shipping period of these cars one-half. When one considers that whenever a gas-electric car is taken out of service, generally speaking, it is replaced by steam, it can readily be seen that it is poor economy to keep a car in the shops. Therefore, a little capital spent on spare units is very quickly repaid.

It is important to remember that whenever new facilities are considered, ample room should be available with overhead cranes, well-constructed pits and floors of concrete, together with best possible lighting and heating facilities. As far as the tool and testing apparatus goes, it should be the best procurable in order to provide for the extreme accuracy which is required in automotive work, especially on large power where continuity of service is paramount.

Statistics, Records, Charts

When an attempt was made to build up the first rail-car organization, it was found that records covering the service of cars were meager and practically useless. In order, therefore, to handle the matter in a logical way and give foundation to a proper organization, it was necessary to have complete statistics available so that trend and direction might be noted and pressure brought to bear on weak points. Charts and statistics cover shopping periods, car miles per failure, per cent of serviceable days, failures per month, car-shop days, maintenance costs, labor and material, such information being divided between lines east and west. If weak spots are to be found, it is necessary that full and complete charts be ready for quick reference in order that concentration may be brought to bear upon any particular item of design, maintenance, or inspection needing attention.

To Organize Is to Economize

With the proper rail-car organization and trained maintenance forces available, there will be ample opportunity to expect economies over steam service on a large number of assignments, to say nothing of the possibilities of supplementing and effectively handling main-line service.

At the time this paper was completed the serviceability for the month on all cars was over 90 per cent, and lines west forces, operating 14 rail cars (5 gas-electric and 9 mechanical), operated three consecutive months without a single road delay of five minutes or over. An improvement of 36 per cent was noted for the first half of 1929 over 1928 in reduction of road delays, and 23 mechanical gear-shift cars operated the entire month 31,349 miles without a delay. If this may be considered good performance, it is the result of a carefully built-up program of maintenance and inspection with a separate organization in charge.

The following views illustrate the method of operation:

Fig. 1 shows the New Haven rail-car organization, supervisor reporting to the general mechanical superintendent, and five specially qualified rail car inspectors reporting to the supervisor. Engineer of automotive equipment reports to the mechanical engineer and cooperates directly with the maintenance and inspection forces toward the betterment of operation in matters pertaining to design.

Fig. 2 shows the location of rail cars on the New Haven

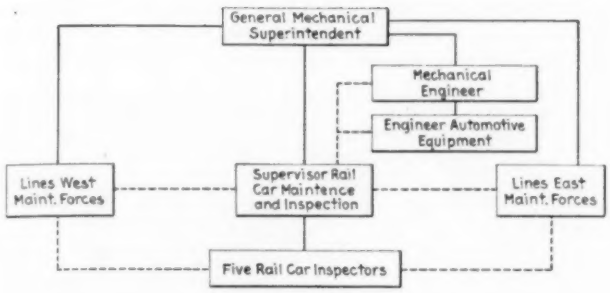

FIG. 1

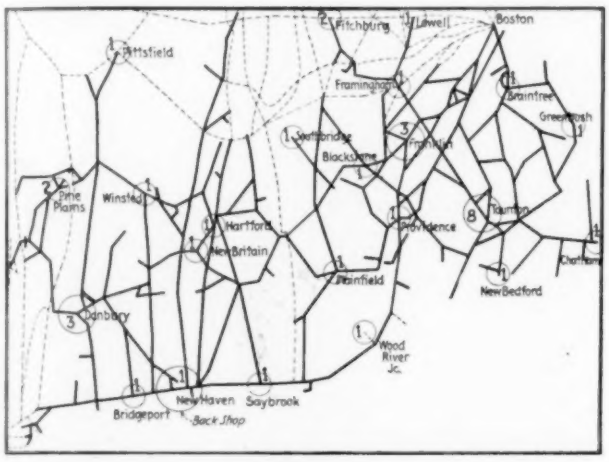

FIG. 2

system. There are 36 of these units, 23 with mechanical drive, 10 gas-electric, and 1 with hydraulic transmission. The cars are scattered over the operating territory, making maintenance difficult.

Fig. 3 shows the failures per car per month for the last five years and indicates the trend due to concentration on organization and maintenance items which have made for greater efficiency. It also shows the number of car-shop days per car per month, also indicating a downward trend toward greater efficiency and serviceability.

Fig. 4 shows the distribution of failures divided between drive, engine, auxiliary, and gas system. This chart was primarily made up to distribute failures between engine, drive, and gas system, as there was considerable difficulty with fuel systems. Fuel system failures for the past months have been zero, largely due to the installation of a fuel system of fuel supply.

Fig. 5 shows a Brill mechanical car having drive truck removed. The body is being raised by a Whiting electric hoist.

Fig. 6 shows the cleaning tank. After the engines are dismantled they are washed in a tank which uses an Oakite solution prepared for use with aluminum. The unit being removed from the tank is a crankcase from a 250-hp. engine. The steam nozzle at side of tank is used in the final operation after the parts are cleansed in the tank. This tank has a depth of 2 ft. below the surface of the concrete.

Fig. 7 shows the connecting rod from a 250-hp. engine having faces squared by means of fly cutter. The arbor exactly fits the bearing. This machine is also used for boring out rod bearings.

Rail Cars on the Union Pacific System

By W. J. WILSON,[1] OMAHA, NEB.

ORDINARY running repairs and servicing operations to Union Pacific rail cars are performed at layover terminals, where also occasional heavy emergency repairs are made to some parts of the car.

Cars are overhauled regularly on a predetermined mileage schedule of approximately 110,000 for the McKeen-type mechanical-drive cars and 120,000 miles for the gas-electric type. This work is done at the principal shops of each railroad of the system, where are maintained a personnel and an equipment for that specialized work. The overhauls are thorough, both for the power plant and the car body. Cars are maintained to as nearly as possible as new condition, and since improvements are added frequently, cars a few years old operate more perfectly than when new.

An example of this servicing policy is seen in the McKeen cars, of which there are still 32 in operation in the Union Pacific System, all old cars, some them over 20 years. Due to the elimination of all weak points, their cars are more economical and reliable than when first constructed.

Improvements to cars and servicing equipment are developed by those interested, usually through collaboration of the automotive section of the engineering department, the motor car supervisor and shop groups.

Some individual details of rail cars in which troubles have been met and overcome and special phases in connection with maintenance will be described.

Crankshafts and Bearings

Little trouble is experienced with crankshafts, but some is had with main and rod bearings.

These in the McKeen-type engines are of solid bronze and occasionally overheat. The construction of these engines permits application of a water stream which keeps them sufficiently cool to reach a terminal where proper attention may be given.

Difficulties with gas-electrics are varied, but are usually the result of some lubrication defect. It is noticed that this occurs with an engine having relatively small bearings, and that another with liberal bearings and counterbalanced shaft is trouble-free.

Dowels and screws do not hold bearing shells tight into the boxes, and improvement results by providing heavy shims, extending around the bolts and nearly into contact with the shaft. When caps are in place, these hold the bearings securely. Caps should be doweled or dovetailed to keep the alignment perfect. Crankshafts are refinished when worn appreciably out of round, those of the McKeen engines being turned with a special crankshaft tool and those of the gas-electric engines being reground. Hand fitting of bearings is unsatisfactory, as it is practically impossible to get both a perfect fit and alignment. This practice has been discontinued.

Main bearings are now fitted with a special reamer bar having both cutting and burnishing blades, except in the case of the McKeen bronze bearings, for which a special line-boring machine is being constructed.

Rod bearings are fitted with a combined aligning, reaming, and burnishing fixture.

Cylinder Heads

Valves and sets give little trouble, regrinding is infrequent, and but little carbon is deposited in the distillate-burning engines, this being attributed to the use of water for control of detonation.

The only trouble encountered consists of cracking between valves, which trouble is corrected by providing unrestricted water circulation through all parts of the head, particularly between the valves, and by the elimination of steam pockets and unwatered areas. Replacement heads designed to the railroad company's specifications are now being made for such engines as require them. Replacement seats and equipment for application are available at low cost, but have not as yet been required.

Pistons and Cylinder Sleeves

Aluminum-alloy pistons are generally superior to cast iron, both in service rendered and effect on other parts of the engine. A 10-in. diameter split-skirt type applied to the McKeen engine, while costing more than cast iron, reduces the effective load on the main bearings and assists in control of detonation by a reduction of the hot area at the center of the piston head.

A plain type alloy piston with a solid skirt and but little ribbing is used in the gas-electric engines. These are purchased at a price lower than patented split-skirt types, and the service obtained is satisfactory. The first set applied more than a year ago is still in service, so no definite mileage is as yet established.

New pistons are usually purchased about 0.060 in. oversize to permit of successive refitting to smaller sizes. Reground or new sleeves are provided to fit. This reversal of the usual automotive practice is economical because of the greater value of pistons as compared to sleeves. New sleeves are manufactured in the railroad company's shops.

Floating wristpins are used in one type of gas-electric engine and in the aluminum pistons of the McKeen engines. The latter have no wristpin retainers, but have an alloy thrust block in the end of the pin, which prevents scoring of the cylinder walls.

Pistons are fitted with a clearance of 0.0015 in. per inch of diameter at the skirt, with an increased amount at the ring lands and top.

Ordinary cast-iron rings have given poor service on distillate engines. Narrow steel rings, two $^5/_{32}$ in. wide in one $^5/_{16}$-in. groove and "Double seal" type rings have proved satisfactory. Both types give a tight seal and have a wide bearing on the ring lands.

Ordinarily rings are fitted with 0.015 to 0.018-in. gap, a similar clearance back of ring, and 0.002 to 0.003-in. groove clearance.

Little trouble has been experienced with the rubber seal rings of the cylinder sleeves or with electrolytic action pitting the outer surfaces of the sleeves.

Lubricating Systems

Some lubricating pumps have a short service life. Rapid wear of small bearings develops excessive internal clearance and results in loss of pressure. A redesign of the pump is the only solution apparent.

Relief valves and seats are subject to rapid wear, and in some instances external reliefs have been applied in the pipe lines.

Oil-distribution manifolds cast into bedplates have accounted

[1] Charge of Rail Motor Car Design, Union Pacific System.

for some car failures. These are removed as engines are shopped, and an external manifold is applied.

Felt cartridge-type oil filters are of value even with the frequently changed clean oil of distillate engines. These are being applied to engines not originally so equipped.

Ignition Apparatus

Since no ignition apparatus wholly satisfactory for rail-car use seems to be available, it follows that considerable attention must be given to keep this apparatus working properly and the duplicate units synchronized.

Magnetos and distributors are serviced frequently, and wiring is replaced to prevent electrical loss through oil-soaked insulation. Insulation coverings which resist oil penetration are preferred. Mallory coils are used on battery ignition systems in place of those originally supplied.

Exhaust Pipes

Earlier designs of exhaust pipes for gas-electric cars consisted of built-up cast- and wrought-steel manifolds, pipes, and mufflers. These were quickly destroyed by the hot exhaust gases and required frequent renewal.

Pipes now used are a special Union Pacific design entirely of cast iron, are of large diameter, and are thin walled. Three pipes are used on a six-cylinder engine, each surmounted by a cast-iron exhaust head to subdue the sharp report of the exhaust. These pipes are of relative light weight and long life, create but little back pressure, and are reasonably quiet.

Pipes on the McKeen cars consists of two light sheet-metal tubes projecting through the roof of car and are connected one to each three cylinders with a cast manifold. No mufflers are used.

Carburetors and Fuel Systems

Maintenance of the distillate carburetors in service consists principally of keeping fuel-line connections tight.

At shopping periods the carburetors are serviced by the manufacturer of the equipment, and all parts are restored to the condition of new.

Little trouble is experienced with stopping up of the small multiple fuel jets, as large strainers and water separators are used on the fuel lines.

Pressure-fuel feed from tanks function satisfactorily, but presents a hazard in case of fire in the engine room.

Such vacuum systems as were tried proved unreliable and were discarded. Where electric energy is available, the most satisfactory system is electrically driven pumps, one being provided for each fuel used. These consist of rotary pumps of the "Viking" type, direct-connected to $^1/_8$-hp. motors. Fuel is delivered at a fixed rate to the chambers on the carburetors, and the excess over engine requirements overflows back to the tanks. All floats and valves are eliminated, and no fuel is stored in the engine room.

Cooling Systems

Radiators of the cellular and flat-tube type become clogged with lime and loose scale where water conditions are bad. For this reason radiators using large diameter tubes are favored. However, cooling systems are now washed out periodically with cleaning compound, which has overcome these difficulties. Where aluminum is used in the cooling circuit, chemicals which attack that metal must be avoided.

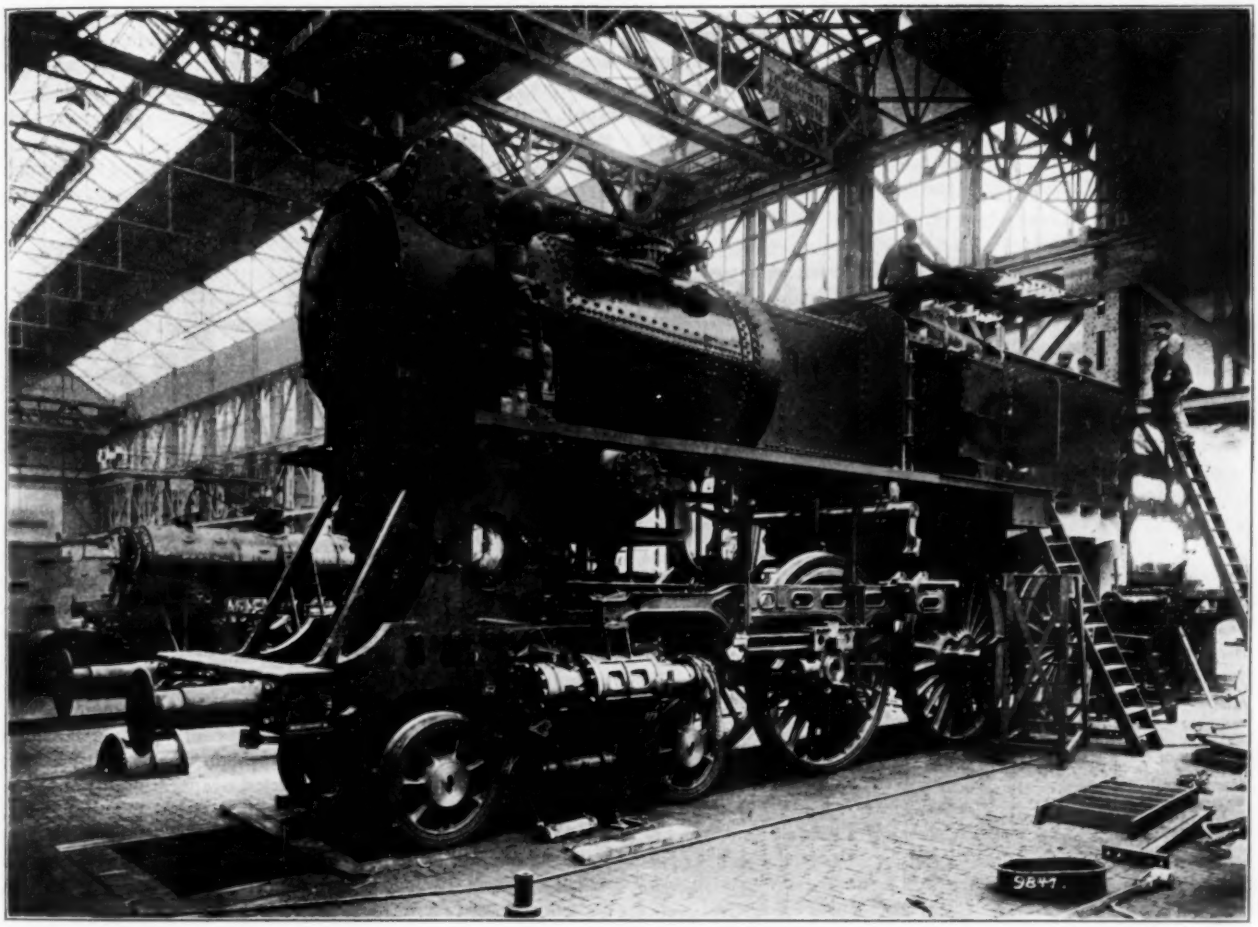
Roof radiators are favored, since freezing is eliminated, because they contain no water during idle periods.

Connecting radiator units in multiple rather than in series is favored on account of freer circulation and resultant increase of water flow from the pump.

Motor-Armature and Suspension Bearings

Occasional replacement of motor-armature and suspension bearings is necessary.

Satisfactory results are realized in the case of armature bearings only when the new bearings are assembled to the motor frame and line-bored or reamed.



Journal bearings of motor trucks give but little trouble. Both A.R.A. and A.E.R.A. types are used.

Wheels

In some districts where many sharp curves are traversed, the flanges of the leading wheels wear rapidly.

Flange oilers reduce this wear, and wheel-truing brake shoes reduce the frequency of shopping for wheel turning. These shoes have carborundum inserts, and an occasional application keeps the wheels close to correct contour. Rolled steel wheels are used.

It is desired that a recital of these troubles does not leave the impression that rail-car operation is attended with unusual difficulties, for, to the contrary, the Union Pacific has found them to be an economical and attractive means of transportation.

THE SCHWARTZKOPFF-LOEFFLER LOCOMOTIVE IN PROCESS OF CONSTRUCTION

High-Pressure Locomotive Developments

BY A. E. STUEBING,[1] NEW YORK, N. Y.

This paper discusses two types of high-pressure locomotives recently built, the Loeffler type and the Winterthur locomotive. The former is an express locomotive of about 2500 hp. with a pressure of 1470 lb. per sq. in. and the latter of about 1200 hp. with a boiler pressure of 850 lb. per sq. in. The Loeffler locomotive is expected to result in a fuel saving of from 40 to 45 per cent compared with modern superheated locomotives. In a road test of the Winterthur locomotive, but 330 lb. of coal was necessary for firing up as compared with double the amount necessary for a conventional locomotive of equivalent output.

PROBABLY the most important development in high-pressure locomotives during the past year has been the more extensive application of the Schmidt double-pressure type. A locomotive of this type has been built in England for the London Midland and Scottish Railroad, and another in France for the Paris–Lyons Mediterranean System. Designs are being prepared for a 4–8–4 type to be tried on the New York Central and a 2–10–4 type for the Canadian Pacific.

The Delaware and Hudson Railroad, as the result of several years' experience with the locomotives Horatio Allen and John B. Jervis, operating at pressures of 350 lb. and 400 lb. per sq. in., has decided to go still farther, and has ordered a locomotive to operate at 500 lb. pressure. The design of the boiler is similar to that of the two earlier locomotives worked out by John E. Muhlfeld, and the engine will adhere to the cross-compound cylinder arrangement.

Many new arrangements are being proposed, some apparently having meritorious features, and others seemingly quite impractical. So much space would be required to describe all that have been proposed that it seems advisable to limit this paper to a discussion of two locomotives recently built, namely, the Loeffler type built by the Berliner Maschinenbau Actien Gesellschaft, sometimes referred to as the Schwartzkopff-Loeffler locomotive, and the locomotive constructed by the Swiss Locomotive and Machine Works of Winterthur.

---

Contributed by the Railroad Division and presented at the Annual Meeting, New York, N. Y., Dec. 2 to 6, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The Loeffler High-Pressure Locomotive

The Berliner Maschinenbau Actien Gesellschaft has been licensed to build locomotives according to the new and unusual design using high pressure patented by Professor Loeffler, and has received from the German State Railways an order to design and build an express locomotive of about 2500 hp. with a pressure of 1470 lb. per sq. in. In close cooperation with the German State Railways, the design of the locomotive shown in the illustrations was worked out. The manufacture of this locomotive is in progress, and it is expected that it will be ready for test soon.

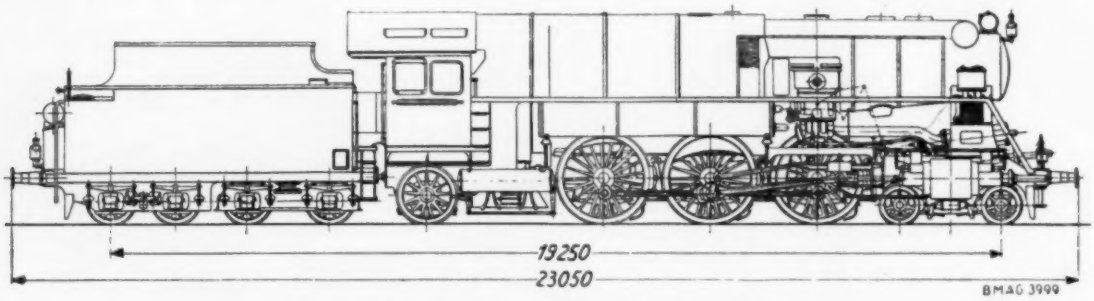

Fig. 1 Side Elevation of Loeffler Locomotive
(The total wheel base is 63 ft. 2 in. and the overall length 75 ft. 7 1/2 in.)

TABLE 1 PRINCIPAL DATA ON THE SCHWARTZKOPFF-LOEFFLER LOCOMOTIVE

Weight in working order, without tender	253,000 lb.
Adhesive weight	132,000 lb.
Diameter of drivers	79 in.
Diameter of leading wheels	33 1/2 in.
Diameter of trailing wheels	49 in.
Steam pressure in high-pressure system	1700 lb. per sq. in.
Steam pressure in low-pressure system	200 lb. per sq. in.
Diameter of high-pressure cylinders	8 5/8 in.
Diameter of low-pressure cylinder	23 5/8 in.
Stroke	26 in.
Maximum speed	75 m.p.h.
Weight of tender in working order	165,000 lb.
Water capacity	8500 gal.
Coal capacity	11 tons
Length of locomotive and tender	75 ft. 7 1/2 in.

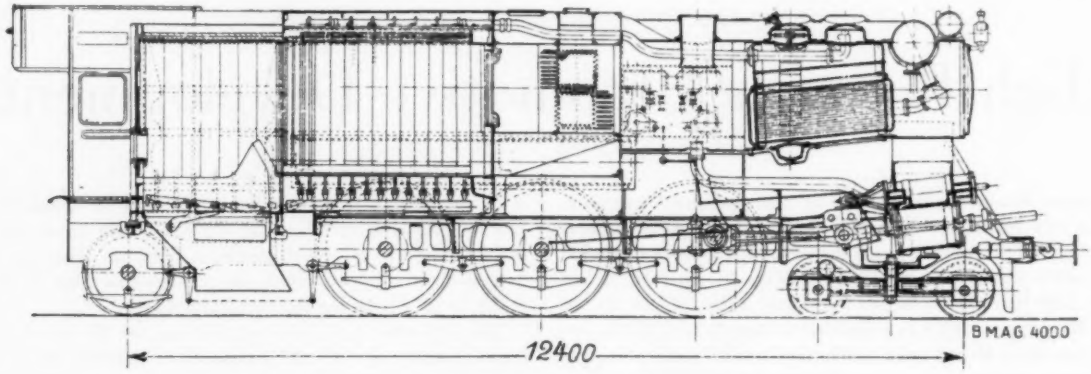

Fig. 2 Section of the Loeffler High-Pressure Locomotive
(The total wheel base is 40 ft. 8 1/4 in.)

According to the Loeffler system the steam is generated in an evaporating drum which is not exposed to the heating gases. Highly superheated steam of the same pressure, i.e., 1470 to 1760 lb. per sq. in., is introduced in a finely divided form into the water in the drum. The steam is taken in a saturated condition out of the steam space of the evaporating drum by means of a circulating pump, and is carried back into the water space of the same drum through a directly heated superheater. A portion of the highly superheated steam is taken off at a point beyond the superheater to do the work in the two high-pressure cylinders of the locomotive. This working steam is only a fractional part of the total steam which is handled by the pump, the steam to be circulated amounting to about 3.5 times the working steam. On account of the small specific volume of steam at this high pressure, the work of pumping the volume of steam necessary is relatively small, and amounts to only about 1 or 2 per cent of the work that can be obtained from the steam generated.

The walls of the firebox are made up of a portion of the tubular elements used for superheating the high-pressure steam, while the remainder of the superheater for the high-pressure steam is located at the front of the firebox. In this closed-tube system there exists a closed pure-water circulation, since the steam in the high-pressure cylinders which is reduced to about 256 lb. per sq. in. is carried into a heat exchanger after having its oil removed, and is there condensed, the condensate being led through a high-pressure preheater connected to the high-pressure superheater, and then back to the indirectly heated evaporating drum. The heat exchanger is used for the generation of low-pressure steam, and furnishes steam at about 214 lb. per sq. in. pressure.

The characteristic subdivision into a closed pure-water circuit with forced circulation, and the special low-pressure boiler was chosen in order to avoid impeding the heat exchange of the high-pressure portion even under the most unfavorable water conditions. High-pressure steam-generating systems, as a rule, are forced to use distilled water. In the Loeffler systems a normally pure feedwater will answer, since a concentration of the scale-forming material, and a deposition of scale is possible only in the unheated evaporating drum where the formation of scale can have no deleterious effect. The water is pumped at high velocity through the high-pressure preheater without any evaporation occurring. Therefore, it has been possible to make the subdivision into separate high-pressure and low-pressure circulating systems without any material loss in efficiency.

The low-pressure steam at about 214 lb. per sq. in., containing approximately 40 per cent of the total work energy, is superheated in a superheater which is also adjacent to the high-pressure superheater. It is allowed to expand in a center cylinder to about atmospheric pressure, and is then used to create draft by means of an exhaust nozzle. The ordinary draft arrangement is thus retained in spite of the closed high-pressure boiler circuit. The lower pressure boiler can be omitted in the Loeffler system because the circulation pumps have a certain reserve by which the boiler performance can be regulated within wide limits.

On account of the shortness of the boiler passages, the heating gases leave the high-pressure boiler while their temperature is still rather high, and therefore, the addition of a preheater for the combustion air seemed advisable. This air preheater is arranged between the smokebox and the superheater for the low-pressure stage.

The heat exchanger, which is not heated by the combustion gases, is arranged in front of the smoke chamber. In front of it in turn is the oil separator for the steam coming from the high-pressure cylinder, and also a preheater for the low-pressure water, from which the low-pressure feedwater passes to the plates in the clarifying dome, where scale-forming material is deposited.

The smokebox and heat exchanger are cylindrical members, and are secured in one piece with the high-pressure boiler so that the continuous form of the modern locomotive boiler necessary for bracing the frames vertically is obtained.

The arrangement of boiler, machinery, and accessories is shown in Fig. 2. The method of operation is as follows: A cylindrical drum partly filled with water constitutes the high-pressure steam generator. In firing up the locomotive, steam generated in some other boiler is used and carried to the pipe which opens into the lower portion of the drum, and is continued inside the drum by another pipe, the latter being perforated, thus giving free exit to the steam into the water, and causing an intimate mixing.

Steam gives up its heat to the water and generates thoroughly saturated steam in the drum, which leaves the steam space of the drum, and is taken off by two pumps which force this steam to the firebox. The firebox is composed of several gratings of steel tubes, and is extended forward by a tube system. The saturated steam reaching the firebox is forced through the tube members. The floor of the firebox is formed by a grate, below which is the ash-pan. Firing may be either by coal, oil, or pulverized coal.

The heat generated by the fire is given up to the steam flowing through the closed circuit of the tubes so that this steam becomes superheated. The steam thus superheated is forced by the rotary pumps to the check valve, and a smaller portion of it through the high-pressure regulator to the two high-pressure cylinders lying outside of the frames. The greater part of the superheated steam, however, is led through a return valve back to the drum. Here it gives up to the water the heat absorbed by it in the firebox and superheater, and again generates saturated steam, the same performance being repeated with continuous pressure and temperature increase.

As soon as steam of the pressure required for operation of the rotary pumps has been generated, the supply of external steam is shut off and the fire on the grates is started. The pressure in this circulating system is kept up to 1470 to 1760 lb. per sq. in., so that the same initial pressure is present in the high-pressure cylinders. The steam temperature after leaving the high-pressure superheaters is about 860 deg. fahr.

After the steam has performed its work in the high-pressure cylinders it leaves these cylinders at a pressure of about 265 lb. per sq. in., and flows through the check valve to the oil separator, whence it flows through the preheater for the low-pressure feedwater to the heat exchanger. This consists of a tubular drum with a steam dome and a feed dome, and a bundle of light gage pipes, which are rolled into the tube sheets. This tube bundle is closed off at the front by a cover which has a connection for the pipe leading from the low-pressure feedwater heater, and at the rear by a cover which has a connection for the condensate.

The exhaust steam from the high-pressure cylinders flows through tubes giving up its heat to the boiler water surrounding it in the heat exchanger, and this generates saturated steam in the boiler. At the same time the high-pressure exhaust steam is condensed, the condensate flowing to the condensate drum.

The low-pressure steam of about 214 lb. per sq. in. generated in the heat exchanger, flows into the low-pressure superheater which is also surrounded by heating gases and is there superheated to about 660 deg. fahr. It then flows through the pressure regulator to the low-pressure cylinder which is arranged inside the frame. After having done its work in this cylinder, the steam flows through the exhaust nozzle into the smokebox and to the stack.

The distribution of the work in the three cylinders of the locomotive is so chosen that the two outside cylinders each do about 30 per cent, and the inner cylinder about 40 per cent of the total for the locomotive.

The two rotary pumps whose first function is to pump the saturated steam out of the drum through the firebox and the high-pressure superheater, are three-crank steam pumps, and their dimensions are such that each of them can do 75 per cent of the maximum work. There is, therefore, a reserve of 100 per cent for average performance. The pumps are operated by steam generated in the heat exchanger and superheated in the low-pressure superheater.

The fire can be started in the firebox only when the pipe system is already filled with steam that is being pumped through them, and in order to shorten the time required to fire up, provision is made to operate the circulating pumps with steam generated at an external point. If there is no external steam supply available, a small auxiliary heating plant for the heat exchanger may be provided by means of which steam may be generated first in this drum to operate the circulating pumps, and to take care of the steam generation in the high-pressure drum.

With the circulating pump there is connected a feedwater pump for the high-pressure drum. This pump sucks the condensate of the exhaust steam out of a container into the pump cylinder, and forces it into the preheater for the high-pressure feedwater which also lies in the current of heating gases. From here it is forced to the high-pressure drum.

Inasmuch as the pumps for the high-pressure feedwater and the circulating pumps run at the same rate, an independent means of regulating the amount of feedwater is provided by a bypass. It may be necessary while the circulating pumps are operating temporarily, to prevent carrying feedwater into the high-pressure drum and a bypass is, therefore, provided for the condensate by means of a valve, so that the condensate which has been sucked in may be pumped back into the heat exchanger during which process it again gives up the heat absorbed in the preheater to generate steam in the heat exchanger.

On account of leaks in stuffing boxes, pipe connections, etc., there will be some loss of steam in the closed circuit of the high-pressure portion, and these leaks are made up by boiler water from the heat exchanger. This make-up water is carried by means of a pump (which is also connected to the circulating pumps) to the condensate drum, and from there to the high-pressure drum. This make-up water supply is automatically regulated when the water is in the high-pressure drum by means of a float in the condensate drum.

To feed the heat exchanger there is provided an injector which forces water from the tender into a feed drum which is equipped

with a purifier, and as a second means of feeding there is provided a feedwater pump which forces water from the tender to the preheater which is heated by the high-pressure exhaust, and then it goes into the feedwater drum. A pipe is provided for carrying high-pressure steam into the heat exchanger, if there should be temporarily too small a steam generation in the heat exchanger.

For safety devices the ordinary safety valves are provided for both the high-pressure and low-pressure systems, and further if in the most extreme case both circulating pumps should fail the fire on the grate can be put out. For this purpose a blow-off valve is placed in a pipe which is operated when the temperature gets too high, and from which a steam line is carried to the firebox.

In order to obtain the greatest possible thermodynamic economy a preheater for the combustion air is located in the current of hot gases. This preheater is arranged on both sides of the locomotive, and the air is carried through a pipe system which is heated by the gases with counter flow. From it, the air which has been heated to 300 deg. fahr. is carried to the ashpan under the grate by two channels arranged under the running boards.

The sub-division of the high-pressure and low-pressure circuits of the feedwater furnishes an effective possibility for a wide margin of power to care for overloads both on account of the water contained in the high-pressure evaporator, and on account of the relatively large water content of the heat exchanger.

The safety of the new locomotive can confidently be said to be at least as great, if not greater, than that of the present locomotives since the evaporation occurs only in evaporators which are not exposed to hot gases, whose walls are heated on both sides, and which are formed without pipe connections.

The operation of the superheater by means of the forced circulation of the high-pressure steam with its high heat absorption is essentially safer than that of the present superheaters in low-pressure locomotives. Corrosion and burning of the superheater pipes are thoroughly prevented, the temperature of the wall being only 70 to 85 deg. fahr. higher than the temperature of the steam.

In the new locomotive the parts of the locomotive boiler of the usual type which require special repairs have been avoided. These include staybolts, expanded tubes which are exposed directly to the fire, riveted joints, etc. The separate steam circuit and the fact that the operating steam is taken out of the superheater circuit prevents water from being carried over, and always gives dry steam for the engine so that damage to the cylinders by water is prevented.

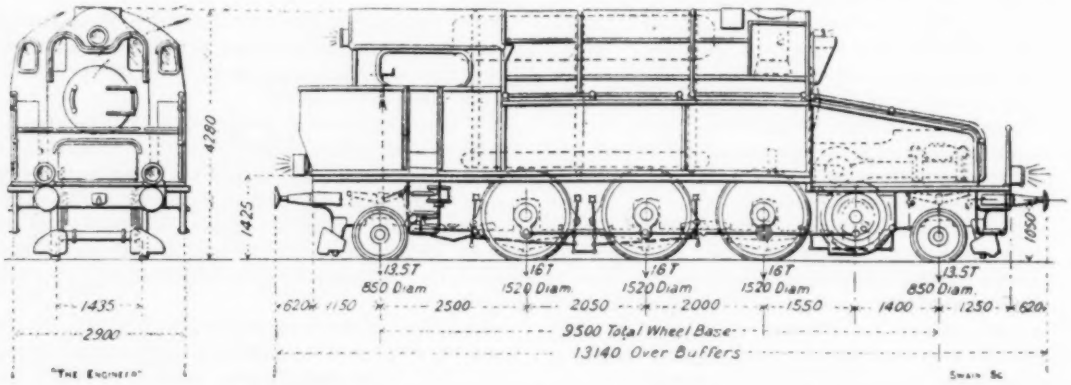

FIG. 3 GENERAL ARRANGEMENT OF WINTERTHUR HIGH-PRESSURE LOCOMOTIVE
(The total wheel base is 31 ft. 2 in., the length over buffers 43 ft. 1¼ in., the height 14 ft. ½ in., and the width 9 ft. 6¼ in.)

ADVANTAGES OF THE LOEFFLER HIGH-PRESSURE LOCOMOTIVE

Theoretically, the locomotive described should furnish a fuel economy of 47 per cent compared with modern superheated locomotives, and actual savings of 40 per cent to 45 per cent can therefore be confidently expected, which means an improvement in the total thermal economy of 80 per cent to 90 per cent.

With regard to the demand for greatest reliability and simplest maintenance which is desired in combination with the increase in economy of the locomotive, the following claims are made: The firing of the locomotive is made very much easier on account of the materially smaller grate for equal power. The materially smaller coal consumption makes it possible to increase the capacity of the locomotive. The water demand is also approximately only one-half that of the present locomotives so that with a tender of about the same size, the locomotive may run twice as long without taking water. The method of regulating the work according to the speed remains as in the present locomotives, namely by means of the valve gear.

By subdividing the boiler into a pure-water high-pressure portion, and a raw-water low-pressure portion, great safety is obtained for the high-pressure portion. The preheater for the high-pressure portion, which also is under high pressure, remains entirely clean even during long periods of service. Scale formation in the high-pressure portion of the locomotive, together with its injurious consequences, is entirely eliminated. On the other hand, a very complete absorption of the heat from the combustion gases is assured through the use of the high-pressure preheater.

In normal operation the steam is carried to the engine at a pressure of about 1470 lb. per sq. in. When the locomotive is standing still the pressure in the boiler can be raised to about 1760 lb. per sq. in. before the safety valves blow off. Due to this and to the small radiation to the superheater pipes, practically all the stand-by steam losses of the locomotive through steam blowing off, are avoided. A high-pressure locomotive of this type can be designed so that it will give the same output as the present low-pressure locomotives with about the same weights and the same dimensions. The coal and water saving can, therefore, be fully realized.

THE WINTERTHUR HIGH-PRESSURE LOCOMOTIVE

Early in 1926 the Swiss Locomotive and Machine Works decided to build a high-pressure locomotive which would work at a maximum boiler pressure of 850 lb. per sq. in., with an average working pressure of about 700 lb., thereby giving a certain working range between the average boiler pressure and the blowing-off pressure. Such a range allowed for a short period of overload, and compensated for the limited water capacity of the boiler, which in the final design was only about half that of the conventional locomotive boiler. From the first, condensing was ruled out on account of the complications it would necessarily have

introduced. Again, a high-speed uniflow engine with reduction gear was decided upon. With a geared locomotive it was possible to construct a standard engine, and to use different gears to meet the varied requirements of express, passenger, or freight service. Again, with a geared locomotive the irregularity of drive, which in the ordinary steam locomotive may be on occasion as high as 25 per cent at the driving wheels is reduced by gearing to 8 or 10 per cent. By this means it is claimed that the adhesive weight of the locomotive is utilized more effectively, so that either the tractive effort may be increased for equal axle pressure, or the number of driving wheels reduced with a corresponding decrease both in weight and first cost. It may also be pointed out that with a spring-borne engine the hammer blows due to the counterbalance are largely eliminated.

For reasons both of simplicity and reliability, a single-expansion engine working on the uniflow principle with poppet admission valves was decided upon. The boiler and engine were constructed first, and these were tested thoroughly for a year on the stationary test bed at the Swiss Locomotive Works. The results obtained were so favorable that the locomotive itself was then built.

The illustrations show the locomotive in its finished form. Details of the design are given in Table 2.

TABLE 2 WINTERTHUR LOCOMOTIVE DATA

Length over buffers	43 ft. 1 5/16 in.
Total wheel base	31 ft. 2 in.
Overall height	14 ft. 1/2 in.
Overall width	9 ft. 6 3/16 in.
Boiler Details	
Boiler pressure	850 lb. per sq. in.
Heating surface of water tubes (fire side)	1050 sq. ft.
Diameter of water tubes	2 3/8 in. inside
Diameter of water tubes	2 3/4 in. outside
Length of top high-pressure drum	14 ft. 9 in.
Internal diameter of top high-pressure drum	2 ft. 2 in.
Length of bottom high-pressure drums	14 ft. 8 in.
Internal diameter of bottom high-pressure drums	7 7/8 in.
Water content at mean level	95 cu. ft.
Area of water surface	31.5 sq. ft.
Heating surface of superheater	215 sq. ft.
Diameter of superheater tubes	2 in. inside
Diameter of superheater tubes	2 3/8 in. outside
Number of high-pressure superheater elements	7
Grate—	
Length	5 ft. 4 1/2 in.
Width	2 ft. 7 1/2 in.
Area	14.4 sq. ft.
Steam Engine Particulars	
Diameter of driving wheels	56 in.
Number of cylinders, single-stage expansion	3
Diameter of cylinders	8 1/2 in.
Piston stroke	13 3/4 in.
Volume of cylinders	738 cu. in.
Clearance—	
Front	5 per cent
Back	5 per cent
Gear ratio	1:2.5
Maximum speed	50 m.p.h.
Weight empty	70.3 tons
Weight in working order	84.0 tons
Tank capacity	13.20 Imp. gal.
Coal capacity	3.0 tons

As will be seen from the illustrations, the water-tube boiler is placed directly on the frames, and it is fitted with a smokebox and exhaust nozzle with a very short stack at its forward end. The boiler is somewhat shorter than usual in relation to the wheel base, and it allows the geared steam engine to be placed in front. Another advantage of this arrangement is that the engine, with the covering hood withdrawn, is accessible from all sides. Power is transmitted through a jack shaft to the driving wheels by means of side rods. As the illustration shows, the cab, side water tanks, and coal bunkers are arranged in the usual way.

The front hood covering the engine protects it against dust and dirt, and reduces the loss of heat due to radiation. At the same time it allows convenient access to the smokebox and the front air-inlet flues. The working principle of the new locomotive is illustrated in Fig. 4, and details of the boiler construction are shown in Fig. 5. The combustion chamber of the boiler is closed in by the tube elements, and is fitted with a normal type of firegrate. The heated gases pass through the water wall past the short stay tubes and reach the superheater and the feedwater preheater, which are accommodated in the boiler flue in front of the firebox. There is an air preheater arranged in the smokebox, and the products of combustion, having given up most of their heat, are expelled by the action of the exhaust, which intensifies combustion in the ordinary manner. The air which is required for combustion is taken in through two openings arranged in the front wall of the smokebox, which are protected by two cowls. It passes through the preheater, and is carried by means of a duct to the underside of the grate. Steam is taken from the regulator on which two safety valves are fitted, and passes through the superheater to the engine. The exhaust steam is led directly to the nozzle, but there is a branch connection to an exhaust-steam preheater for the feedwater. A supply of auxiliary steam from the cab is taken for the feed pump, and this is superheated in a separate coil. The feed pump is of the high-pressure compound type, and its duty is to lift the water from the feed tank, and force it through the feedwater heaters. The first is heated by the exhaust steam from the feed pump, and by a part of the steam from the engine cylinders.

The feedwater is thus heated up to about 175 to 195 deg. fahr. before it enters the main feedwater heater within the boiler itself, in which it is raised to the boiling point before it passes through the check valve into the top boiler drum.

The arrangement of the various heating elements may be noted. The generating elements, the superheater, feedwater heater, and air heater are placed in series, so that the heat from the gases is fully utilized, and only small surfaces are required, while a high degree of efficiency is attained. An important feature of the system is that there is no incrustation or scaling in the steam-generating elements themselves, any action of this kind taking place in the exhaust steam and main feedwater heaters, which are designed so that they can be inspected and scaled conveniently.

Boiler Design and Construction

Fig. 5 shows the boiler construction. The large-diameter top drum acts as a steam accumulator, and it is connected with the two smaller bottom drums by means of tube elements. The drums are also interconnected by the water-space walls, which are made of flanging-quality steel connected by short stay tubes. The water-space walls are welded to the drums. When the boiler is assembled and welded it forms a very stiff structure, which it is claimed, is particularly well adapted for locomotive work. Before the actual boiler was built each part was tested separately, and a series of boiler and heater elements were subjected to very high water and steam pressures, with rapid changes of temperature, without showing any defects. Both the superheater and the feedwater preheaters are built in such a way that they can be dismantled easily into simple pipe units for thorough inspection.

The High-Pressure Steam Engine

The steam engine works on the double-acting uniflow principle. Its principal dimensions are given in Table 2. The separate cylinders are bolted to a flange on the crankcase, which is placed

between the frame plates, and acts as an effective cross stay. A three-cylinder arrangement was chosen as giving the minimum number of cylinders, and at the same time a relatively simple distribution gear without sacrificing uniformity in torque and ease of starting. The valves are of the single-seated poppet type, and are operated mechanically by stepped ahead and reverse cams arranged on a sliding camshaft. There are six cams for each direction of running, and the camshaft is driven from the crank shaft through spiral bevel gearing.

STATIONARY AND ROAD TRIALS

Extensive bench trials were run with the engine arranged on a special stationary test bed, and the boiler and engine were tested thoroughly over a total running period of 350 hr. At first the superheat was a little high, but that was remedied by reducing the surface of the superheater. In the early trials it was also necessary to make some alteration in order to regulate the combustion, but when they had been made, the boiler was shown to be satisfactory in every respect. Under normal load conditions a total of 8500 lb. of steam per hour, not including the steam required for the feed pump, were produced, which corresponds to an evaporative factor of 8, and a production of nearly 600 lb. of steam per square foot of grate surface per hour.

Some of the actual pressure and temperature readings are as follows: With an initial feed temperature of 70 deg. fahr., the water was raised to 190 deg. fahr. in the exhaust-steam preheater, and further to 450 deg. fahr. in the main preheater within the boiler. The feedwater thus entered the top drum at a temperature of 50 to 70 deg. fahr. below the boiling point. The feed heating was, therefore, practically complete, while the range of super-

heat from 720 to 780 deg. fahr., according to the load, was higher than that used in conventional locomotives.

In the bench trial the steam engine was tested under load, being run for 8 1/2 hr. several times in order that reliable consumption figures could be obtained. The indicator diagrams were not unlike those of a Diesel engine with a high compression and a strongly marked admission. The stepped cam operating the inlet valve gear can be set on one of six positions. Positions 1 to 5 are those for running, and position 6 is for starting only. With a boiler pressure of between 700 lb. and 780 lb. per sq. in., and with the engine running at a speed of 550 r.p.m., the following outputs were recorded by the brake: Position 1, 470 b.hp.; 2, 800 b.hp.; 3, 1000 b.hp.; 4, 1200 b.hp., which is a very good performance for an engine weighing, with all its accessories, only 10,800 lb. The average steam consumption was 13.2 lb. per b.hp-hr. corresponding to 1.75 lb. of coal per b.hp-hr. After the tests had been made the whole plant was examined carefully, and no solid scale was found in the boiler. A fine mud had collected in the lower high-pressure drums, which was easily washed off.

The first road tests were carried out in November, 1927, and the engine was shown to be very smooth on the road and easily started. Only 330 lb. of coal were necessary for firing up compared with double the amount necessary for a conventional locomotive of equivalent output. The boiler was steamed within 1 1/4 hours of lighting up. Comparative road tests were made in January with a conventional 170 lb. pressure twin-cylinder superheated locomotive of the B 3/4 type No. 1341, belonging to the Swiss Federal Railways, of equal output, and under similar conditions as regards train load, express trains of 250 tons to 300 tons being hauled. This locomotive had a grate area of 23.7 sq. ft., compared with the 14.3 sq. ft. grate of the high-pressure locomotive. The accompanying table shows the results of the tests.

COMPARATIVE TEST RECORDS OF LOW- AND HIGH-PRESSURE LOCOMOTIVES

Section	Load in tons, excluding locomotive	Type of train	Locomotive boiler pressure, lb. per sq. in.	Coal consumption Lb. total	Coal consumption Lb. per b.hp-hr.	Water consumption Lb. total	Water consumption Lb. per b.hp-hr. A locomotive of the same type has been designed for an output of 3000 hp. with a 4–8–2 wheel arrangement and separate tender. The weight of the locomotive is estimated at 145 tons and of the tender 70 tons. The overall length is 77 ft., the height 14 ft. 1/2 in., and the width 10 ft. 1/2 in.

The writer desires to acknowledge his indebtedness to the manufacturers for information, and to the paper by Herbert Brown before the Institution of Locomotive Engineers for details of the Winterthur locomotive.

Discussion

JOHN E. MUHLFELD.[2] The paper gives the most detailed descriptive information relating to Loeffler and Winterthur (Wiesinger) types of high-pressure locomotives that has come to the writer's attention. It is interesting to note that the Loeffler locomotive of about 2500-hp. capacity, making use of a maximum of 1470 lb. steam pressure, with a total temperature of 860 deg. fahr., will produce a fuel saving of from 40 to 45 per cent; and that the Winterthur locomotive, of about 1200-hp. capacity, with a total temperature of 720 to 780 deg. fahr., will produce a fuel saving of from 25 to 35 per cent. These performances indicate that relatively high steam pressures and temperatures can be made use of in steam locomotives, not only safely but with substantial results in efficiency and economy.

There is an economic urge for further improvement if the steam locomotive, which can be designed to operate at a much greater overall efficiency and economy than any other mobile unit of equivalent hauling capacity, is to forge ahead as a transportation machine. According to Geo. A. Orrok, in 1919 the steam central power stations in the United States produced a total of about 32 billion hp-hr. at an average of 2.34 lb. of coal per hp-hr. By 1928 central-power-plant economy had been so much improved that the average cost for the 71 billion hp-hr. that year was only 1.34 lb. of coal per hp-hr. More than 20 of the larger stations now use less than 1.12 lb., and six are averaging at or about 0.8 lb. of good coal per hp-hr. These comparative figures are deserving of serious consideration by railway executives.

A greater investment per unit of drawbar pull can be justified in a steam locomotive operating in a relatively level country with a high average load factor than one operating in a rolling and mountainous country with a relatively low load factor. However, any engineering improvements that will produce greater boiler efficiency and capacity, and fuel savings equal to 10 per cent or more net, are worthy of practical application.

Of the questions of predominating interest to steam-locomotive users, the tendency toward higher steam pressure and higher combustion and superheated-steam temperatures, which decrease the heat units required and improve the efficiency of the transformation of calorific energy into mechanical work, is the most popular. From developments to date initial steam temperatures can be considerably increased without lubrication, maintenance, or dissociation or velocity of steam difficulties, so that the resuperheating of steam between high- and low-pressure multiple-expansion cylinders will not be required as steam at 500 lb. pressure, when superheated to a total temperature of 1000 deg. fahr. will be dry when it is expanded adiabatically to the atmosphere.

The problem, however, is what shall the limit of pressure and temperature be to take advantage of these favorable qualities? The writer believes that in a non-condensing steam locomotive, 500 lb. steam pressure and 850 deg. fahr. temperature is a reasonable limitation, at least with the present state of the metallurgical art and of the utilization of the pressure-heat combination. An

[2] Railway Consulting Engineer, New York, N. Y.

attempt to use, in a practical and economical manner, the theoretical advantages of a higher pressure-temperature in a multiple and regenerative type of locomotive will be a very difficult proposition.

The first waste of heat units occurs in the furnace, and the boiler, therefore, requires urgent attention, after which the steam distribution gear must be improved to provide quicker and larger admission and exhaust openings and greater precision, reduce the cylinder and piston clearance spaces, and improve the means for the utilization of the exhaust steam and the flue gases to heat the feedwater and the combustion air.

Much has been said about the dissociation of hydrogen and oxygen in high-pressure-temperature steam with resulting oxidation of the metal with which the steam is in contact. The dissociation of steam in contact with steel at high temperatures has been observed in the presence of hydrogen, in both saturated and superheated steam, and traces of it have been found in water as it enters and leaves the feedwater heaters. Therefore, unless combustion is completed before the furnace gases reach the superheater elements, and the steam velocity is high and the flow is properly distributed between the superheater elements, the low-carbon steel tubes may reach temperatures at which oxidation, due to steam dissociation, will occur. However, reports made to date by the research department of the Detroit Edison Company and the Prime Movers Committee of the American Society of Mechanical Engineers indicate that any dissociation which may ordinarily obtain is apparently so infinitesimal that it will have no serious effect on material now obtainable which can be used in the parts subjected to such steam.

In the boiler design serious consideration should be given to the use of all possible self-supporting shapes. A sphere requires the least material to contain a given volume and pressure, and the more spherical and cylindrical hollow shapes used in the design of a boiler, the greater will be its volumetric and self-supporting capacity per unit of tare weight. Other essentials in locomotive boiler design are: Maximum firebox volume and evaporation surface and gas area through fire flues and tubes; relatively short fire flues and tubes in combination with combustion chambers versus longer flues and tubes without combustion chambers; increased combustion temperature by limiting the size of the grate area or by burning fuel in suspension; full utilization of radiant heat for evaporation; rapid circulation of water through or around all evaporation surface plates, siphons, and tubes; removal of all steam-delivery pipes and throttle valves from inside the boiler and smokebox; an adequate water capacity and saturated-steam space at the top of the boiler and the collection of the saturated steam from over a large surface area of the steam-generating water, to avoid priming and the use of the superheater as a secondary evaporator. The steam-delivery pipe and main throttle valve should be of such design and dimensions as will reduce the frictional resistance between the boiler and the steam chests to the minimum.

With respect to the superheater equipment, in order to increase the firetube gas area, reduce the cylinder back pressure, and increase the engine tractive power, it would be preferable to remove the superheater elements from the fire flues, either completely or in part, in order to provide for the free passage of the products of combustion and reduce the liability for their obstruction. As the net gas area and length of the fire flues and tubes govern the amount of draft required to burn a certain amount of fuel, the smaller this net area the more draft will be required, and the greater will be the engine horsepower loss resulting from the increased cylinder back pressure. Such an arrangement of a counterflow type of superheater would also prevent the present loss of heat due to the superheated steam being required to traverse the coldest part of the boiler, and would enable reduction of existing wasteful smokebox temperatures without loss of superheat, and carrying on the superheating process in a zone of higher gas temperature would reduce the pressure drop, or loss of steam pressure, between the boiler and the cylinders. Even with the conventional fire-flue type of double-loop superheater elements, a reduction in the forward-end length of the upper-loop portion, in order to eliminate more of the superheater heating surface from the cold zone of the boiler, i.e., locate the upper forward return bends about one-third of the flue length from the front-tube sheet, should be advantageous.

The average coals in the United States, when burned in locomotives on grates and fired either by hand or mechanical stoking, will produce the best results when the grate area is proportioned for the burning of from 90 to 110 lb. of coal per sq. ft. of grate area. However, the usual method of firing and burning run-of-mine or sized grades of coal and other solid fuels on grates is a clumsy, inefficient, and uneconomical method for obtaining its heat value. By pulverization and burning coal in suspension in the same manner as gas or oil, the fuel and air can be regulated to produce almost perfect combustion under all conditions of working; maximum radiant-heat absorption will be obtained; smoke and standby losses are reduced to the minimum; the discharge of unconsumed fuel is largely reduced; and a great heat value of the fuel is obtained.

In the utilization of the waste heat in the exhaust steam and flue gases for feed-heating with the higher boiler pressures, i.e., from 250 to 500 lb. pressure, an exhaust-steam injector in its present state of practical development seems to be out of the question, and a mechanically driven feed pump will substantially reduce the life steam required for the boiler feed operation, for the reason that the higher the boiler pressure the greater will be the live steam consumption for this purpose with a direct steam-driven feed pump. Also the most effective feedwater heater is the one which allows the best use of the heat in the exhaust steam, with the smallest use of live steam. Therefore, the open type of condenser or heater appeals, because it uses the total heat of the exhaust steam, and in addition about 13 per cent less water need be heated, due to the reclamation of the condensed steam.

Scientific treatment of unsuitable boiler water is most essential to prevent priming, foaming, and the depositing of scale, with its resultant embrittlement and corrosive pitting and grooving action on the boiler metal. Likewise, pure water will dissolve iron, and when dissolved oxygen is absent a galvanic corrosion occurs.

In regard to the preheating of the combustion air, wherever the firing equipment is such that the fire doors can be kept closed, as in the case of oil and pulverized-fuel burning locomotives, then the preheating of the combustion air has many advantages. Where the furnace doors are opened, or can be left open, the use of preheated air cannot be of much practical benefit.

Cylinder back pressures, with exhaust-steam draft, should not exceed from 5 to 7 lb., and any improvement that will provide for greater entrainment of the smokebox gases by the exhaust steam or, if necessary, by mechanical draft, in order to lower cylinder back pressure, will be a marked step in advance. In some of the smaller and now obsolete types of steam locomotives with plain round long smokestacks and short exhaust-nozzles openings, the efficiency of the exhaust steam in creating smokebox vacuum and draft is, in some cases, as high as 30 per cent, whereas in the larger and more modern types of locomotives with the increased diameter and shorter smokestacks and higher exhaust nozzles, it is difficult to obtain an efficiency of 20 per cent, and the majority of these locomotives have stack and exhaust-nozzle equipment which will produce not more than from 5 to 10 per cent efficiency of the exhaust steam.

The location of all cylinders, valve chests, and valve gears outside of the main engine frames provides the most practical and accessible arrangement. This has been demonstrated for many years through the substitution of the Walschaerts type of outside for the Stephenson type of inside valve gear, and by the two-cylinder, single-expansion or compound, rigid-frame, and the four-cylinder single-expansion or compound, articulated-frame types of locomotives. Where rigid-frame locomotives are desired, and sufficient horsepower cannot be produced in two outside front cylinders, then consideration should be given to the application of two outside cylinders at each of the front and rear ends of the chassis, in combination with outside crankpins spaced at right angles in the usual manner, in preference to the use of intermediate third and fourth cylinders in combination with inside cranks and the complicated and inaccessible inside valve gear and reciprocating and revolving parts.

With high-pressure-temperature locomotives it is most important that the insulation, lagging, and jacketing of all of the boiler and engine parts and the piping, which are subject to radiation loss, be insulated to an efficiency from 96 to 98, or even higher.

In the use of the high-pressure-temperature steam it is of the greatest importance that an adequate range of expansion be provided, either by the compounding or uniflow principle. Limiting the cut-off merely results in limiting the otherwise available boiler, engine, and adhesive weight capacity of the locomotive.

With a piston valve and outside-motion gear, decreasing the cut-off increases the compression, which gives high efficiency for normal working conditions only. With increased cut-off the compression becomes insufficient, and with decreased cut-off it will be too high, resulting in a part of the power being worthlessly used in the cylinder itself. Therefore, a rotative-motion outside-type of poppet-valve gear, wherein the cut-off can be independent of the compression, due to the separate admission and exhaust valves, which in themselves provide a certain uniflow and enable reduction in cylinder clearances, should be favorable to the more efficient utilization of the high-pressure steam in the engine cylinders. The cylinder indicated horsepower will also be increased by the quicker admission and exhaust opening and the smaller clearance spaces and reduced cylinder back pressure. This type of valve gear also has advantages in the utilization of a higher pressure-temperature of steam, with less lubrication and without the necessity for a power reverse gear. It also overcomes the disadvantages of the small areas for the entering and exhausting steam, even where the double-ported type of piston valve is made use of.

The principal advantages of uniflow are the flow of the admission steam from the hottest to the coldest point in the cylinder, and a reduction in the flow of heat from the cylinder walls to the steam, as well as a decrease in the cylinder port and piston clearance spaces. With uniflow the steam leaves the cylinder at its coolest point, and with the least opportunity to remove heat from the cylinder walls.

To reduce track-rail lateral and vertical pressures and stresses and rail wear, and to improve the guiding and riding qualities of the locomotive, lateral-motion devices that will equalize rail pressures between the leading truck and the forward driving wheels are not only essential but will, in many cases, enable the elimination of otherwise necessary non-productive truck wheels.

Nosing, fore-and-aft vibrations, and side swaying of a locomotive are due to track and rail conditions, the unbalanced reciprocating forces, and to wheel and rail clearances; deficiency in counterbalance results in hammer blows on the rail; and dynamic augment is due to excess balance on account of the reciprocating weights, and to the component of the piston thrust, which latter trackrail pressure may be somewhat reduced by the use of longer main rods.

Small diameter driving-wheel centers make the counterbalancing of a two-cylinder locomotive a difficult problem in other than the Mallet type of locomotive. In a three-cylinder type with the cranks spaced 120 deg. it is even more difficult because of the additional force at the main crankpins, due to the components of the piston thrusts resulting from the spacing of the cranks.

All revolving and reciprocating parts which must be counterbalanced should be designed of the minimum weight consistent with strength by the use of high-elastic-limit, tough, ductile material, and this applies as well to all other unsprung parts such as driving axles and wheel centers. The centers of gravity of the counterweights in each driving wheel should be designed as close as possible to the centers of gravity of the planes of the revolving and reciprocating parts.

The American Railway Association formula for counterbalancing, especially as applying to main driving wheels, is obsolete for modern locomotives which have the vertical planes of the revolving parts and the counterweights considerably removed. The counterbalancing of 100 per cent of the revolving weights, with the division of this counterweight pro rata between the main and the coupled driving wheels, and the counterbalancing of 50 per cent of the reciprocating weights, with an equal division of the same between the coupled, exclusive of the main driving wheels, should best take care of both the static and the dynamic loading.

In view of the axle-load limitations of existing track and bridge structures, new locomotive boiler, chassis and machinery, total and detail weights must be reduced to the minimum. This applies especially to the elimination of all unnecessary leading and trailing truck or non-productive wheels and to the unsprung weights in driving axles and wheel centers, main and side rods, and to the other revolving and reciprocating parts. As yet, alloys and heat-treated steels, when subjected to repeated loads and high pressures and temperatures, have not demonstrated the anticipated reliability, durability, and resistance to fatigue. The magnetic treatment of ferrous metals, now being experimented with, may be able to effect such changes in the sub-atomic structures as to produce more satisfactory results. In the meantime, service test of high-elastic-limit, low-carbon, high-manganese steel castings have shown remarkable resistance to stress and strain; to surface checking and progressive fracturing; and to corrosion, pittings, and grooving. It is predicted that with the rapid improvement being made in steel-casting production facilities, it may soon be possible to make use of high-pressure locomotive integral cast-steel boiler shells, wheel centers and axles, piston heads and rods, and main and side rods and like units as a substitute for rolled and forged parts, the metal of which now originates in a cast ingot. By this change, much of the present excess weight, forming, punching, shearing, riveting, welding, machining, fitting and fabrication, and the delay and cost incident thereto, can be dispensed with.

On the Delaware and Hudson, during the past five years, it has been found, in the "Horatio Allen" (D & H No. 1400) freight locomotive, making use of 350 lb. boiler pressure and multiple expansion; and during the past two and one-half years, on a similar type locomotive, the "John B. Jervis" (D & H 1401), carrying 400 lb. boiler pressure, that the use of these higher steam pressures, even in combination with relatively low superheat, without feed-heating and hand-fired, can develop high tractive power, comparatively large economies in fuel consumption, and can be handled with as great safety and with as little maintenance as the conventional superheated steam locomotive of 200 lb. pressure.

The Delaware and Hudson Company expects soon to have its "James Archbald" (D & H No. 1402), which will make use of 500 lb. pressure and from 700 to 750 deg. fahr. total temperature of the steam, in service as a final consummation of its experimental

work with locomotive high-steam pressure, at least for the present. This pressure will be utilized by multiple expansion, in the same manner as on the D & H Nos. 1400 and 1401. While the latter two locomotives have driving wheels of 57 in. diameter, those of the 1402 will be 63 in. diameter. Other changes and improvements will incorporate a Dabeg mechanically driven, double-acting type of feedwater pump-exhaust steam heater; Wagner single-seated type of balanced outside front end throttle valve; counterbalancing of the revolving and reciprocating parts of the locomotive for a speed of 75 m.p.h.; increased superheat capacity; greater boiler-flue and tube gas area; enlarged furnace volume; grate area limited to maintain maximum furnace temperatures; reduced cylinder-port and piston clearances; silico-manganese steel boiler plates; nickel-steel forgings and boiler tubes and flues; low-carbon, high-manganese steel castings; and insulation, lagging, and jacketing of from 96 to 98 per cent efficiency.

Comparing the "James Archbald" with the conventional steam locomotive carrying 200 lb. boiler pressure, making use of superheated steam in single-expansion cylinders, and equipped with exhaust-steam feedwater heating, it is calculated that it will perform equivalent work at the tender drawbar with approximately two-thirds less fuel. Inasmuch as next to labor the fuel bill is the largest single item of expense in steam-railroad operation, this reduction in fuel consumption will represent a very large saving in transportation expense.

The "Horatio Allen" and "John B. Jervis" locomotives are hand-fired, and with relatively low superheat and without feed-heating operate at 8.75 and 9.5 per cent, respectively, thermal efficiency, in terms of the heat value of the coal, at the tender drawbar. With the higher boiler pressure and superheat, feed heating, reduced cylinder and piston clearance space, increased diameter driving wheels, and other changes incorporated in the "James Archbald," it is calculated that it will operate at between 11 and 12 per cent thermal efficiency, in terms of the heat value of the coal, at the tender drawbar.

There seems to be but little question as to the ability to generate high-pressure and high-temperature steam, safely, successfully and economically, but the problem, as I see it, is how can this combination of pressure and heat energy be best and most efficiently converted into work in a locomotive engine and maintain a dependable and practical machine from the standpoint of fuel saving, operation, and maintenance? Experience on the Kansas City Southern Railway showed that steam at 250 lb. pressure, with a total temperature of 1000 deg. fahr., can be produced and used in a locomotive, but the cutting and disintegrating action of the steam on the various materials is a factor to be reckoned with. Experience on the "Horatio Allen" and "John B. Jervis" locomotives, during the past five years, has demonstrated that 350 and 400 lb. steam pressure, with moderate superheat, is satisfactory and economical, and that 500 lb. pressure in combination with about 850 deg. fahr. total temperature will be practical, but about as high in both pressure and temperature, as should be used with the present state of the metallurgical art and efficient utilization of the pressure and heat to convert it into work.

In the original design of the "Horatio Allen" high-pressure type of boiler, use was contemplated of it for both slow and fast freight, and also for high-speed passenger service. With the improvements that the railways are making on their main line roadways, in the way of easier curves, lower grades, deeper ballast, and heavier crossties, tie plates, rail, and other track appliances, there is no good reason why, in combination with grade separation, automatic signaling and automatic train control, steam locomotives and rolling stock cannot now be designed and operated at speeds of from 110 to 120 m.p.h. This rate of movement will afford much more intensive competition with airplane, airship, and various public highway means of passenger, mail, and express transportation, and with much greater safety, convenience, and comfort.

By applying the "Horatio Allen" high-pressure type of boiler, which is designed with a small-diameter main cylindrical shell in order to clear the driving wheels to a 4–6–2 or a 4–6–4 type of locomotive, with 500 lb. steam pressure, 850 deg. fahr. total temperature of the steam, 90-in. diameter driving wheels, and a modified system of uniflow steam distribution, the vertical center of gravity of the locomotive can be maintained sufficiently low for the higher speeds, and by eliminating stops, train schedules equivalent to commercial airplane service can be maintained readily. Existing steam locomotives, with smaller diameter driving wheels that have been operated at speeds of from 85 to 105 m.p.h., have demonstrated that the proposed higher speed is entirely safe and practicable.

With respect to the modern steam-locomotive design in general, it is suggested that the American builders and railway mechanical engineers give greater consideration to increasing boiler pressure, steam temperature, and sustained boiler-horsepower capacity; improving the utilization of the steam in the cylinders, and reclaiming the waste heat in the exhaust steam and smokebox gases.

H. B. Oatley.[3] In regard to steam temperatures obtained on American locomotives, one or more engines on the Delaware and Hudson Railroad are working with the steamchest temperatures above 800 deg. fahr. Engines on the Canadian National and the Canadian Pacific Railways are also working with temperatures in excess of 750 deg. fahr. Exhaust-steam temperature is higher with the longer cutoffs. The engines referred to are in freight service on the Western Maryland Railway and operate during a large proportion of their running time, with essentially full cutoff so that the mean steam temperature in the cylinder is higher than on high-speed locomotives working with the same initial steam temperature, but with relatively short cutoff. While the conditions on these Western Maryland engines are quite severe, there should be no serious trouble with lubrication nor with the packing on pistons and piston rods.

Stress has been laid on the large percentage savings of the Winterthur locomotive. While these figures are correct, as may be seen from the table given at the end of the paper, there is other significant data which should not be lost sight of. In the table referred to, the coal and water consumption per horsepower-hour is given both for the low-pressure and for the high-pressure locomotive. The coal consumption of the low-pressure engine ranges between 3.46 lb. and 4.10 lb. per hp-hr., and for the high-pressure locomotive the range was between 2.50 and 3.04 lb. per hp-hr. The low-pressure locomotive was far from economical in its performance, and while economies of from 25 per cent to 30 per cent are credited to the high-pressure locomotive, the unit consumption figures are by no means remarkable. Many engines of the conventional type, and with steam pressures not over 250 lb. per sq. in., have shown on the Pennsylvania Railroad testing plant and in dynamometer-car tests on the road both here and abroad coal-consumption figures lower than those shown by the Winterthur engine.

Data on the performance of high-pressure locomotives obtained on road tests are not available in such volume. Dr. Nordmann, however, has published in the March, 1928, issue of *Zeitschrift des Vereines deutscher Ingenieure*, some data obtained from road tests of the Schmidt high-pressure, double-pressure locomotive. It is shown that a coal consumption of 2.02 lb. per drawbar hp-hr. was obtained. This was with a fuel that had 12,700 B.t.u. per

[3] Vice-President in Charge of Engineering, The Superheater Company, New York, N. Y.

lb. The coal used on the Winterthur locomotive tests had 13,300 B.t.u. per lb. Compared therefore on a heat-unit basis, the consumption of the Schmidt engine was equivalent to 1.93 lb. per drawbar hp-hr. It may also be said that the tests of the Schmidt locomotive were conducted at speeds of 50 m.p.h., while the tests of the Winterthur engine were at average speeds of between 25 and 26 m.p.h. As the resistance increases with the speed, the performance of the Schmidt locomotive becomes very significant, and were the figures of both engines to be reduced to an indicated-horsepower-hour basis, the fuel economy of the Schmidt engine would be still more impressive.

A. Giesl-Gieslingen.[4] The Floridsdorf Locomotive Works in Vienna, Austria, developed the Loeffler system of steam generation. After the elements of construction had been exhaustively tested with perfect success, their 2000-kw. generating plant was adapted to use steam of 1700 lb. pressure and a temperature of 910 deg. at the boiler, 890 deg. at the engine. This temperature is maintained constant throughout the whole range of output, one of the special features connected with the Loeffler system. The newly installed reciprocating engine develops 500–600 hp. in a single cylinder of 6.7 by 18 in. at 300 r.p.m., exhausting into the earlier two-cylinder compound-condensing engine at about 200 lb. and 430 deg. A good grade of American cylinder oil and graphite is used. The total absence of lubrication troubles is due to the high pressures to which the oil is subjected at all times, as was clearly demonstrated by comparison with the Swiss locomotive. Tests carried out at Winterthur showed that the maximum steam temperature that could be safely carried was about 77 deg. as stated by Dr. Brown of the Swiss Locomotive Works before the Austrian Society of Engineers. That engine is of the single-expansion type, and there is approximately atmospheric pressure in the cylinder for about half the time, while, in the Floridsdorf compound the pressure never drops below 170 lb., which enables the carrying of higher superheat. This point seems not to have received consideration so far.

As to rod packings, a test plant was installed at Floridsdorf comprising a cylinder in which a piston rod was moved by electric drive with 20-in. stroke and 300 r.p.m. The packings were subjected to a constant steam pressure of 1500 lb. at 850 deg., representing more severe conditions than in normal service, where cylinder pressure is variable. Metallic and soft packings were received from many parts of the world and tests proved to be very time-absorbing. Holding tight was no problem, but damage to the rod often developed after more than 100 hr. of service. After having used pure soft asbestos with fairly good results, various metallic packings were found to be perfectly successful, while others failed entirely. The problem is solved, there being only a question of materials. A very hard surface of the piston rod is essential with these pressures.

An American Loeffler locomotive would probably look considerably simpler than it appears on the chart presented; the sharp guarantees that had to be given apparently influenced the designers.

An important fact should not be neglected when pointing out the most economical steam pressure or the increase in performance by the use of high-pressure steam: Contrary to the turbine, the reciprocating engine makes a much better use of the heat units available in the high-pressure part; the classic tests of Schmidt with his 850-lb. quadruple-expansion condensing engine of 1921 showed an efficiency of about 95 per cent compared with the Rankine cycle in the high-pressure cylinder, and a little over 70 per cent in the lower ranges. The conventional locomotive cylinder efficiency equals the latter figure, and there is a gain proportionally much more by the use of high-pressure steam than is shown by the Rankine cycle.

While Europeans look for fuel saving, Americans want increase in performance. In the design of heaviest power, these items proved to be closely related, as the limits of grate area and combustion space have been reached, and 5000 to 6000-hp. engines demand grates of over 100 sq. ft. in the conventional locomotive. The Loeffler engine, however, where the heat consumption should be nearly cut in half, has a grate area of 28 sq. ft. for a rated output of 2500 hp. This gives a good outlook for future development, as 10,000-hp. boilers will be possible within the existing clearance limitations, and 10,000 hp. is not at all out of question if one looks at the Virginian electrification and other developments of modern railroading.

Replying to Mr. Oatley's remark on the excessive fuel consumption of the normal locomotive which was compared with the Winterthur high-pressure design on the Swiss railways, this, indeed, is an important point, and the Swiss 2–6–0 type which has been taken for comparison is not up to date. It must be considered, however, that the high-pressure engine is the first of its kind and much can unquestionably be perfected to improve its efficiency. Great economic achievements have been made in conventional locomotive design during the last decade without fundamental changes in construction. The German standard Pacific of 1927 gets 25 per cent more work out of one pound of coal than the representative ten-wheeler of 1921, although the engines have both feedwater heaters and look of equal qualities to the average observer. Still, much remains to be done. Immediate development of the conventional locomotive is urged as great returns are possible by refinements in design and moderately higher pressures, until the field is ripe for general conquest by super-pressure steam.

James M. Taggart.[5] In connection with the development of high steam-pressure locomotives it seems proper to take into consideration the experience which has been obtained in the generation and utilization of high-pressure steam in other fields and to analyze it with reference to application to locomotive power plants.

It is also well to keep in mind that the progress aimed at by European development is toward a somewhat different goal than is desirable for this country. Thus the main advantage to be expected from high-pressure steam locomotives in this country is an increase in power capacity relative to locomotive weight, while in Europe the chief end is a reduction in fuel bills. To a certain extent both of these features are related as are also the other cost factors involved, such as maintenance, labor, and reliability.

One of the principal objections to the present type of locomotive is the potential destructive force inherent. All development should be with a view of increasing safety, and should aim at a final elimination of any danger from boiler explosions.

An economic success in the use of high steam pressures up to 1400 lb. per sq. in. has been already attained where the conditions have been favorable. Troubles encountered are found to be of the same order as for lower pressures. They have been due primarily to defects in furnace, combustion equipment, boiler, and auxiliary apparatus. Some defects that were of minor importance at low pressures have proved to be major items at high pressures. In all cases where standard or near-standard types of boilers have been used for high pressures the safety factor with reference to burned tubes has been found as reduced. The use and proposed further use of high pressures has led to considerable research work aimed at determining the physical characteristics of steam at high pressures and temperatures, and the reactions of

[4] Member, Austrian and German Society of Engineers, Vienna, Austria.

[5] Consulting Engineer, New York, N. Y.

metals under stress at high temperatures. The extended tests on steam undertaken by the A.S.M.E. have not been completed as yet. As far as they have been carried they show only minor variations from former tables, calculated from miscellaneous tests.

With regard to metals a new theory has been developed—namely, that there is a continuous creep in all metals under stress at any temperature. This theory has not been proved as yet. Even if proved true for certain alloys or for certain temperatures it may still not apply to homogeneous metals, other alloys, or at all temperatures. It will undoubtedly be several years before this theory can be conclusively investigated. Its probability is, however, sufficient to warrant its consideration when designing equipment that will be exposed to high temperatures.

Experience With Boilers in Stationary Plants

Almost all of the high-pressure boilers now operating in the United States or being installed are of standard type, though somewhat modified in detail and arrangement. As before stated troubles experienced have been of the same order as for lower pressures. Increased care in maintaining a feedwater free from all impurities, slightly alkaline, and free from air has in some cases been sufficient to reduce maintenance to a negligible item. In other cases changes in furnace and combustion equipment have been required to reduce burning of tubes. With some installation changes in circulation have been made with good results. In all cases, however, though the improved efficiency has overshadowed the troubles experienced, the safety factory against burning of tubes has been materially reduced.

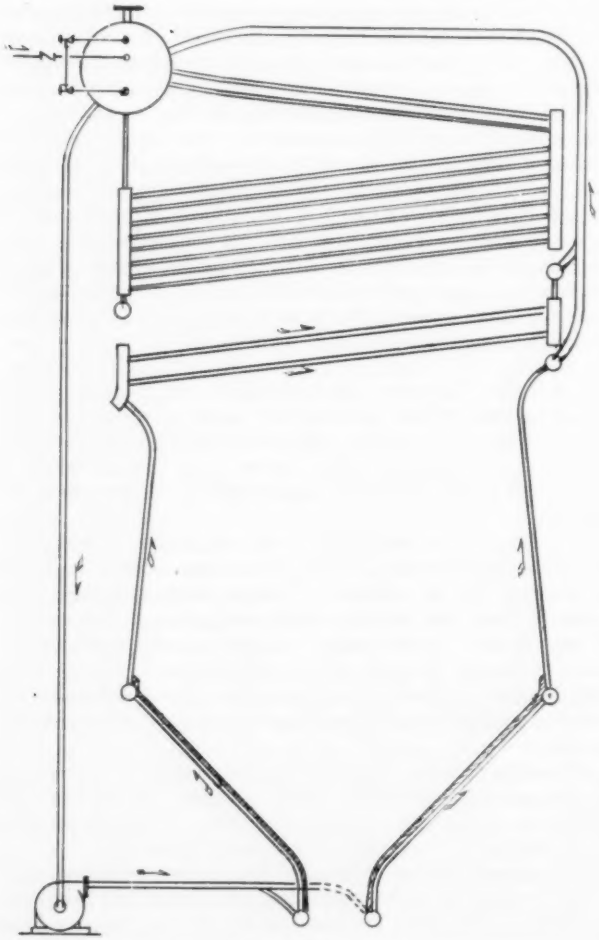

Fig. 6 Standard Type Boiler With Forced Circulation for Water Walls

In Europe high-pressure installations have been generally with special types of boilers. All the types used have complications that will apparently limit their field of usefulness even if they should be developed to achieve low operating maintenance costs.

One type, the Benson boiler, is a straight flash boiler operating above critical pressure. In other words, the flash point is removed outside the boiler proper. Where the steam is to be used at, say, 1600 lb. pressure, the extra power required for pumping against something over 3000 lb. is a considerable item. The Schmidt boiler uses an indirect heating effect. Distilled water heated to steaming temperature by the furnace is condensed in coils contained in the boiler drum. This boiler is evidently intended for use where the feedwater is dirty. The pressure of the steam produced is limited, since it must be well below the pressure of the steam in the closed circuit.

The indirect heating effect of this boiler renders it very expensive without any advantage over standard-type boilers where the feedwater is clean. Other defects are the very low velocity of circulation and a tendency for the capacity to fall off if the heating coils in the drum become coated.

The Loeffler boiler is an adventure into high temperatures, since steam is used to carry the furnace heat into the boiler drums. Forced circulation of steam is used through coils exposed to the furnace heat. Early small installations were more successful than the writer would have expected. Reports of larger installations indicate high maintenance costs. All of these special types of boilers are difficult to repair in case of trouble and, judging from the designs published, cannot be cleaned or inspected thoroughly.

Circulation of Steam and Water in Boilers

Velocities of natural circulation within any standard type of boiler reduce rapidly as the operating pressure is increased. Also there is a further tendency to reduce velocities of circulation due to the use of smaller tubes at high pressures. As to what velocities are attained in present practice or what are required, there is a wide divergence of opinion. Numerous velocity tests have been made. Even those tests made with the most care cannot be considered as more than approximately correct for the special conditions involved.

At pressures of, say, 200 lb. the velocities of flow are very high at high ratings, running up to over 40 ft. per sec. as the tube inclination approaches the vertical and with types where the flow resistance is low. At 1400 lb. pressure there would be a reduction in flow velocity in the ratio of one to six compared to 200 lb. pressure.

More important on the side of safety than actual flow velocities where the same are not abnormally low are consideration of the probable interruptions to flow due to surging within the boiler, steam laneing, and the possibility of deposit on the inside of tubes.

Surges may be caused by sudden load changes, irregular feedwater regulation of flow, and in some cases where the design is unsuited to the loads carried, by excess steam formation in the tubes exposed to the radiant heat. Surges are apt to cause temporary reversed circulation, and in some cases they may interrupt the supply of water to the down-comer tubes. Surges are more to be anticipated in low-pressure boilers than at high pressures. At high pressures any interruption to circulation is dangerous.

Steam laneing will occur at low flow velocities along the heated sides of vertical tubes and along the top sides of horizontally inclined tubes. It is evidently more to be feared at high pressures than low, due to the lower prevailing flow velocities. Deposit

on the inside of tubes is of course non-existent with absolutely pure feedwater. In most plants there will be times when a certain amount of dirt or scale forming solids will get into the feedwater. At high pressures on account of low velocities there will be a greater tendency for any scale or dirt present to accumulate on the tube surfaces and at the same time a slight scale or deposit, that would do no damage at low pressures, is dangerous.

In view of the numerous troubles with water walls, especially at high pressures, some manufacturers are now providing forced circulation in accordance with the La Mont method, for this part of the boiler. This is apparently a step in the right direction, since in most cases water-wall circulation is naturally slow because of the form of connections used. For high-pressure boilers it would be preferable to extend the forced circulation. Thus in Fig. 6 is shown a standard type boiler with forced circulation provided for the water walls and slag screen. The forced-circulation system shown is independent of the natural circulation for the rest of the boiler. Thus the feedwater connection and steam outlet from the drum are standard.

This arrangement should keep the surfaces exposed to radiant heat cooler with high pressures. It would also tend to prevent scale formation on the hottest surfaces. The power reqiremen ts for the circulating pump should be very small to obtain a higher velocity flow than can be had with natural circulation at high pressures.

The arrangement shown in Fig. 6 while a step in the right direction can apparently be improved. Thus the heat absorption would be improved slightly by extending the forced circulation to the convection section of the boiler. In addition by paralleling the feedwater with the forced circulation the cooling effect can be increased and a safety factor added. In Fig. 7 such an arrangement is indicated. Provided the circulation pump should fail the feedwater flow would with some induced circulation normally keep the boiler surfaces free from burns provided the feedwater were clean.

Heat Storage in Boiler Drums

The drums of high-pressure boilers are the weakest part where standard construction is used. The thickness of metal required is very great since tube holes cut away much metal. As a result seamless forged-steel construction is required at a large expense. Furthermore with standard construction the question of heat effect on the shell is problematical. This later consideration has led to their being shrouded from the hot gases.

As a heat accumulator the drum plays just as important a part as at lower pressures. Approximately the same water storage volume would be required to give the same heat reserve for the same percentage drop in pressure. The amount of storage required to give steady operation or to take care of load fluctuations depends on the character of the load, the type of combustion equipment, and the effectiveness of the combustion-control equipment. Thus with stoker firing and a large extent of refractory walls more heat storage will be required to take care of load variations than with pulverized coal and water-cooled walls. With standard drums it would be excessively expensive to provide sufficient storage to take care of the extreme cases.

Aside from storage the drum furnishes the steam liberation surface or separation space. With high pressure the separating area and volume required is much less than with low pressure. Based on the relative size of steam bubbles and velocities of flow the surface area required for 1400-lb. pressure is only one-fifth of that needed at 200 lb. In reality standard boilers as normally constructed have only a small portion of their water surface effective as steam-liberation surface at maximum loads.

Consideration of the above features would indicate that standard boiler drums are incorrect practice for high pressures. The use of forced circulation would allow for a more logical arrangement of drums.

In Fig. 8 is shown a design with a circulation similar to that indicated in Fig. 7 but with the drum or drums outside the setting and in a vertical position. Also in the connection from the top header to the boiler drum there is placed a separator having a centrifugal effect. From this separator a connection conducts the separated water to below the low-water line of the drum. The steam connection to the drum should be made so that the drum head will act as a secondary separator. This arrangement would

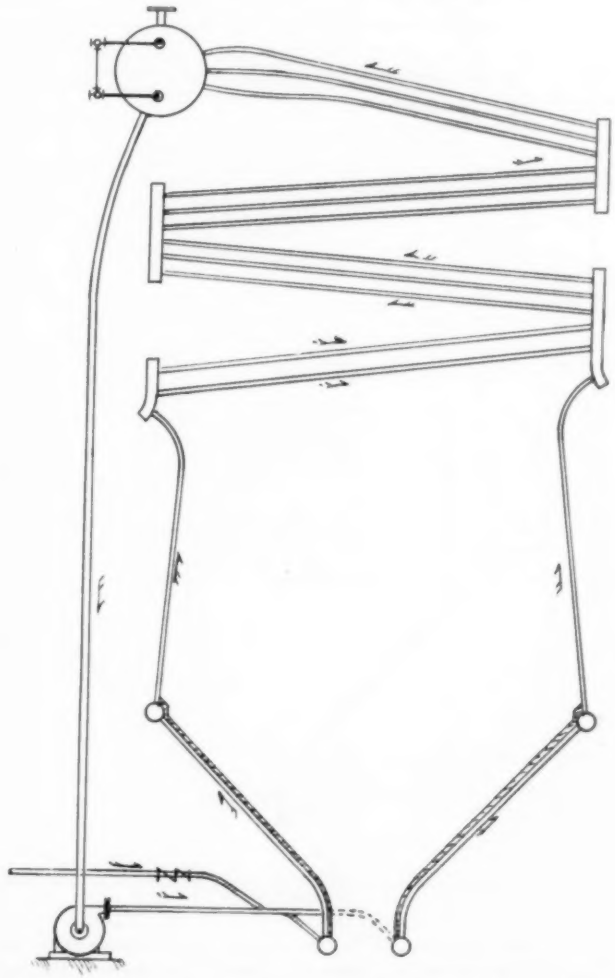

Fig. 7 Boiler With Feedwater Paralleled With Forced Circulation

allow for a considerable increase in storage volume relative to drum volume. Normally steam storage if required in excess of the drum-head volume should be provided near the source of steam usage. Thus the volume in the drum above the water line would be determined by the separating effect required. In an arrangement of this type it would also be desirable to increase the height of water-line variation, say to 3 or 4 ft.

With drums as shown the connections can be made so as not to weaken the shell. Thus the weight of metal required would be a minimum for the diameter and pressure. Where large storage is desirable or very high pressures used several drums can be connected up in multiple so as best to suit the storage or pressure requirements. The use of the separator in front of the drum provides a convenient method for removing the solids, where

dirty water will be used occasionally. Thus the water connection could be run through a pocket provided with a continuous blowdown connection.

An examination of the boiler outlined in Fig. 8 shows it to be in effect a flash boiler with storage and a supplementary recirculation superimposed. With the velocity flow greater than for standard high-pressure designs it is obvious that the heat-absorption rate will be increased per unit of surface for the same furnace temperature and velocity of gas flow through the boiler. Since the main resistance to heat flow is from the gas to the tube metal the total heat absorption is actually not markedly increased by the increasing rate of flow. This accounts for the fact that boilers with high circulation velocities are not materially more efficient than those with much slower rates of flow. The second largest resistance to the heat flow is from the metal to the water. Provided the metal were continually in contact with moving water this part of the resistance to heat flow would be materially less. As the rate of steam generation increases this later resistance increases. For high-pressure forced circulation with its higher continuous velocities of flow would reduce this resistance. It is, however, probable that a further large reduction in this resistance can be attained.

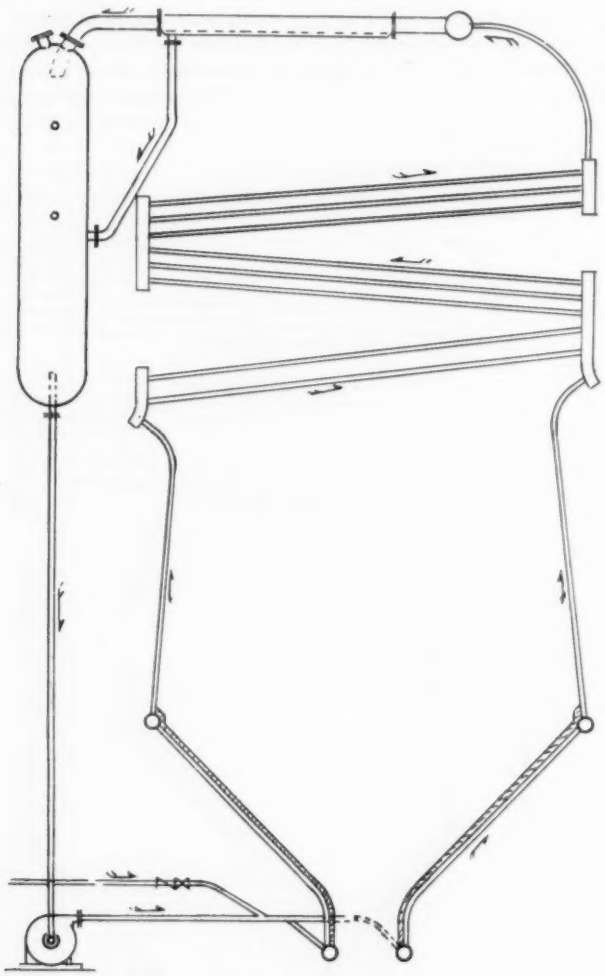

FIG. 8 BOILER WITH DRUM OUTSIDE THE SETTING IN A VERTICAL POSITION

In various heat exchangers twisted plates or spiral coils have been used to increase the heat-exchange effect for an equivalent pressure drop. Where the conditions have been favorable and the design correct considerable gains have resulted. Formerly when all boilers were designed for use with dirty water and a natural circulation it has been rightly deemed inadvisable to clog the internal-flow areas of boilers in any way whatsoever. With forced circulation and with practically absolutely clean water required for high pressures it seems proper to consider what advantages could be realized and the probable effect of an induced centrifugal flow. With the mixed vapor and fluid content it is apparent that centrifugal flow would force the fluid against the tube walls or in the place it is desired.

It would thus wipe off steam bubbles from the heating surface and prevent the formation of a lagging water film. On account of the fact that the largest resistance to heat flow—namely, from the gas tube—still remains, it is doubtful just how much the heat absorption would be increased. (Tests of the revolving elements of the Atmos boiler indicate a large gain.) It is certain that a decided increase in the safety factor relative to burns would be attained. In fact, it seems possible in this way to obtain a boiler free from any danger of burning as long as the feedwater was maintained reasonably clean. There is a further advantage of a gyratory circulation in that all surfaces of the tube inside would be kept wet whether the tube were vertical, inclined, or horizontal, and whether the flow was upward or downward through the tube.

One form of spiral core is shown in Fig. 9. This core would allow a clear opening through the center and would be clear of the tube surface. Thus there would occur in the center a direct flow of the steam and the swirling water would wipe the surfaces and carry along any contained solids. To obtain the best results from the use of such a core, tests should be run to determine the proper pitch and size for each design of boiler. It seems certain that with the gyratory effect increased heat absorption and at the same time a reduced pressure drop through the boiler could be achieved.

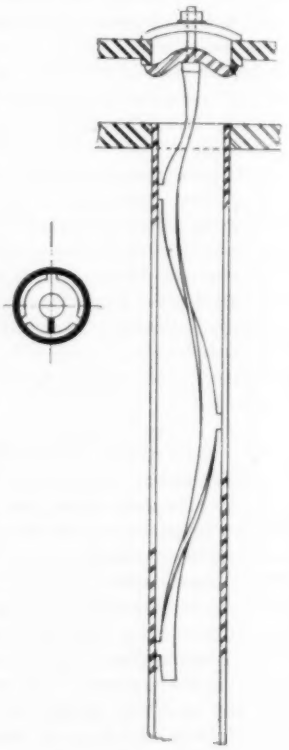

FIG. 9 SPIRAL CORE

With stationary plants where load variations are due to external causes and thus where automatic combustion control must start subsequent to the load change, heat storage is necessary for satisfactory operation. This would also be true where a large bulk of incandescent fuel or refractories are present in the furnace. On the other hand, with locomotive power plants, where a liquid or pulverized fuel is used and where the large load variations are operatively determined, large heat storage is not needed and may often be a detriment to good operation. For in this case pre-regulation of combustion control combined with the rapid response of a flash boiler to changes in combustion intensity should suffice to take care of large load changes. With small load variations only nominal heat storage is required. A properly designed flash boiler and combustion control should have ample. Where, however, there is probability of having to operate for intervals with dirty water a small storage with recirculation

effect should be added to prevent scale or deposit lodgment on the tube surfaces during low loads. Normally it would be so advantageous for locomotive power plants to eliminate extra storage that it would seem advisable to provide for always operating with clean feedwater.

In Fig. 10 a sketch of a flash boiler is shown. Since the economizer, superheater, and boiler sections proper are all parts of one heat absorber in the case of a true flash boiler they are included in the sketch. This arrangement assumes the use of cores in the boiler sections. It is probable that they should be used in the superheater also.

In connection with the construction of such a boiler as is indicated in Fig. 10 as well as for all high-pressure boilers, it is pertinent to state that all tubes, drums, and headers should be placed, built, and arranged so that they can be internally cleaned, inspected, and replaced without displacing or altering other parts of the boiler.

Combustion Control

At present there is no combustion control equipment used with or suited to locomotive power plants. There are, however, two factors that render its application to them easier than for central stations. The first is the possibility of allowance for pre-regulation as noted before. The second is that normally a much higher draft drop through the heating surfaces is used. On account of the latter characteristic a more positive force is available for regulation. Thus there are stationary plants operating very satisfactorily with automatic combustion control where the draft drop through the heating surfaces varies only from 0.05 in. to 0.8 in. water pressure per square inch for a load variance of 50 per cent to 300 per cent. With a locomotive power plant the variance in draft drop would probably have to be made at least 5 in.

There are different methods by which pre-regulation can be obtained. One would consist in operating during stand-by and while driving at different pressure ranges. For illustration, consider a master controller suited for regulation either between 1225 and 1175 lb. pressure or between 1250 and 1200 lb. Standing by, with only auxiliaries running, the master controller would be set to control combustion between 1175 and 1225 lb. On starting to drive opening of the throttle would first change the master controller's pressure range to between 1200 and 1250 lb. Thus the combustion intensity would be increasing as the throttle valve opens.

On stopping or throwing off of load the reverse procedure would be followed. One form of emergency overloading would need to be guarded against for locomotive plants—namely, wheel slippage. To take care of this and to prevent any excessive boiler pressure drop either an auxiliary automatic throttle valve or attachment on the main valve should be installed to close off gradually in case of excessively low boiler pressures. Any such arrangement should be provided with compensating and dampening effect.

Feedwater-Flow Control for Flash Boiler

In the past one of the main troubles experienced with flash boilers and one that especially prevented their use in large sizes was the failure of the automatic controls provided. Combustion control was not understood at the time and the methods tried were defective in principle and design. At present the requirements are fairly well understood and there should be no trouble in developing suitable equipment.

With the small flash boilers in use and formerly tried out two methods of automatic flow control have been used. One is regulating the feedwater flow by the boiler pressure and the other by the temperature of the out-flowing steam. The latter method apparently is the correct way for large sized units producing superheated steam. An analysis of possibilities would suggest the use of the saturated vapor pressure of mercury. It is possible that a direct regulator with a mercury generator in the steam outlet and a diaphragm-actuated flow valve could be evolved. This would, however, require careful consideration of relative volume, expansion, and temperature characteristics. A surer way would be to utilize the oil-pressure hydraulic system, required for the combustion control, to regulate the flow valve and feedwater-pump governor. Then the mercury-vapor pressure would only have to actuate a small four-way oil valve.

At first glance it appears that temperature regulation of flow control would act inversely to requirements. Thus on increase in loading, the pressure drops, coincidentally, the velocity of flow

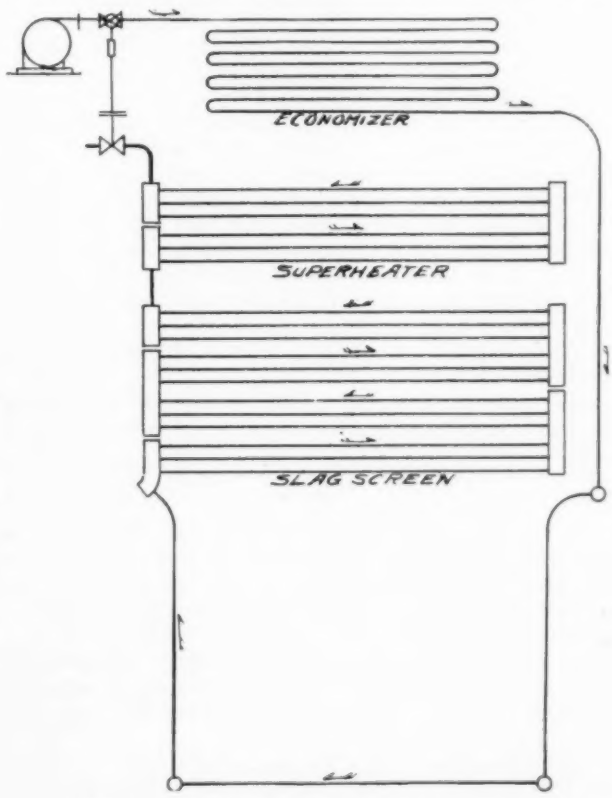

Fig. 10 Type of Flash-Boiler Construction

increases, both factors tend to drop the steam temperature and thus through the flow regulator to reduce the feedwater flow. Thus for a few seconds the increasing load is carried on stored or partially stored water. The control, however, would restore conditions to a balance before any possible damage could result. Meanwhile temperature control should insure a much closer adherence to a uniform temperature of steam than could be obtained where the steam temperature depended on many varying factors as with water-line control of feedwater.

With temperature-flow control the functions of the superheater, boiler, and economizer are interchangeable to a certain degree. Thus as the load increases the superheating section of the boiler decreases in extent, and steam formation will probably take place at an earlier point in the flow or in what would normally be the economizer.

On this account it would be impractical to provide temperature regulation of flow where any storage and recirculation effect is used.

Boiler Auxiliaries

Aside from the boilers high-pressure plants have experienced some troubles with boiler feed pumps. In some cases where hydraulic balancing was used it was found necessary to use special thrust bearings. This same trouble has often occurred to a less extent at lower pressures. In other cases there were minor troubles in keeping the high-pressure glands tight. A cure for both of these troubles would appear to be to use balanced-stage types of pumps with the stages arranged so that the lower pressure stages are on both ends.

Combustion

Experience of recent years has show more fully the feasibility of burning pulverized coal at the intensities requisite for use with the largest powered high-pressure steam locomotives where a fair efficiency is attained. Experience has also emphasized the importance of providing fine pulverization, preheated air, slag screens, complete water walls, or water-cooled furnace walls, adjustable turbulent burners, and a positive automatic combustion control where high intensities and efficiency are aimed at. Compromises have proved futile.

Dangers feared from storing and handling pulverized fuel have not developed. However, for locomotive power plants it would be advisable to eliminate all danger by storing in an atmosphere of CO_2. This can easily be drawn off from the fuel gas through a separator and a small amount constantly forced into the storage space. The storage compartment should then only be vented at the top through a seal. With a straight flash boiler pulverized coal or oil would of course be required. When supplementary storage and recirculation are added to the boiler, stoker firing can be used. Suitable automatic combustion control should always be used.

Drive

For stationary high-pressure plants both turbines and engines have proved satisfactory on the score of reliability and efficiency. Troubles encountered have been few and easily remedied where suitable materials have been used and where the temperatures have not been excessive.

With locomotives high-pressure engine drives with atmospheric exhausts have been used, and are showing up well as far as reliability is concerned. The types used have not been such as to attain a good machine efficiency.

The turbine drives used on locomotives have mostly been standard pressure, condensing with gear transmission. The efficiencies at high speed have been fairly good. Apparently the maintenance of the gears and the unsuitable characteristics of the variable-speed turbine will always limit this type of drive to a few special services and conditions.

Electric transmission, with Diesel-engine-driven locomotives and for marine service with turbine drive, has shown an all-around economic superiority over gear transmission. For turbine-driven steam locomotives the superiority of electric over gear transmission should be even more pronounced.

At present it appears that for large locomotives the combination high-pressure direct-acting compound engine with a low-pressure turbo-generator drive promises the best economies. For smaller units a compound engine drive with the high-pressure cylinder of standard type and the low-pressure cylinder a modified uniflow construction would show fair efficiency and low first cost. Complete turbo-generator electric drive while more expensive and not as efficient as the combination drive would suit many conditions better. It would have better acceleration than complete engine drive and could be arranged for operation from a trolley over electrified zones.

Condensers

In high-pressure steam locomotives provided with an efficient regenerative heating effect the size of the condenser required would be much smaller than for standard-pressure locomotives. At the same time the desirability of condensing effect is greater with high pressure due to the necessity of a clean feedwater for the boilers.

Present condensers used on locomotives have been fairly successful in producing condensing effect. They are at the same time too bulky and expensive to warrant the assumption that they are a successful solution. The writer has analyzed the problem and is convinced that an evaporative condenser with forced air circulation and cooling sprays located near the front can be built to give a fairly high vacuum.

Two designs have been sketched out for a 28,000,000-B.t.u. cooling effect with a 24-in. vacuum at 70 deg. temperature and 60 per cent humidity. The surfaces were based on a heat transmission derived from various tests on indirect hot-air heaters, automobile steam condensers, and some early evaporative condensers. There are no tests that would apply closely to the conditions involved. With the assumptions taken the volume requirements would be very small relative to types of condensers used for locomotives. In addition the first cost would be even smaller in ratio due to the simplicity of a direct effect. The essential details work out so as to provide amply for steam flow, air flow, expansion, and structural strength. Placed at the front of the locomotive the power required for the fan would be small during most periods of operation. With low temperatures or low loads very little condensing water would be required. At freezing and below, fair vacuums could be maintained without any condensing water. At high temperatures there would be little reduction in the vacuum obtained due to the large increase in evaporative effect for a small temperature rise. Spray and fan operation could easily be made to regulate automatically from the condenser pressure. Apparently the probable advantages of this type of condenser are so great that a thorough trial would be justified.

Oil Separation

With cylinder drive and condensing effect a separation of the cylinder oil is required. With stationary plants large gravity-type separators when properly designed and of suitable size have proved satisfactory. With locomotive power plants there is not sufficient space to use this type.

For pressures above atmosphere there are one or two designs of centrifugal separators that will remove most of the oil and moisture from the steam. At condenser pressures they are not so efficient. There is one design of separator with a revolving core that would be especially efficient with an outside drive that would maintain at all times the proper speed for maximum separation.

In addition to any separation used, filtration should be provided. There are several filtration mediums that will clean the water of all oil as long as they are kept clean or the filterant replaced at frequent intervals.

Conclusion

At the present time the writer feels that progress toward high-pressure steam drive for locomotive power plants is tending in the direction of exploitation of special patented devices combined with a retention of undesirable features of standard practice.

Most of the experience and knowledge are now extant which if combined could produce a safe high-pressure steam locomotive that would give a real all-around economy without adventuring in excessive temperatures or dangerous conditions. Such further knowledge as is required can be obtained at a reasonable cost and with a small effort. Offhand statements as to practicability or vice versa are of no value.

RR-52-6

High-Pressure and High-Temperature Steam for Locomotives

By C. F. HIRSHFELD,[1] DETROIT, MICH.

The author states his position as that of giving to railroad men the benefit of experience had in stationary steam-power-plant practice and not as that of telling them what to do in locomotive practice. The advantages of high pressures and temperatures in stationary practice are considered separately for condensing operation and for back-pressure operation, respectively, and the differences are stressed. Certain experiences and observations regarding the behavior of metals and the boiler circulation under extreme conditions are given, and these are followed by speculations regarding the possible lines of development of locomotives.

LET me start this paper by making several statements having nothing to do with high steam pressures and temperatures.

First, I know practically nothing about steam locomotives in the sense in which railroad men know about them;

Second, I have great respect for the engineers who have developed the steam locomotive to its present state; and

Third, I am not presumptuous enough to believe that I can teach such men anything about that which they know so much about and with respect to which I know so little.

With such an introduction one might well inquire why I present this paper. To be perfectly frank, it does not result from any spontaneous ebullition of ideas insistent upon being disclosed to the world at large or to a particular group in that world. It was asked for by your Division, apparently in the belief that one familiar with modern developments in stationary steam practice might be able to bring you useful thoughts and experiences from that field. I recognize this as a possibility and, remote as it may be, it must serve as my excuse.

Some thirty-odd years ago the stationary-plant engineer began a march of progress which probably represents one of the most remarkable advances ever made in a like period. It happens that my life in the capacity of wage earner started at about the beginning of this period, and that a teaching experience of some years caused me to become familiar with the history of power-plant engineering in the preceding period.

The combination has often led me to contrast mentally the radically different rates of progress and to speculate as to the cause of such differences. At first I saw the cause in the development of this or that piece of equipment, but I have finally come to realize that the basic cause was a change in the outlook of the human beings who served as leaders. I am convinced that when the progress of stationary-plant engineering during the first third of the present century is viewed in retrospect, the most striking characteristic will be found to be the willingness of the leaders to cut loose from the past and to try new things, to strike out boldly into unexplored fields.

Looking at the steam locomotive through the eyes of an engineer who has concentrated his efforts in the stationary field, I am struck by the fact that it appears to have improved little during the period in which my own field of endeavor has made such rapid progress. To be sure, it has been made bigger, superheaters have been adopted, feedwater heaters have been added, and so on, but the locomotive that I viewed with wonder as a small boy and the locomotive that I view more understandingly as a middle-aged man are essentially the same.

Now of course this might be due to the fact that the locomotive of my youth was already so well developed that no further improvement of a basic or fundamental type could be made. Or, it might be due to the fact that after reaching that stage in the development of this device its designers became conservative, refused to make radical departures and contented themselves with improvements of a minor character. Or again, it might be due to the fact that the railway industry did not require any more radical changes to enable it to operate satisfactorily under the economic conditions which have existed. Admittedly, I am not sufficiently skilled in this particular field to enable me to judge. However, I sense the fact that the second and third explanations are probably the correct ones, with most of the weight upon the third.

Basic Changes in Locomotive Design Apparently Necessary

If one may judge from the presently evident movements in the field, the economic conditions have altered to such an extent that basic changes in locomotive design are felt to be necessary. If this be the case, designers will have to bestir themselves and acquire a new point of view. No longer will it be sufficient to improve by whittling here and adding there. It will be necessary to consider the whole problem *de novo*, to depart temporarily from all the traditions of the past, to let the imagination have free rein in team with analytical ability. What will evolve may possibly be guessed at; it certainly cannot be predicted.

It is natural that in considering any radical change from past practice, designers should give thought to what has happened in more or less parallel fields, as for instance in that of the stationary power plant. Such developments may or may not be applicable to the plant required to move about as does a locomotive, but the facts cannot be determined except by analysis and possibly also by experiment.

When the locomotive designer begins to study recent stationary-plant development he discovers marked increases of steam pressure during a comparatively short period, and latterly a very evident tendency toward radical increases of steam tem-

---

[1] Chief, Research Department, The Detroit Edison Company. Mem. A.S.M.E. Mr. Hirshfeld received the degree of B.S. from the University of California and his Master's degree in Mechanical Engineering from Cornell University. Until 1913 he served as a member of the faculty of the latter institution, then becoming associated with The Detroit Edison Co. He has continued his consulting practice in the electric light and power industry. During the War he was granted a leave of absence to serve in the Ordnance Department of the Army, being commissioned major and advancing to the rank of lieutenant-colonel.

Contributed by the Railroad Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

perature. It is but natural to ask whether these are proper items for serious consideration in his field of endeavor.

In stationary practice there are two radically different conditions leading to the use of high steam pressure. The first is the higher thermal economy obtainable in condensing plant. The second is the greater quantity of power obtainable from steam expanded in engine or turbine and then exhausted, at pressures near or above atmospheric, for process or heating purposes. Such reasons have underlaid an increase of average steam pressure from about 180 lb. gage in 1900 through 200 lb. gage about 1913 to about 450 to 500 lb. gage today with increases to 1400 and

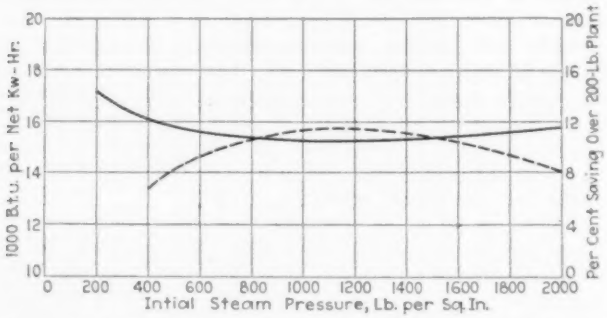

FIG. 1 SOLID CURVE SHOWS STATION HEAT RATE, RANKINE CYCLE, NO REGENERATIVE FEED HEATING, STEAM AT 700 DEG. FAHR. BROKEN CURVE SHOWS PER CENT SAVING OVER 200-LB. PLANT

1800 lb. in a few exceptional cases. The average steam pressure in representative locomotives is today about 220 lb. gage, with a pressure of about 280 lb. as the highest normal value. Higher pressures are in use, but may still be regarded as more or less experimental. The figure of 280 corresponds to the value reached in stationary practice in exceptional cases about fifteen years ago, and in very common use about eight to ten years ago. I can still remember very vividly the shaking of heads that accompanied the first increases above that value.

BELIEF THAT THERMAL ECONOMY INCREASES INDEFINITELY WITH INCREASING STEAM PRESSURE ERRONEOUS

There is a popular belief that thermal economy increases indefinitely with increasing steam pressure and this belief has been responsible for quite a bit of loose thinking. Comparatively simple calculations suffice to show that it is erroneous.

The thermal economies obtainable with various steam pressures and temperatures in condensing operation are shown in a convenient way in Table 1. In preparing this table certain assumptions were required; it is not believed necessary to recite them here, suffice it to say that they were so made that the figures given are directly comparable, and that these figures give conservative values for well-operated turbine equipment of moderately large size.

A brief survey of these figures will show what appear to be extraordinarily good performances for low-pressure, low-temperature plants. The figures are believed to be approximately correct in this respect. They reflect the fact that during the progress to higher pressures and temperatures we have made other improvements in plant design. If these improvements were carried back to the low-pressure plant, the performance of the latter would be much better than the performances mentally associated with such pressures. This is a fact which should not be overlooked; at least a good part of the credit that has been given popularly to higher steam pressures in modern plants belongs properly to improved plant design.

For the purpose of indicating both the thermal advantages and limitations of higher pressures and temperatures in condensing operation, a few numerical relations will be considered. Take, for example, the decreased heat consumption resulting from the increase of pressure at a given temperature and using the Rankine cycle, that is, without regenerative heating. These values, taken from Table 1, are plotted in Fig. 1, using steam at various pressures but at a single temperature, namely, 700 deg. fahr. As a matter of fact the curve is partly non-realizable because beyond about 500 lb. initial pressure the water content of the steam at and near exhaust pressures would become too great to be economically usable with available turbine equipment. It is at once apparent that the great improvement with increasing pressure occurs in the lower ranges for such conditions as are indicated in Fig. 1, and that there is a reversal, that is, an actual loss if the pressure is carried high enough. It is questionable whether any pressure higher than 500 to 600 lb. could be justified for such conditions. A higher initial temperature would alter the conditions slightly. With an initial temperature of 1000 deg. fahr. there would be a continuous improvement up to and including 2000 lb., but the total reduction in passing from 1000 to 2000 lb. would be only 350 B.t.u. as against almost 2000 B.t.u. in passing from 200 to 1000 lb.

A great part of the saving that is achieved through the use

of high-pressure steam in condensing stationary practice is achieved through the use of regenerative feedwater heating. The higher the pressure, the greater the effect of this process. Thus, using figures from Table 1, the saving resulting from regenerative heating in four stages at 200 lb. and 700 deg. fahr. is 1410 B.t.u., whereas at 2000 lb. and 700 deg. fahr. it is 2274 B.t.u. However, even with regenerative feedwater heating,

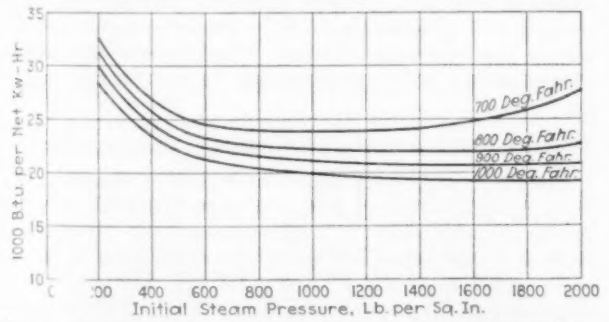

FIG. 3 STATION HEAT RATES FOR VARIOUS INITIAL STEAM PRESSURES AND TEMPERATURES. 5 LB. PER SQ. IN. BACK PRESSURE. FEEDWATER HEATED TO 212 DEG. FAHR. LARGE TURBINE PLANT—(20,000-KW. UNITS)

the gains obtainable with like pressure increments become increasingly smaller as the pressure increases and ultimately reverse. This is shown in Fig. 2, which corresponds to Fig. 1. Comparison of the percentage curves of the two figures will show the effect of regenerative feed heating in increasing the saving resulting from increased steam pressure.

Inspection of these curves indicates that at 700 deg. fahr. there is probably little justification in exceeding about 600 lb. without regenerative heating and something like 800 to 900 lb. with four-stage regeneration, unless reheating be resorted to. In practice the limits are set in both cases close to 500 lb. because of the serious effect of condensate in the steam. The situation is naturally improved by increasing the initial temperature. If 1000-deg. fahr. steam could be used, the practical or commercial upper pressure limit without reheating would probably be in the neighborhood of 1000 lb.

THE QUESTION OF STEAM CONDENSING LOCOMOTIVES

The question of whether condensing operation is possible or desirable with steam locomotives appears to be unanswered as yet. If the experiments that are now being made with condensing turbine-driven locomotives should prove such construction to be commercially feasible, the figures just given may serve to indicate the extent to which steam pressure may be profitably carried when viewed with respect to thermal considerations only.

There are, however, other considerations which may also be weighty, particularly in the case of locomotives. Thus, for example, high-pressure steam occupies much less space per unit of weight than does saturated steam. One pound of steam at 200 lb. absolute and 700 deg. fahr. occupies a space of 3.4 cu. ft., whereas the same weight at the same temperature, but at a

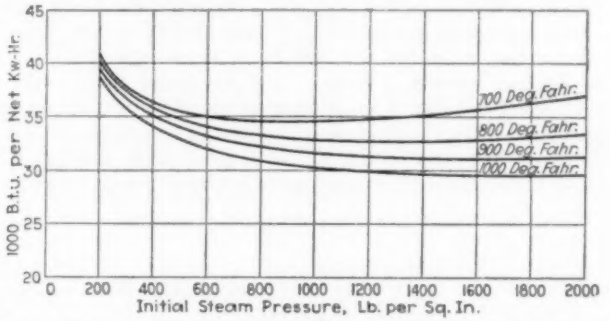

FIG. 4 STATION HEAT RATES FOR VARIOUS INITIAL STEAM PRESSURES AND TEMPERATURES. 5 LB. PER SQ. IN. BACK PRESSURE. FEEDWATER HEATED TO 212 DEG. FAHR. SMALL TURBINE PLANT (2000-KW. UNITS)

pressure of 1400 lb., occupies only 0.4 cu. ft. As a result of this fact, pipes and other parts for high-pressure steam may in fact weigh less than for the equivalent amount of low-pressure steam. Many peculiar effects follow from this and other characteristics of high-pressure steam, and it is almost certain that the thermal savings will not be completely determinative.

When non-condensing operation is considered we obtain an entirely different sort of picture from that disclosed above. I

shall present it as it appears when considered with respect to industrial plants in which steam is exhausted for process purposes. You who are more familiar than I with the locomotive engine can translate my figures easily to the terms in which you deal.

Numerical values for this condition are given in Tables 2 and 3, and certain of the tabulated numbers and values obtained therefrom are shown in Figs. 3, 4, 5, 6, and 7. It should be noted that these values are developed for steam-turbine plant, and that large and small units, respectively, are considered. In reciprocating plant running under conditions of greatest economy the values would probably lie between those shown for the two sizes chosen.

Inspection of Fig. 3 shows the same sort of reversal in the 700-deg. fahr. curve that was noted for condensing conditions. With the highest initial temperature a continuous improvement is shown with increasing pressure. The really significant figures for non-condensing operation are those plotted in Figs. 5 and 6, giving the net output per 1000 lb. of steam expanded down to 5 lb. gage pressure. Even at the low initial temperature of 700 deg. fahr., Fig. 5, an increase of output of over 20 per cent is obtained from a given weight of steam by raising the initial pressure from 200 to 400 lb. It is particularly interesting to note the comparatively small gains resulting from increasing the

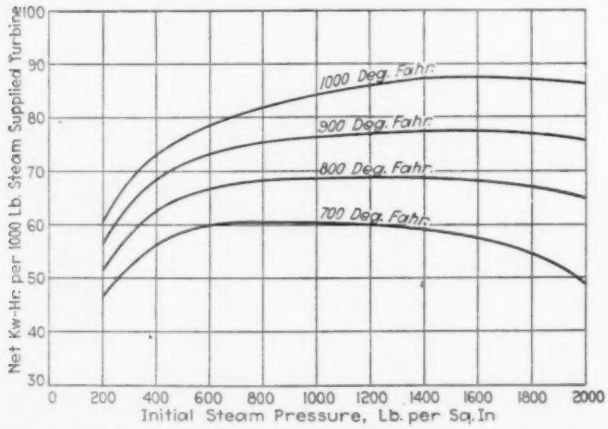

FIG. 5 NET POWER MADE AVAILABLE FROM A GIVEN WEIGHT OF STEAM AT VARIOUS INITIAL CONDITIONS AND 5 LB. PER SQ. IN. BACK PRESSURE. FEEDWATER HEATED TO 212 DEG. FAHR. LARGE TURBINE PLANT (20,000-KW. UNITS)

initial pressure above 800 lb., even at comparatively high initial temperatures.

DECREASE IN ENGINE SIZE WITH INCREASE OF PRESSURE

The curves given in Figs. 7 and 8 probably put this matter in somewhat more significant fashion for the locomotive designer. These curves show the decrease in "engine size" with increase of pressure. In this case this means area through the last set of blades and volume of exhaust casing. In the case of a reciprocating engine it would correspond roughly to piston displacement under conditions of minimum cut-off. It will be noted that the decreases in engine size are really significant, and it should be remembered that similar or greater decreases occur in all steam-carrying parts. It will also be noted that the greater part of the decrease is attained in most cases by the time a pressure of 600 to 800 lb. is reached.

It is at least conceivable that the combination of decreased fuel consumption per unit of output and the decreased volume might be used in locomotive practice in either one of two ways. One would be the increase of capacity without increase of grate area or its equivalent; the other would be decreased size of parts for present output. It would take much more technical knowledge of the field than I possess to evaluate the significance of such possibilities. I shall have accomplished my end if I have shown you that, even in such simple matters as thermal performance and output per pound of steam, the situation is highly complicated and requires detailed study; that it is quite erroneous to assume that improvement in these respects must necessarily follow increase of steam pressure or temperature.

It should be helpful to consider what may be expected if theoretical considerations along such lines as are suggested above

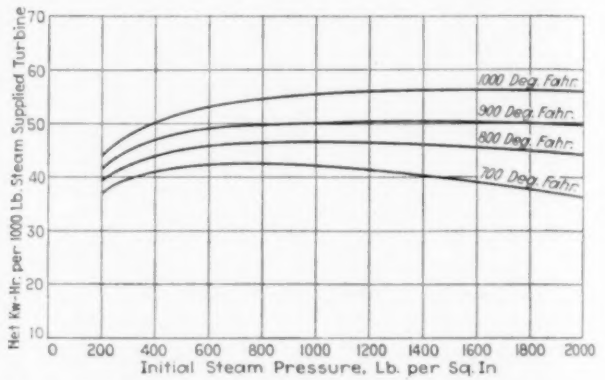

FIG. 6 NET POWER MADE AVAILABLE FROM A GIVEN WEIGHT OF STEAM AT VARIOUS INITIAL CONDITIONS AND 5 LB. PER SQ. IN. BACK PRESSURE. FEEDWATER HEATED TO 212 DEG. FAHR. SMALL TURBINE PLANT (2000-KW. UNITS)

should show that radical increases of pressure and temperature promise worth-while results in locomotive practice. Enough has been said to indicate that initial temperature is very closely bound up with initial pressure in turbine practice. The same thing is true to some extent in reciprocating-engine practice, even in non-condensing operation. Therefore the consideration of permissible initial temperature appears to be the logical starting point.

TEMPERATURE LIMITATIONS IMPOSED BY METALS AVAILABLE

Experience with steam superheated above a temperature of 750 deg. fahr. is still too meager to make it safe to draw final conclusions with respect to higher temperatures. At present it looks as though carbon-steel tubes can be used safely to produce steam with a temperature of 800 to 850 deg. fahr. provided the metal temperature does not rise too high. The limit in this respect is taken at present at about 950 deg. fahr. provided the steam is practically free of oxygen when it reaches the superheater tubes. It is also necessary to so design that the unit stresses in the metal do not exceed something of the order of 4000 lb. per sq. in.

The importance of oxygen-free steam cannot be ignored as experience indicates that very rapid attack upon the metal may be expected at such metal temperatures if any appreciable quantity of oxygen is present in the steam.

This is also the temperature at which reaction between iron and steam begins to become noticeable. As a matter of fact, this reaction does not occur to a sufficient extent at 950 deg. fahr. to be at all significant, but it becomes of great importance at between 1000 and 1050 deg. fahr. The reaction is such that a very closely adherent magnetic-oxide scale is formed on the steam side of the tube and hydrogen passes off with the steam.

Higher temperatures may be used with alloy steels such as the nickel-chromium alloys and others which show higher creep strengths than the carbon steels. Such metals have been used in experimental equipment delivering steam at 1100 deg. fahr., and there is no indication of short life due to creep, simple oxida-

tion, or reaction with steam. Unfortunately the available alloys are all very high priced, and their metallurgy and physical behavior are not yet well understood.

These facts would seem to indicate that we are limited to steam temperatures of the order of 800 to 850 deg. fahr. if restricted to carbon-steel tubing, and that we can probably extend this temperature to 1000 or 1100 deg. if the cost of the more expensive alloys can be justified. These figures immediately enable us to determine the highest steam pressures that show thermal advantages under any selected set of conditions. It must be realized, however, that the thermal considerations

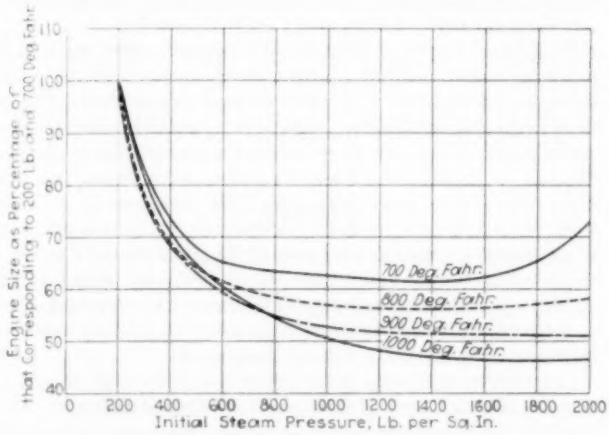

Fig. 7 Effect of Initial Steam Conditions on Physical Size of Engine. Large Turbine Plant. 5 Lb. per Sq. In. Back Pressure

alone are not completely determinative. There are many others of operating and economic character which are equally important, and much more difficult to evaluate with respect to any particular field.

Boiler Characteristics at High Pressures

If one chose about 800 deg. fahr. as the highest temperature which now seems reasonably possible under locomotive conditions, it would appear from thermal considerations as though a pressure in the neighborhood of about 800 lb. might be usable for non-condensing operation. It becomes pertinent to inquire into boiler characteristics at such pressures. Stationary experience with the higher pressures has been had with water-tube boilers exclusively, and with comparatively clean and pure boiler water. It is a long cry from such conditions to those found in average locomotive practice.

With properly designed water-tube boilers there has been no evidence of any intrinsic limitations to adequate natural circulation at pressures in the neighborhood of 600 to 700 lb., and there is no reason to expect such trouble at 800 lb. On the other hand, when pressures of 1200 to 1400 lb. are reached, the forces causing natural circulation appear to be approaching such magnitudes that very small changes of design or condition may lead to serious trouble.

In this country we have succeeded in obtaining commercially satisfactory operation at such pressures with water-tube boilers of what one may call conventional design, but it has required careful design and careful operation. European engineers, on the other hand, calculated in advance the forces that should be available for creating natural circulation, and concluded that somewhere in the neighborhood of 1200 to 1400 lb. one entered the questionable region. It is possible that this is responsible for some or all of the radically new types of high-pressure steam-producing equipment now being experimented with in Europe.

Speaking first in general terms, the temperature of saturated steam rises with its pressure. Thus, even though the metal surfaces be scrupulously clean on the water side and even though we assume the same thickness of metal in all cases, the average temperature of the boiler metal increases as the pressure under which steam is generated increases. It is also true that with similar structures the metal thickness would increase with pressure, so that at a given rate of heat transfer its average temperature would also increase slightly because of the slightly greater temperature drop through the metal. It is also obvious that an increasing rate of heat transfer through the metal must correspond to an increasing temperature drop through that metal and thus to a higher average metal temperature.

In stationary practice and with clean water no limit to increase of pressure has yet been set by such phenomena. However, two things of interest have been uncovered. An almost unbelievably small amount of scale on the water side in 1200- to 1400-lb. pressure boilers is fatal to those surfaces subjected to high rates of heat transfer. And it is possible to show by calculation that, with heat-transfer rates which may be regarded as possible of achievement, the metal of exposed tubes in a 1400-lb. pressure boiler may reach temperatures at which the existing stresses will cause fairly rapid creep.

If one may judge from such meager evidence, it would seem that even if the locomotive boiler were modified structurally so as to

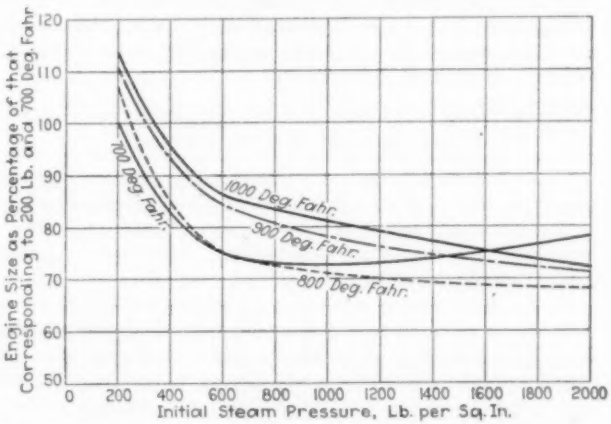

Fig. 8 Effect of Initial Steam Conditions on Physical Size of Engine. Small Turbine Plant. 5 Lb. per Sq. In. Back Pressure

adapt it to use with pressures of this order of magnitude, the feedwater conditions now characteristic of locomotive practice would make operation at such pressures impossible. In fact, I greatly doubt whether operation at a pressure as low as 400 lb. could be conducted commercially without great improvement over present feedwater practice as it exists throughout the country.

Feedwater Problem One of the Most Important

Looking at this field from the outside, I am impressed with the feedwater problem as one of the important ones that must be solved before any great advance of pressure can be contemplated safely. The situation of the railroads in this respect appears to me to be similar to that of the stationary plant of the better sort only a comparatively short time ago. It is only seventeen years since the first equipment for supplying distilled make-up in condensing stationary plants was installed, and even now we are only beginning to understand the treatments required in cases in which we cannot return an adequate supply of condensate. I confess that I do not know just how the problem should be

handled in railroad practice, but I am convinced that some better solution than that now in hand must be found before great increases in steam pressure can be safely contemplated for general use. It may be possible that the savings of various sorts that may be made through the use of higher pressures will be found sufficient to justify large, well-distributed feed-water-treatment plants, with transportation of treated water to various intermediate supply points. Or it may be that sufficiently skilful chemists can develop more perfect and simplified treatments which can be applied on the individual locomotive with such talent as is available in its operating crew. Or it may be that condensing operation will be found feasible, even though condensation be conducted at or near atmospheric pressure. I leave such considerations to those sufficiently skilled in the economics of railroading. But I do feel that the crux of the problem lies right in this factor, and that solution calls for radical thinking, for a deliberate reorientation and a new attack upon the problem.

I am also convinced in my own mind, possibly because of my ignorance with respect to the details of the problem, that the present type of locomotive boiler must pass out if much higher pressures are to be used with the maximum of economic results. Much as I admire the peculiar fitness of the present type, I cannot but feel that it represents one of those things which, surviving through its peculiar fitness, has served to limit the possibilities of improvement of major character. We have been through this thing in the stationary field and in the marine field, and it is possibly only natural to assume that we may expect a parallel development in the railway field.

Possible Devices of Locomotive Development Utilizing High Pressures and Temperatures

I have even been so bold on occasion as to endeavor to picture just what sort of boiler I would design for a high-pressure locomotive if that problem were put up to me. That it must have a water-cooled firebox is almost self-evident. That the water-cooled surfaces should take the form of tubes for high pressure instead of plates is almost equally obvious. I suspect also that the conditions of use are such that a large reservoir of steaming ability must be available in some form. Beyond these rather rudimentary specifications one would appear to have a very clear field, provided always that the problem of a satisfactory feed-water supply can be solved.

Such thought as I have given to the matter always brings me back to substantially the same picture, which I give you for what it may be worth. I conceive first of a rather large reservoir which shall be adapted to hold a volume of water substantially at boiler temperature and which shall serve as a source of steam supply to meet sudden short-time demands. Associated with this reservoir is a system of water tubes serving as a water-tube boiler. These form the firebox and, besides, give such added surface as is required to reduce the products of combustion to an acceptable temperature. Circulation through these tubes is produced by a pump which draws from the hot-water reservoir, and the tubular surface is so arranged as to discharge to that reservoir. The water tubes simply serve as a collection of heating paths starting at the pump discharge and ending at the pump suction, i.e., the reservoir from which the pump draws. Steam made is tapped off this heating system as required. I imagine that the pump speed will be regulated with respect to steam demand so that it will always circulate a large excess of water.

This may appear to you to represent very radical thinking. In one sense it is. In another, it represents a fairly logical mental extension of the path that we have followed in stationary practice. Whether it has any merit other than that of provoking comment and thus the exercise of the imagination, I know not. I do know that the imaginable solutions of the problem are so numerous that it is almost a foregone conclusion that our present one is not in all respects the best one, particularly when one considers its age and the air of assured respectability that age has conferred upon it.

One familiar with locomotive design will undoubtedly view with alarm the steam temperatures that have been suggested as desirable with higher pressures. Even a temperature of 800 to 850 deg. fahr. is not a pleasant thought in connection with locomotive engines of present design. But, once more, assuming that we retain the reciprocating engine, is the present design a necessary result? I think not.

It is almost certain that some type of poppet-valve mechanism will have to be substituted for the present types in which metal slides on metal. But I cannot see that this necessarily offers insurmountable difficulties. Cylinder lubrication, as we now understand it, will also have to be abandoned. It is at least possible to conceive of a design of piston reciprocating in a cylinder which does away with actual metallic contact between these parts and, thus, with the necessity for cylinder lubrication of any sort. Guiding and support of the piston would then have to be taken care of externally and two packings would be required. Incidentally, packing against steam at high pressure and at a temperature of 800 deg. fahr. is no mean problem but even here promising solutions are now imaginable.

If we cut loose from present designs and adopt the condensing turbine solution, many of these problems disappear, but others of equal or greater magnitude make their appearance. However, they do not seem to me in my ignorance to be more difficult than many that have been solved successfully in other fields in recent years by the simple method of breaking completely from the conventional and considering all possibilities without too great reference to past convictions.

It seems necessary to call attention to one other feature of high-pressure plant that has not been touched on. The values given in Tables 1, 2, and 3 and illustrated in several figures were calculated on the basis of a constant boiler-plant efficiency. This involved an assumption which is important in the present consideration. This assumption was that the tendency of the temperature of the flue gases discharged from the boiler to rise with increase of steam pressure, due to the increased saturation temperature, was balanced by the proper addition of heat-absorbing surface of some form. A similar problem will develop in locomotive practice if very high pressures are resorted to. It may be that the economics of the situation will prove to be such that a net gain may result from the use of higher steam pressure in spite of a greater loss to the stack. On the other hand, it may prove necessary to install auxiliary heat-absorbing equipment, such as economizers or air preheaters. The facts can be determined only by a most detailed analysis and possibly by later experiment.

In closing, I should like to repeat in slightly different form what I said in starting. I am merely commenting on your field as a rank outsider. As such an outsider I have the disadvantage of lack of familiarity with details. But I have a corresponding advantage; namely, that the knowledge of details does not prevent me from wandering mentally over many possibilities which one skilled in the field would be apt to dismiss peremptorily because of preconceived ideas.

To me your locomotive of the present day appears as the product of a marvelous development which has been carried to, or close to, its logical end. To me it appears as though the developments in other fields during the past three decades and the changes of mental attitude that have occurred in a still shorter period indicate the probability that your field is about ready to

substitute, in the near future, revolutionary changes for the evolutionary ones that have characterized it in the past. And, if this be the case, it is probable that high steam pressures and accompanying high steam temperatures, with all that they appear to portend in the way of greatly modified forms, will come in for real consideration and ultimate adoption. Such development will call for the exercise of the best that is in you, but I do not doubt but that you who have brought the locomotive to its present high state of specialized perfection will prove equal to the task if you will only attack it with a conscious rejection of all preconceived ideas; if you will test each possibility with open minds and not in the light of some generalization based upon findings, or supposed findings, of a bygone generation. I am certain that if you do attack your problem in this way you will find much valuable information in the field in which I am more at home, and I am also certain that you will find the engineers in this field more than willing to give freely of their accumulated experience for such use as you may be able to make of it.

Discussion

JAMES M. TAGGERT.[2] The author brings out several features that are essential for real progress in the application of high steam-pressure drive to locomotives.

In the first place, it is necessary to entirely change the general design from present standard practice. The present arrangement is dominated by the type of boiler used, and this type of boiler is obviously unsuited to high pressures. In the second and third places, respectively, purity of feedwater, required for high pressures, and condensation of the exhaust, requisite for efficient utilization of the steam, coordinate. Present central-station practice indicates that only by condensation can a pure feedwater supply be assured at a reasonable cost. Thus the solution of the condenser problem apparently depends on the solution of the feedwater problem.

The problem of combustion is not touched on in the paper. It is, however, intimately concerned with the other features involved in considering high-pressure steam drive for locomotives. Thus at present one of the largest losses is due to the high temperature of stack gases. With high pressures the temperature of the gases leaving the boiler would evidently be higher except as the high pressures would reduce the amount of fuel. Economizers and air preheaters would be needed to reduce this loss. On account of the increase in temperature difference in this equipment, the steam-generating efficiency could be increased without much, if any, space increase, provided a suitable design were selected.

A further large loss in present locomotives is due to incomplete combustion, especially at high loads. There is therefore required a method of fuel burning that will provide for complete combustion at higher combustion intensities within the furnace. Fortunately, pulverized-coal burning supplies this need. Recent progress indicates that with suitable fineness of pulverization, preheated air, a slag screen, and a properly designed furnace, sufficient combustion intensities can be attained for locomotive practice, provided an efficient high-pressure steam drive is used.

In connection with combustion, the question of storage of heat and combustion control is associated. Thus the author visions for the future high-pressure locomotive a rather large reservoir of water at boiler temperature. Is he not in this respect allowing himself to be influenced by present locomotive construction? With pulverized-coal feed and automatically controlled combustion, the writer is inclined to think that a properly designed flash boiler can be used. It should be considered that, except for operative control, locomotive loading depends on speed, and momentary changes in speed are not of vital importance.

All large variations in load are operatively determined. Thus combustion can be pre-regulated. This feature, combined with the ready response of a flash boiler to combustion changes, should eliminate the need of storage where pulverized or liquid fuels are used. With stokers some storage would evidently be needed, but the amount required would be less than for central stations where loading must be sustained and where combustion control is subsequent to load changes.

In considering efficiencies of steam utilization, the form of drive and arrangement are essential factors. Over the high-pressure range direct drive with steam cylinders properly designed should give a higher ratio of tractive horsepower to Rankine effect than any turbo-generator referred to electrical output. Over the lower pressure range with condensing effect, turbines are essential for good efficiencies.

The writer has taken up these points in a paper presented at the November 15, 1927, meeting of this section, and in the discussion before this section at the annual meeting last year, as well as in articles published in the September and October, 1927, issues of *Railway Mechanical Engineer*.

K. A. MAYR.[3] There are few men that have as much experience with high-temperature and high-pressure steam as Mr. Hirschfeld, and though his experience and activities may be mainly on the stationary power-plant side, the writer believes that we are to be congratulated because he gave his ideas on the application of high-pressure and high-temperature steam to locomotives. Since the locomotive engineer has so many more limitations and has to answer requirements so radically different from those with which the stationary power-plant engineer is concerned, we can understand that each step deviating from the customary design meets considerably more obstacles than if the same step is made in a stationary plant. We can understand that the locomotive designer prefers to leave the pioneering and experimenting to the stationary plant engineer, although he does not quite live up to the tradition of the early locomotive pioneer when following such a policy.

The author left the possibility of steam reheating, when using higher steam pressure, entirely out of his report. Because of the very heavy load variations on a locomotive power plant, it will be difficult to carry the initial steam temperature so high as we have it, or certainly shall soon have it, in the stationary plant. On the other hand, the much smaller and much more compact locomotive power plant lends itself quite easily to the use of steam reheaters. If reheating is introduced, we have not only dry steam in the low pressure stages of the plant, also, if we use only moderate initial steam temperature, but we are able to bend all the curves shown on the author's diagrams much more in favor of the higher initial steam pressures, and we would have a much more increasing economy for steam pressures above 1000 lb., and could continue a material improvement even up to pressures as high as 2800 lb.

The writer wishes to refer to the figures given in his paper on the ultimate steam pressures and temperatures, which was published in *Power* on April 1, 1930. These figures would favor the higher pressures still more if it would have been assumed that the high-pressure stages of the plant would be performed in a piston engine and only the low-pressure steam would work in turbines.

High steam pressures, particularly in plants of comparatively small output, such as locomotives, can be used more economically in a piston engine than in a turbine, the piston engine giving at the same time a better means to take care of the high starting torque

[2] Consulting Engineer, New York, N. Y. Assoc-Mem. A.S.M.E.

[3] Chief Engineer, Siemens-Schuckertwerke A. G., New York, N. Y. Assoc-Mem. A.S.M.E.

demanded on a locomotive. The economy of the piston engine is not so sensitive to pressure variations, and a forced or speed-flow boiler can be used with small storage capacity, but built for sufficient high pressure, so that a high torque can be obtained from small cylinders. Such a boiler responds immediately to an increase in draft, and if artificial draft is provided, heavy loads can be started or accelerated with great economy. One could think of condensing the exhaust from the piston engine of, say, 200 lb. in an evaporator, as it is done with the exhaust steam of the high-pressure engines at the Deepwater Station. The feedwater question for the high-pressure boiler would thus solve itself automatically, and at the same time the water contents of the evaporator would mean a considerable steam storage capacity, so needed in locomotive service. The steam generated in the evaporator could be superheated and used in a turbine, which inherently lends itself more effectively to low-pressure steam. Feedwater heating stages could be arranged in such a system, and a condenser, which is a very difficult problem on a locomotive, could be dispensed with.

The author has already mentioned something of the decreasing dimensions of engines for steam of higher pressures. Considering the smaller amounts of steam per horsepower, the boiler heating surfaces become smaller, or if customary dimensions per horsepower are retained, become much more efficient. The same applies to the combustion chamber, and reflects itself on the space requirements for water and fuel.

The present-day locomotive already uses the allowable space to the limit, although much more power-fuel units are desired. Higher pressures would mean that 25 to 30 per cent more power could be made on the same space.

There is one point which is of great importance in these days of smoke-abatement campaigns. One need not be a combustion expert to find out when sitting on the observation platform of a modern railroad train that the combustion chamber of the present-type locomotive is too small and burns, at least on the upgrades, only half of the coal which is shoveled in. Now, if we need 30 per cent less steam to generate the required power, we need 30 per cent less coal, and as we need 30 per cent less steam, we can make it on a smaller boiler; and if we care to retain the same overall dimensions as we have them on the present locomotive, we can use not only the same size combustion chamber, but could even make it a little bigger, and the writer wonders whether that chamber would not burn 30 per cent less coal with much less smoke and certainly much more efficiently.

H. B. Oatley.[4] The Railroad Division in particular, and the railroad engineering fraternity in general, are to be congratulated on having this paper. Coming from one who has made such a thorough study and who has reached such sound conclusions, it deserves, and without doubt will have, careful consideration given to the suggestions contained therein.

It is refreshing to have this question of higher steam pressures and higher steam temperatures, as applied to the locomotive, discussed in the broad and dispassionate manner in which the author has treated it. We have in the past frequently had this question presented as a completely solved one, and have had laid down in front of us new locomotives with all of the appurtenances that are found in the up-to-date industrial plant; and while unquestionably the design on paper would show thermal advantages that commanded attention, the practical difficulties of space and weight limitations very often appeared to have been entirely overlooked. The fact that the locomotive designer cannot build a multistoried structure, nor does he have a city block on which to erect his boiler, is many times not fully appreciated by the industrial engineer who offers remedies for locomotive ills. The writer repeats, therefore, that the author of the paper has recognized these limitations, and because of that recognition, his paper has greater value than any similar presentation before the Railroad Division.

The author also has appreciation of the fact that regular attendance of a trained personnel, as found in the industrial field, becomes, with the locomotive, a case of handling and maintenance by dozens of different groups in as many different roundhouses and shops. He appreciates also the severity of operating conditions as imposed by weather, by vibration, by the use of all kinds of water, and also by the rapid and wide variation in output demand to which the locomotive must respond.

The author has pointed out the thermal advantages of increasing the steam pressure and the steam temperature, and has also indicated that there are limits beyond which thermal gain should not be expected. This is a fact that must be kept in mind in considering the further development of the locomotive and its parts.

There does not seem much doubt that the conventional form of locomotive boiler will give way to a structure in which the use of flat surfaces subjected to the higher steam pressures will be eliminated. It is true that stay-bolted fireboxes are being used for pressures up to 300 lb. per sq. in. and that flat-stayed surfaces have in a few instances been retained for pressures somewhat above this figure. In general, however, staybolts, radial stays, and diagonal bracing have disappeared when steam pressures have exceeded 300 lb., and in their place there is found the water-tube firebox with relatively small diameter steam and water drums. The indications are that this is the direction in which locomotive boilers will be developed. In marine and industrial practice, staying has almost entirely disappeared for pressures above 250 lb. per sq. in.

The point was made that with increasing steam pressures, the steam-carrying parts, as well as the prime mover, become smaller in bulk and less in weight. In the locomotive field particularly, the matter of weight is constantly before the designer, and from this angle alone the use of higher steam pressures has a decided appeal. Where reciprocating engines are used as in the locomotive, the decrease in weight of reciprocating and rotating parts is a particularly attractive feature. Should the turbine replace the reciprocating engine for locomotives, the decrease in turbine size would appear to be particularly advantageous as it would equate in some measure for the added weight of the transmission which appears to be a necessary unit of the turbine-driven locomotive.

The use of highly superheated steam has been part of the locomotive design since early in this century, and it may be added that the use of a high degree of superheat on the locomotive antedated its use in industrial practice. Steam temperatures of 650 deg. and upward have been considered as standard for the past 15 years.

The increase in steam temperature does, as the author points out, offer advantages of no small amount. The designer of boiler and superheater, and particularly the latter, is confronted with the lack of materials available for use at prices which are not prohibitive. He is in reality sitting on the doorstep of the metallurgical field, waiting for the handout of a steel which will have noticeably better physical properties and which may be worked through the same shop manufacturing operations as the carbon steels now used. It must be available at a much lower price than the heat-resisting alloy steels now on the market, many of which, while superior in physical characteristics, are not available in the forms required. As an illustration of the point, there might be mentioned the use of seamless alloy-steel boiler tubes which are available and have been used to some extent. While

[4] Vice-President in Charge of Engineering, Superheater Company, New York, N. Y. Mem. A.S.M.E.

they may meet the requirements of the water-tube boiler where tube safe-ending is rarely if ever resorted to, it would at the present time be a very expensive luxury for locomotive conditions, both on account of the increased initial cost and the fact that the safe-ending of such tubes is uncertain, if not impracticable. For the superheater construction and for steam pressures thus far used in locomotive service, carbon steel to the standard specifications and for steam temperatures up to 800 deg. fahr. has served remarkably well. As we step up another 100 deg. or 200 deg. in steam temperatures, it seems reasonable to believe, as the author has pointed out, that we shall require steels having higher physical properties at elevated temperatures as well as being more oxidation resistant at the higher temperatures to which they will be subjected.

The whole tone of the paper strikes a responsive cord. To quite an extent some of the suggestions he has made have already taken form and substance. The elimination of stayed surfaces, which has already been mentioned, is not a recent development in locomotive boilers, either here or abroad. The forced circulation of water through the firebox tubes has been worked out and includes the use of a scale-free heat-absorbing medium. Forced circulation of steam through a tubular firebox structure has already been used. The multi-pressure locomotives, built and building, represent a step, possibly several steps, toward the goal which has been set by the author. In these locomotives a steam pressure of 850 lb. per sq. in. and a steam temperature of 750 deg. fahr. has been provided. This high-pressure steam is indirectly generated by steam at 1300 lb. per sq. in. generated from distilled water, circulating through water tubes forming firebox and combustion chamber. The use of this heat-transfer medium thus avoids the hazard of scale on the surfaces subjected to the high-pressure and high temperature, and, at least in part, meets one of the suggestions which the author has made.

The matter of natural versus forced circulation is admittedly a topic for thought and discussion. Forced circulation has advantages as well as disadvantages. It must be admitted that if a natural circulation which is stable and which is of sufficient intensity to protect the heat-transfer surfaces can be assured, it is preferable to a forced circulation which requires absolutely continuous operation of the circulating unit. Whether or not it is necessary to rely upon a mechanical device for such a circulation in locomotive practice, appears to be undetermined. There is no difficulty in providing it in the multi-pressure system, although thus far natural circulation has been shown to be adequate.

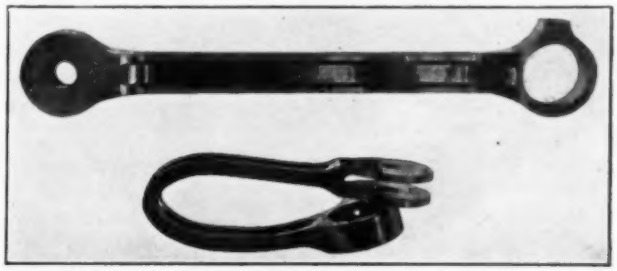
Alloy Steels in the Railroad Field

By CHARLES McKNIGHT,[1] NEW YORK, N. Y.

There is increased interest in the use of alloy steels by railroads. They are used purely as a matter of economics. Better work must be done at the same cost or the same work at less cost. The use of alloy miscellaneous castings materially cuts down weight with the same strength and same cost as carbon-steel castings. There are three ranges of steels: carbon steels are used for the vast majority of railroad purposes, with alloy steels for special applications, and semi-alloy steels, which are slightly more expensive than carbon steels and with slightly better properties, as a compromise. Some of their uses include boiler materials, forgings, and castings. Corrosion-resisting materials, nitriding, and miscellaneous metals are discussed and the economics of operation are given.

INTEREST among railroad technical men in the use of structural alloy steels is a very live one at the present time. This is undoubtedly due to the present necessity for lightness, strength, and increased reliability, and as the development of motive power progresses the use of these alloys will become larger and larger. As a matter of fact, the railroad field is showing a larger growth in the use of such alloys than any other one.

Steel is the most used and most useful structural material because of its cheapness and its adaptability. It is the strongest commercial material, the maximum obtainable ultimate strength being over 300,000 lb. per sq. in., yet sometimes it is used where weakness is desired, as for shear pins in machinery. It is capable of being rendered intensely hard, yet it must be very soft for such purposes as stampings and wire. With strength, toughness is usually demanded of it, yet certain so-called "screw-stock" steels are intentionally made very brittle.



With so many contrasting qualities, it is easy to infer that steel is not simple by nature. In fact, it is a very complex material, so complex that it is difficult even to define "steel" in a satisfactory manner. Essentially it is elemental iron with varying amounts of other elements, such as manganese, silicon, phosphorus, sulphur, and carbon. Carbon is the Damon to iron's Pythias. It is very difficult to produce iron free from carbon, and it is the influence of carbon that so radically changes the characteristics of steel. A piece of soft wire, a machine bolt, a razor blade, a locomotive cylinder are all essentially the same except for the carbon content.

It is the carbon in steel which renders it so susceptible to heat-treatment; cooled slowly it becomes soft, and cooled quickly, as by plunging in water, it is capable of becoming almost glass-hard.

The history of steel is the history of man learning to produce irons with varying proportions of carbon, and learning to control and use them after they were produced. About the middle of the last century it was possible to produce commercial steel with any desired carbon from the few hundredths of a per cent that are in mild sheets up to the range where steel merges into the shadow of cast iron. At this time the empirical knowledge of the heat-treatment of steel was well abreast of the necessities of the day, although little was known of the actual role carbon played. However, industry was beginning to demand more of steel than the metal of the day could give, and these demands became more pressing as time went on. Eventually the answer came in the form of alloy steels, which opened up a new field in metallurgy and broadened tremendously the scope of engineering.

The two first alloy steels to be developed were the 14 per cent manganese steel and silicon transformer steel, but owing to their restricted uses they were not available for structural purposes. The first structural alloy steel was nickel steel. The origin of this steel lies back beyond history because all meteors are essentially nickel steel, but the first recorded use was in the Middle Ages when some of the famous Damascus swords are known to have contained nickel. In 1885 the commercial manufacture of nickel steel was begun in France, and in 1889 Riley read his paper on the subject before the Iron and Steel Institute.

This began the real growth. Creusot in France made some 3.5 per cent nickel-steel armor plate which demonstrated its superiority so conclusively that in 1890 the United States Navy

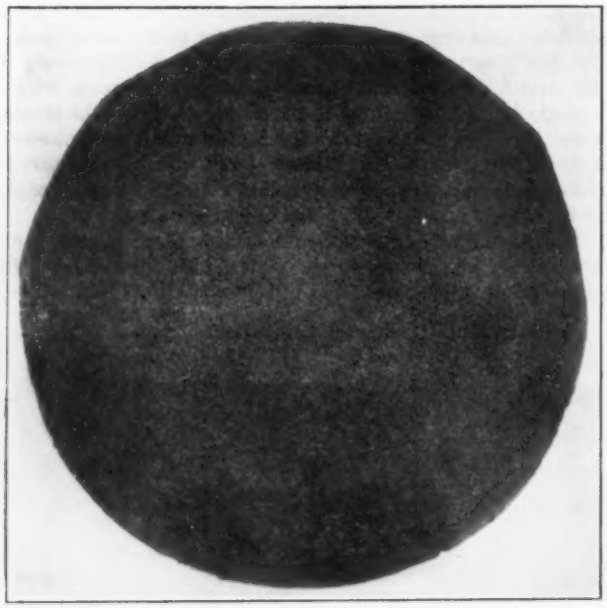
Low-Carbon Alloy-Steel Side Rod Bent Cold to Show Ductility

adopted it for armor after a conclusive and competitive test. Authorities state that the adoption of nickel steel for armor plate was as revolutionary as the construction some twenty years later of the "Dreadnaught."

By 1896 alloy steels were being used quite widely in naval vessels, for guns, armor plate, and projectiles, in heavy machinery, to a limited extent in the railroads, and quite largely for bicycles. The development of the automobile helped the growth, and from 1900 on till the present the production curve mounted steadily.

Some confusion has occurred because steels are being sold today under names indicating that they are alloy steels when, as a matter of fact, the content of "alloying element" is very slightly above that normal to all steels. An example of this is the so-called "silicon steel" which is used for ship plate and structural shapes. The silicon is actually only a few hundredths of one per cent higher than usual and the term is a misnomer. Such steel could better be called "killed steel" than "silicon steel." On the other hand, the two elements common to all steels, manganese and silicon, have valuable alloying properties, and recently these properties have been taken advantage of to produce a cheap and satisfactory steel.

An alloy steel may be defined in a general way as a steel containing an appreciable percentage of one or more elements (other than iron and carbon) conferring special virtues on the metal. This definition, however, does not tell the whole story. To be worthy of the name, alloy steel must necessarily be of a better quality and made better than a similar straight-carbon



[1] The International Nickel Co., Inc.

Contributed by the Railroad Division and presented at the Annual Meeting, New York, N. Y., Dec. 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

steel. Otherwise a large part of the advantage gained by the alloy addition is lost. It is probable that, were it possible to remove the alloy from steel after manufacture, the alloy steel would still be superior to ordinary steel, simply on account of the additional precautions taken.

This quality is one reason for the additional cost of alloy steels. If the price per pound of alloy steel is analyzed, it will be found that the alloy addition alone is not sufficient to account for the excess cost. For example, 3.5 per cent nickel steel is currently quoted in bar form at 4.15 cents per pound, while

ETCHED SECTION OF FORGING FOR MAIN DRIVING AXLE SHOWING AVERAGE STRUCTURE

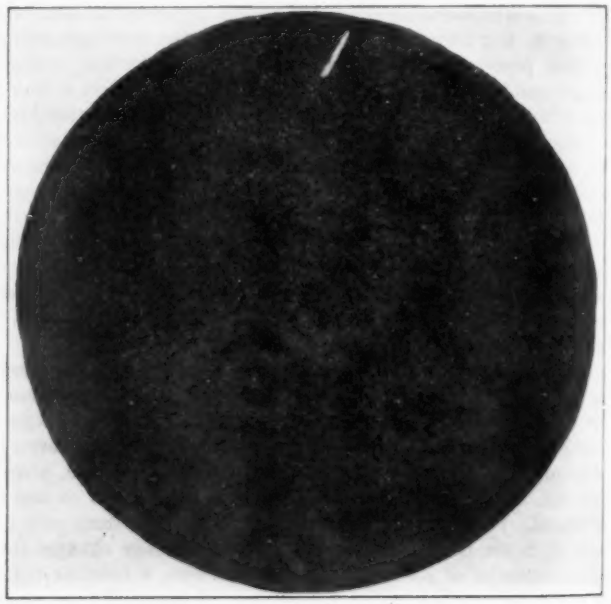
carbon-steel bars are a little under 2 cents per pound. The nickel addition alone, even at 35 cents per pound for nickel, accounts for not quite 1.25 cents. Therefore, almost one cent, or little less than the cost of the alloy, goes for the "quality factor." Although this may seem out of all proportion, it is not unfair for the steel manufacturers to make such a charge, providing the steel is really of good quality.

The designing engineer finds at his hand three types of steel.

Carbon Steels. These steels are used for the vast majority of purposes for very good and economical reasons. There is a tendency, in the view of recent metallurgical developments, rather to belittle carbon steel, but it should be remembered that conscientiously made carbon steel will in most places give more per dollar than any other structural material. The field of locomotion by land, water, and air furnishes an outstanding exception to this generalization.

Alloy Steels. Alloy steels are essentially special steels for special purposes. The growth in their use has been and will be rapid, but it is a mistake to use an alloy steel where its use is not justified.

Semi-Alloy Steels. This term is really a misnomer as there should be a sharp distinction between alloy steels and carbon steels. At the present time, however, there are steels on the market which have had relatively small extra additions of metalloids ordinarily used in making steel. They are slightly more expensive than carbon steels with slightly better properties. They are a compromise between the two other grades, and it remains to be seen if they can justify themselves economically.



ALLOYING ELEMENTS AND CHARACTERISTICS

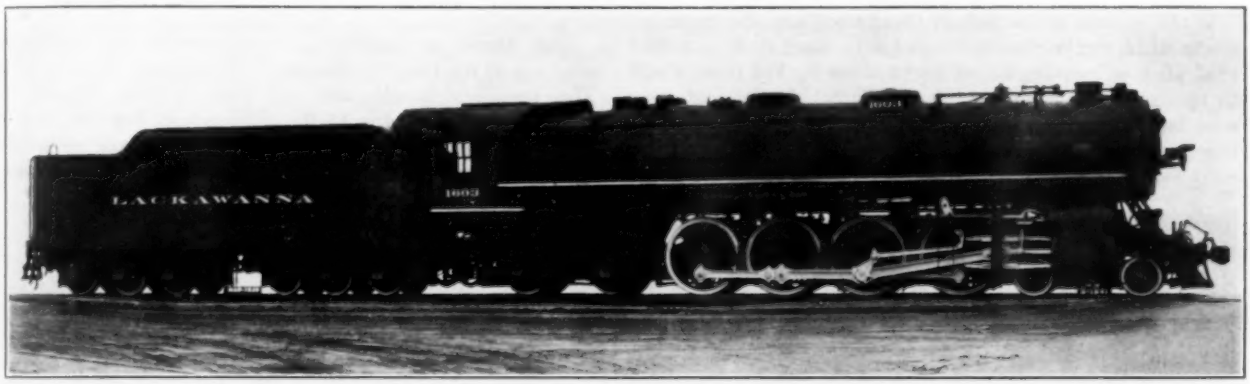
The most common alloys used in the manufacture of structural steels are nickel, chromium, vanadium, molybdenum, manganese, and silicon.

Nickel. It is used in ranges from 0.50 to 5.0 per cent for structural steels, but its useful range is from 0 to 100 per cent. It alloys with iron in all proportions, but does not form carbides or oxidize in a furnace. It responds to heat treatment and is added for toughness, strength, and hardness.

Chromium is used in ranges from 0.25 to 2.00 per cent for structural steels, and in higher ranges for corrosion- and heat-resisting purposes. It acts on steel through carbide formation, oxidizes in steel-making processes, and responds to heat treatment. It is added for hardness and strength.

Vanadium is used in ranges of not over 0.25 per cent in structural steels, though up to 2.0 per cent in high-speed tools. It acts through carbide formation, oxidizes very easily, and is, therefore, a powerful scavenger. It responds to heat treatment and tends to refine grain. It usually is used in combination with other alloys, and is added for strength and toughness.

ETCHED SECTION OF FORGING FOR MAIN DRIVING AXLE SHOWING VERY POOR STRUCTURE



Molybdenum is used in ranges up to 0.50 per cent in structural steel. It acts principally through carbide formation, does not oxidize, responds to heat treatment, throws scale in forging operations, is rarely used alone, and is added for strength and hardness.

Manganese is present in all steels below 1.0 per cent. It is used in ranges from 1.0 to 2.0 per cent in structural steels, acts through carbides, but is also dissolved in iron constituent, oxidizes readily and is a very good deoxidizer, and responds to heat treatment, but gives somewhat erratic results and requires great care. With some other alloy acting as a restrainer and toughener, it is much less erratic and is added for strength.

Silicon is present in all steels up to 0.60 per cent, as it is added for a deoxidizer. It is not used in strict structural service except for springs, where it is used in ranges from 1.00 to 2.00 per cent and is most used in electrical transformers in ranges of from 3.00 to 5.00 per cent. It oxidizes very readily. It is interesting to

note that the strongest steel (not cold-worked) of record is a nickel-silicon.

Of these alloys, nickel is the most used either alone or in combination with other elements such as chromium and molybdenum. The reason for this is that in addition to the benefits derived through the effect of the alloy itself on the steel, nickel is the only alloy which goes entirely into the iron constituent of the steel, thus rendering it independent of the carbon. It is one of the two alloying elements which do not oxidize in the steel furnace, thus making the process of manufacture simpler and more certain, as well as making it possible to recover all nickel from scrap, and it has a wider useful range (0 to 100 per cent) than any other alloy.

Locomotive Using Alloy-Steel Forgings

Forgings of Alloy Steel

The locomotive designer in recent years has adopted alloy steel for forgings more generally because of the larger power units, and because the size of forgings cannot be increased indefinitely. Strictly speaking, it is not a new development. In the early days of alloy steel the railroads were among the first users, but alloy steels got quite an unsavory reputation with them. The reason for this was that it was not then appreciated that mass makes a great difference in the properties of forgings, and that the heat treatment must conform to the size of the piece. It is manifestly ridiculous to compare the $1^1/_4$-in. rear-axle shaft of an automobile with a 10-in. or 12-in. locomotive driving axle, and yet, in the early days, the same steel and the same heat treatment were used for both with disastrous results in the case of the driving axle.

Fifteen or so years ago, after a temporary lapse, alloy steels again began to be used with intelligently written chemical specifications, and intelligently conceived and controlled heat-treatments. While quite a number of alloy-steel forgings are still heat treated by quenching in some liquid medium such as oil or water, it is generally conceded that such drastic treatment, while producing higher strength, is not conducive to the greatest reliability. Strength is, therefore, sacrificed to a slight extent, the cooling medium is air instead of a liquid, and the large forgings of today are much freer from strains and cracks.

The heat treatment in general use today for large railroad forgings is specified by the term "normalize and draw" or "normalize and temper." In this process the metal after forging but before machining is slowly heated to a predetermined temperature, and is held at that temperature one hour or more for each inch of cross-section. The predetermined temperature is one higher than the so-called "critical point" of the metal, at which the various constituents of the steel merge into an amorphous solid solution. This critical point varies with the carbon and alloy content of the steel. The higher the carbon, the lower the critical point. The alloy having the most marked effect is nickel, which has a tendency to lower it. Sixteen hundred deg. fahr. is, in the absence of accurate data, taken generally as a safe temperature for normalizing. Higher temperatures than this induce excess grain size, and lower ones are not safely above the critical point.

After the steel has remained at this temperature the required time, it is removed from the furnace and is allowed to cool in still air, free from draughts and not exposed to rain, snow, or other chilling agency. When it has cooled so it is no longer red, it is replaced in the furnace and heated to the "drawing" or "tempering" temperature. This is in order to free the metal from stresses set up by cooling, and to put it in the best condition for service from a metallurgical standpoint. The drawing temperature must, of course, be lower than the critical point. It is usually about 1100 to 1200 deg. fahr. and the forgings are again kept at that temperature for one hour or more for each inch of cross-section, after which they are cooled either in the air or furnace. It does not matter greatly which cooling method is used, but probably the air cooling is preferable.

Good heat treatment of alloy-steel forgings is an essential, but again quality is a great factor. No alloy ever made bad steel good. It is necessary, as a metallurgist has aptly said, to begin the manufacture of alloy steel with its pre-natal care, and, as a railroad man even more aptly said, to choose your steel-maker as you would your physician. Quality brings in so many details, such as method of manufacture, rolling vs. pressing, etch-tests, etc., that they can hardly be hinted at, much less discussed, in a paper of this length.[2]

The majority of alloy-steel forgings now made conform to one of the following types:

1 Carbon-vanadium steel, normalized and tempered.
2 Nickel steel, normalized and tempered.
3 Chrome-vanadium steel, quenched and tempered.
4 Nickel-chromium steel, quenched and tempered.

The first two air-treated types probably account for more than 75 per cent of all alloy-steel locomotive forgings, as the latter two are not widely used.

As representative of what may be obtained from an alloy-steel forging of large size, normalized and tempered, carbon-vanadium steel analyzing:

Carbon	0.40–0.50 per cent
Manganese	0.75–0.90 per cent
Vanadium	not less than 0.18 per cent

[2] For an extended discussion of these factors, the author recommends the paper on "Locomotive Forgings" by Lawford H. Fry. Transactions of the American Society for Steel Treating, to be published presently.

will give on the average tensile values of:

Ultimate tensile strength	90–100,000
Yield point	60– 70,000
Elongation in 2 in.	22–28 per cent
Reduction of area	40–45 per cent

For comparison, carbon steel with about the same carbon (0.45–0.50) will give:

Ultimate tensile strength	75–85,000
Yield point	40–50,000
Elongation in 2 in.	18–25 per cent
Reduction of area	35–42 per cent

In the opinion of the author, these are about the maximum results which can be obtained from a normalized steel, no matter what alloy or combination of alloys is used. Yet there is still an uncomfortably large number of failures. In the past there were failures with wrought iron, so steel was adopted; there were failures with steel, so alloy steel was adopted. Perhaps our reasoning has been wrong, and strength is not the absolute criterion of a good locomotive forging. In the past six years there has come into prominence and popularity a steel which deliberately sacrifices a little strength to obtain a lot more toughness and shock resistance. The carbon content is much lower than is usual, and nickel is the supporting alloy. Such a steel, normalized and tempered, has in large locomotive forgings given an average of:

Ultimate tensile strength	83,535
Yield point	60,371
Elongation in 2 in.	31 per cent
Reduction of area	60 per cent
Carbon	0.24 per cent
Nickel	2.58 per cent

Impact tests are illuminating. Izod impact values on this steel, made on test pieces from large forgings, run 50, 60, 70 ft-lb., and even higher. This indicates more than double the shock-resisting capacity of the usual higher-carbon alloy steel. Such a steel merits attention.

Alloys Used in Castings

A large proportion of the weight of a locomotive is made up of castings, both steel and iron. The frame alone constitutes a considerable part of the locomotive weight. Alloys are employed in these castings either to strengthen and toughen them, or by strengthening, to make possible the employment of lighter sections. Sometimes special characteristics are sought, such as wear resistance in cylinder bushings and heat resistance in iron grate bars.

It is believed that the first alloy-steel castings to be extensively used by the railroads were carbon-vanadium. This was introduced for locomotive frame castings some fifteen years ago, and excellent results have been obtained with it.

The alloys, alone or in combination, most employed in railroad work for steel castings are, vanadium with content not less than 0.18 per cent, manganese 1.00 to 2.00 per cent, and nickel 1.50 to 3.00 per cent. With a carbon content of from 0.30 to 0.40 per cent, these alloy steels give minimum physical characteristics of

Ultimate tensile strength	80,000
Yield point	45,000
Elongation in 2 in.	25 per cent
Reduction of area	45 per cent

Such figures are obtained on large castings, such as frames, after a heat treatment consisting of normalizing and tempering. This treatment is essentially the same as that detailed for forgings. However, due to the difference in the structure of castings as compared with that of rolled or forged steel, it is quite usual to employ a preliminary heat treatment known as a homogenizing treatment. This is carried out at a higher temperature (1600–2000 deg. fahr.), and the castings are air-cooled. By it the original casting structure is more completely broken up. Smaller castings will have somewhat higher properties, and for such castings it is often permissible to use the "quench-and-temper" treatment to obtain even better results, provided the section is not too intricate. In this field, too, interesting results have been obtained by departing from the conventional, and using a low-carbon alloy steel.

Alloy-Steel Side-Frame Casting Weighing 13,250 Pounds

A valuable application of alloy steels for castings was brought out by the chief mechanical engineer of one of the largest systems on this continent. He could obtain low-carbon alloy-steel castings at approximately 35 per cent increase in price over ordinary steel castings. He therefore designed some new power to use alloy-steel castings, cutting down the section on all castings to $^1/_3$ of the former size, but maintaining a minimum section of $^1/_4$ in. By these means the net cost of the castings per locomotive was the same, but the total weight of castings was $^1/_3$ the previous figure, and the strength was slightly higher. The saving in weight per locomotive was on the order of 10,000 lb., which could be applied to power-producing purposes.

In the past few years there has been a vogue for the one-piece locomotive frame. These intricate and large castings are a tribute to the skill of the steel foundrymen. Hitherto they have been made from an ordinary low-carbon steel, both for simplicity and to facilitate welding. Some few frames have recently been made with a low content of alloy and it may be predicted with confidence that future developments will include the further use of alloys in order to improve the strength and toughness of these castings.

Boilers of Nickel Steel

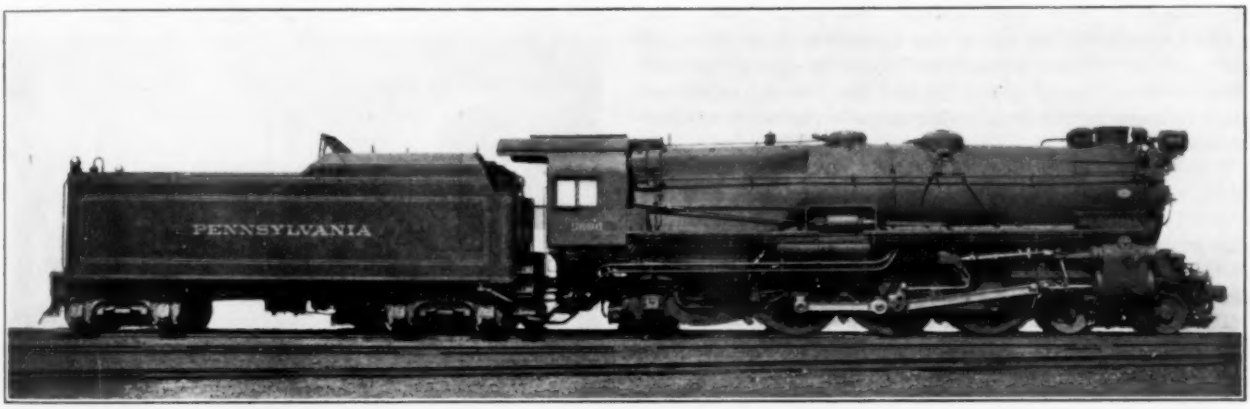
The present tendency toward higher boiler pressures has made the designer turn to other materials for boiler construction. Increased boiler pressure means increased boiler weight, if carbon steel is employed. In addition, in many cases the thickness of the plate now being used is about the maximum which can be handled.

Faced with this problem, in 1926 the Canadian Pacific Railroad adopted nickel steel for boilers, and succeeded in increasing the boiler pressure 25 per cent without any increase in weight. The steel employed, a 3.0 per cent nickel steel with a minimum tensile strength of 70,000 lb. per sq. in., was approximately 30 per cent stronger than carbon steel, and therefore the factor of safety in spite of the increased pressure was actually higher than before. On this first order 44 locomotives were constructed, 24 Pacific type and 20 Mikados. Today there are over 150 such boilers in service on the railroads of this country and Canada, and in no development is there greater interest among railroad operators.

While this step was apparently unprecedented, inquiry has since developed that in 1904 a locomotive was built employing nickel steel for the boiler and this is still in service. Some years earlier this plate had been used for the tubes and boilers of the *U.S.S. Chicago*, so the question of how the material would stand service was answered.

For high-pressure boilers the only two steels used in any quantity have been manganese, from 1.00 to 2.00 per cent, and nickel, 1.75 to 3.25 per cent. The vast majority of alloy-steel boilers, in fact practically all, have been made from nickel steel for two reasons. First, boiler plate is per se a low-carbon material, and nickel not being dependent for its alloying qualities on carbon confers higher properties than any other alloy. Second, while it is possible to obtain as high or higher strength with other alloys, nickel steel develops to a very high degree resistance to embrittlement and aging,[1] and has unusually satisfactory strength at boiler temperatures, a necessity often neglected.

The tensile results obtained with a 3.0 per cent nickel-steel boiler plate, together with those of carbon-steel plate for comparison, are shown in the following table:



AVERAGE OF 385 TESTS ON CARBON STEEL BOILER PLATE

	Average per cent		Average
Carbon	0.193	Ult. Tens. Str.	59,200
Manganese	0.041	Yield Point	36,200
Phosphorus	0.022	Elong. in 8 in.	28.64 per cent
Sulphur	0.033	Red. of Area	(Not determined)
		Impact, Izod	(Not determined)

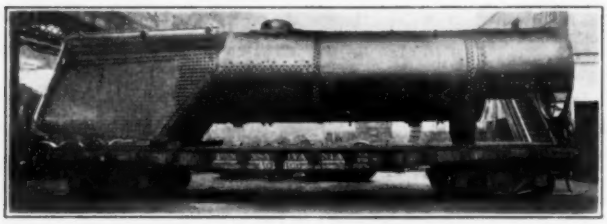
The mechanical engineer may ask what will happen if even higher pressures are required in the conventional fire-tube boilers. The answer is that nickel-steel boiler plate can be manufactured with a tensile strength of 100,000 lb. or more, but it is not desirable to do so at present.

Corrosion Reduction

There are two types of materials which are useful for use under corrosive conditions: (1) Corrosion-resisting materials, and (2) non-corroding materials.

Locomotive With a Nickel-Steel Boiler

Under the corrosion-resisting type of materials are found such metals as wrought iron and commercially pure iron (Armco), together with low-carbon steels bearing slight percentages of such corrosion inhibitors as copper, molybdenum, and nickel. While these materials are not offered as being rustless or corrosion-proof, they have proved in long service that under certain corrosive conditions and also exposure to the atmosphere, their life is much longer than that of ordinary steel. Economically they are attractive because, being essentially a steel, their cost is not very much greater than ordinary carbon steel for the same purpose. They are suitable for such purposes as car plates, underframes, firebox sheets, etc.



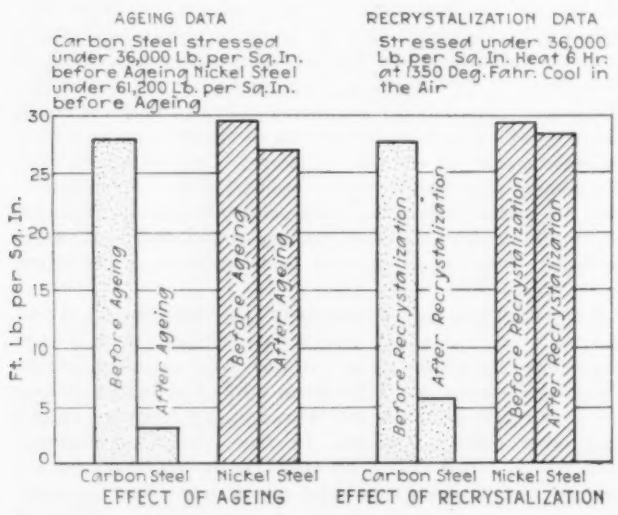
The second field is a comparatively new development. About ten years ago laboratory experiments indicated that a steel containing chromium around 20 per cent exhibited certain "stainless" properties. These steels were of fairly high carbon, i.e., about 0.30 per cent, and were first developed for cutlery and other similar purposes. In this original development it was soon found that their resistance to corrosion was not perfect, and depended to a great extent on the heat treatment which had been given the material and on the finish. The next step was to reduce the carbon as low as possible so that the alloy was really a chrome-iron rather than a chrome-steel. This material was soft and ductile, and not dependent for corrosion-resistance to the same degree on either heat treatment or finish. It has proved very acceptable. For the next step we are indebted to German metallurgists when they

[1] For further discussion of these phenomena see "Alloy Steels for Boiler Construction." Trans. American Society for Steel Treating, 1928.

AVERAGE OF 523 TESTS ON 3.0 PER CENT NICKEL-STEEL BOILER PLATE

	Average per cent	Specified per cent		Average lb. per sq. in.	Specified lb. per sq. in.
Carbon	0.163	0.20 Max.	Ult. Tens. Str.	77,880	70,000 Min.
Manganese	0.557	0.40–0.80	Yield Point	47,550	50 per cent U.T.S.
Phosphorus	0.021	0.045 Max.	Elong. in 8 in.	36.33 per cent	1,600,000 U.T.S. Min. 20 per cent
Sulphur	0.029	0.045 Max.			
Silicon	0.203	Not Spec.	Red. of Area	54.15 per cent	50 per cent
Nickel	2.960	2.75–3.25	Impact Value, Izod 63.4 ft-lb.		

added nickel to the alloy. This resulted in a material which was superior to either of the other two in resistance to corrosion, in appearance, and in workability, and it is now probably the preeminent type of non-corroding steel. It is, of course, sold under a trade name but is manufactured by several companies in this country.



High-Pressure Nickel-Steel Boiler for Locomotive

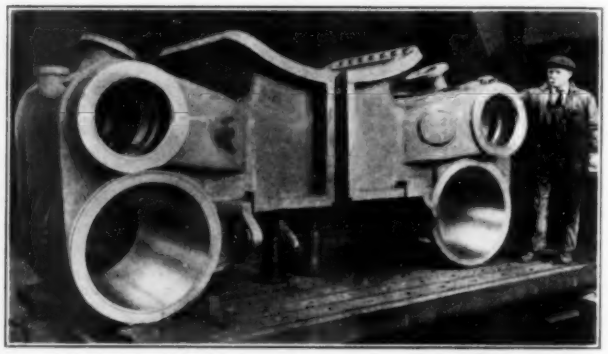
The economics in the use of this material is that, due to its high price, say 30 cents a pound and higher, it can only be used where the conditions of service are such that the cost is justified either in longer service or in saving cost of replacement of other materials.

It has been used successfully for such purposes as condenser tubes, boiler tubes, superheater parts, etc. To date it is not known that it has been used for firebox sheets, but its use has been contemplated and it would appear that this would be an excellent application on sections where the corrosion conditions are very bad.

The physical characteristics of the chromium-nickel-iron alloy (chromium 18 per cent, nickel 8 per cent, carbon less than 0.16 per cent) are as follows:

Ultimate tensile strength	85–95,000 lb. per sq. in.
Yield point	30–40,000 lb. per sq. in.
Elongation in 2 in.	57–60 per cent
Reduction of area	70–75 per cent
Brinell hardness number	130–145

Comparative Aging and Recrystallization Tests of Alloy Steel and Carbon Steel for Boilers



This alloy in addition has excellent characteristics which make it valuable for high temperature work and it can be continuously employed at temperatures as high as 1700 deg. fahr.

It should be noted that in order to develop the maximum resistance to staining or rusting, the surface must be carefully freed from all scale and should be polished.

Miscellaneous Uses of Alloy Steels

There are a number of miscellaneous uses for alloy steels in the railroad field. For example, engine bolts are quite frequently made from alloy steel and are used in either the case-hardened or the heat-treated condition. Nickel-steel staybolts are quite general. Rivets, especially for alloy-steel boiler plate, are often of the same material as the plate itself. Roller bearings, which seem to be coming into favor with the railroads, are, of course, entirely made from alloy steel.

In this connection the use of roller bearings will probably develop a demand for an alloy steel or iron wheel. The length of installed life of a roller bearing is today not dependent on the bearing itself, but on the wheel life, and if the wheels can be made more wear-resisting, it will not be necessary to dismantle axle units so frequently. There is no question that wheels, either steel or iron, can be improved by the addition of alloys, such as manganese, chromium, nickel, and molybdenum. There

Alloy Cast-Iron Locomotive Cylinders

are today in service many thousand wheels in which manganese is used as an alloying element, and experiments are being undertaken by some of the largest wheel manufacturers to improve their product. It is possible to make a chilled-iron wheel containing alloys which will be much stronger and more wear-resisting than the present chilled wheel, but the decision to use these wheels must come from the railroads. As one chilled-wheel manufacturer stated some time ago, their business is to trade a new wheel for one discarded by the railroad, plus 80 cents. Naturally, an alloy wheel cannot be furnished on this basis.

Chilled wheels, however, are not the only places where cast iron is being improved by alloys. In the last three years there has been a tremendous growth in the use of alloys in cast iron, and today in railroad service such castings as cylinder bushings, cylinders, packing rings, etc. are being made from an iron bearing either nickel, chromium, or molybdenum, alone or in combination. Two of the largest locomotive manufacturers are making nickel-cast-iron cylinders which compare so favorably with steel cylinders that it is doubtful whether it is worth while to use the cast-steel cylinder.

Another new development which is being watched with interest by the railroad men is that of "nitriding." While the process might still be called in the experimental state, and there is no finality as yet, there is considerable promise that this will prove to be a valuable tool in railroad work. By this method a chrome steel with 1 per cent of aluminum and with or without other elements[4] is machined to the final shape ready to be used, heat-treated, and then exposed to an atmosphere of ammonia

[4] The analysis most used in this country is chromium 0.80–1.30, aluminum 0.60–1.20, molybdenum 0.15–0.25.

gas at 1000 deg. fahr. or slightly less. After some time at this temperature and exposed to this gas the metal takes on an intensely hard surface. It is possible to procure a surface hardness of around 1000 Brinell, whereas about the hardest steel obtainable by other methods of heat-treating is in the vicinity of 600 Brinell. In addition, since the temperature used is comparatively very low, there is practically no distortion or warping of the parts. The value of such a hard material can be easily appreciated, and numerous applications to railroad work can be thought of. For example, one might mention piston rods, crosshead guides, crank pins, valve-motion work, and even axles. One manufacturer is today experimenting with main driving axles where the journal alone is nitrided, and the wheel fit and main body are blanked off so that the ammonia gas does not affect them. The value of this remains to be proved.

Nitriding has been developed to a higher degree in Europe than it has in this country, and recently an opportunity was presented of observing the process as practiced by one of the largest companies in Europe. They were nitriding such parts as automobile cylinder blocks, railroad bumpers, valve-motion pins, piston rods, crank pins, pump shafts, gears, and a large variety of other parts, and it was easy to gain the impression that this process was applicable to practically everything. A word of caution, however, would not be inadvisable at the present time as it is quite probable that enthusiasm will run away with common sense. In the author's opinion, one should be very careful in using parts which have been treated by nitriding where there is any impact, such as in gears, because the hard case on this material is extremely thin and also extremely brittle, and spalling is almost inevitable. On the other hand, where the pressures are not too heavy, and where the contact is either sliding or continuous, it would seem that nitriding steels offer a very great advantage.

Conclusions

In a very general way the use of alloy steels by the railroads has been covered. Necessarily also, the treatment has been brief. It would be possible to write a fair-sized book on the subject without exhausting it. In closing, we recommend that these remarks be considered in this light and that, in case any question whether or not to use alloy steels arises, metallurgists competent to deal with the problem be consulted.

Discussion

G. L. Norris.[5] The use of alloy steels for various purposes is of great interest and importance to the railroads, as is shown by the increasingly large tonnages they are using.

The constantly increasing size and power of the modern locomotive have developed a condition that requires the use of special or alloy steels of higher strength than the carbon steels heretofore in general use, not only to meet the higher stresses, but to keep the wheel loads within the specified limits and to lighten the reciprocating and revolving parts, thereby permitting of better counterbalancing and reducing dynamic augment. Strength is the primary requirement, coupled of course with a good degree of toughness and shock and fatigue resistance.

With reference to failures, records and investigations show that the greater number, possibly 90 per cent or more, are due to mechanical causes, such as fit, finish, and maintenance, and only a very small percentage to actual inferior quality of the material. Tool marks, sharp fillets, and lack of lubrication are the fruitful causes of many failures.

With reference to vanadium, which is the alloy element in 90 per cent or more of the alloy-steel locomotive forgings and castings in use today, the writer would like to correct the impression that the paragraph on the second page of the paper describing its characteristics might leave—that it is used as a deoxidizer or scavenger when added to steel.

Vanadium has a special place in the periodic system of the elements, as it lies between those elements used as deoxidizers and those used as fixed additions and carbide forming. While it can serve both purposes, it is not employed for deoxidizing, but is added for its alloying qualities after the deoxidation has been accomplished by cheaper and more powerful deoxidizing elements, such as silicon and aluminum. It is therefore used solely as an alloying addition in imparting fine grain size and greatly improving the strength and other properties of steel.

Vanadium in combination with carbon acts with the greatest intensity of any of the elements in improving alloys of iron—that is, in small quantities. Steels containing vanadium in appreciable amounts, sometimes even as low as 0.05 per cent, show much less dendritic segregation than do vanadium-free steels, almost complete freedom from Widmanstattian patterns after casting and before thermal or mechanical treatment, and are generally characterized by extremely fine grain size. They likewise retain this fine grain size at higher temperatures than vanadium-free steels.

Vanadium has a very strong affinity for carbon, even stronger than oxygen, and when added to steel is found combined principally with the carbide or cementite and partly with the ferrite. The ferrite containing vanadium is stronger, tougher, and harder than ordinary ferrite. The carbide is likewise greatly strengthened and hardened, shows a very much less tendency to coalesce or form into large masses, and tends to remain in the sorbitic condition. Therefore, segregation of carbides is less common in vanadium steels, and lamellar pearlite does not readily occur at ordinary rates of cooling. This tendency of vanadium to form sorbitic pearlite, even in large forgings, is a unique and valuable property.

The benefits of these various effects of vanadium on steel are immediately apparent in improved physical properties and uniformity of response to heat treatments. The tensile strength is increased and the elastic ratio raised without materially lowering the ductility. The resistance to shock or impact, reversal of stresses, or fatigue and resistance to wear or abrasion are very considerably increased. Vanadium also imparts thermal stability to steels by hindering the growth of carbide particles and by restraining the decomposition of the carbides at elevated temperatures.

With regard to quenched and tempered forgings, probably the troubles encountered with these were due largely to the lack of equipment and experience on the part of some of the manufacturers. It was to overcome this that the normalizing and annealing treatment of locomotive forgings was developed with alloy steels. By this treatment no unrelieved quenching strains are left in the forgings, and physical properties are obtained practically equal to those by a mild quench and tempering treatment.

Typical physical properties of normalized and tempered or annealed carbon vanadium forgings are:

Yield point, lb. per sq. in.	65,000
Tensile strength, lb. per sq. in.	97,000
Elongation in 2 in., per cent	24
Reduction of area, per cent	45 to 52

The minimum physical properties given by the author for alloy-steel castings are not those to which most of these castings are made today. These should be:

Yield point, lb. per sq. in.	55,000
Tensile strength, lb. per sq. in.	85,000
Elongation in 2 in., per cent	22
Reduction of area, per cent	40

[5] Vanadium Corporation of America, New York, N. Y.

Typical values of castings to this specification are:

Yield point, lb. per sq. in.	57,000
Tensile strength, lb. per sq. in.	90,000
Elongation in 2 in., per cent	24
Reduction of area, per cent	47

Recently there has been developed a nickel-vanadium cast-steel specification that gives the same tensile properties with increased ductility. The specification for this steel calls for the following minimum properties:

Yield point, lb. per sq. in.	55,000
Elongation in 2 in., per cent	25
Reduction of area, per cent	50

The average properties obtained are:

Yield point, lb. per sq. in.	59,000
Elongation in 2 in., per cent	28
Reduction of area, per cent	58

Typical composition of this steel is:

Carbon	0.20
Silicon	0.35
Nickel	1.50
Manganese	0.80
Vanadium	0.10

It will be noted that the percentage of carbon is considerably lower than given by the author for the other alloy-steel castings.

With reference to embrittlement and aging of nickel-steel plates, it is noticed that the data given are all for 5 per cent nickel steel. It would be valuable if such data could be given for the 3 per cent and lower nickel plates generally used in boilers.

There is one very important and growing application of alloy steels on the railroads that the author has overlooked; this is locomotive and car springs. There are several thousand springs of chrome-vanadium steel already in successful service.

A direct comparison between springs in which carbon steel is used and chrome-vanadium practice is perhaps as good a way as any to demonstrate the advantage gained through the use of vanadium steel for railroad springs. Under average manufacturing conditions and heat treatment, the physical properties of the two steels will be about as follows:

	Carbon	Chr. van.
Elastic limit	135,000	190,000
Ultimate strength	180,000	200,000
Elongation in 2 in., per cent	6	10
Reduction of area, per cent	15	30

In addition to these tensile properties, and of more practical importance, it has been found that the safe commercial stress range for carbon steel is somewhere between 55,000 and 60,000 lb. per sq. in., while in the case of chrome vanadium it has been found safe to increase this to 75,000 to 80,000 lb. per sq. in. Also, the fatigue and impact values, no matter how measured, are very much superior in the case of chrome-vanadium steels.

Since these engineering characteristics are the limiting factors in determining the design and performance of a spring, it is apparent that the superior values obtained in chrome-vanadium steel may be used to a practical economic advantage in spring construction. One may either safely increase the flexibility of the spring and hence obtain easier riding qualities, or increase the length of life of the spring under any given service conditions, or reduce the weight of the spring, or adopt some desired combination of these three.

C. F. Pascoe.[6] The recent developments of the so-called stainless steels and nitriding alloys are being closely watched by the Canadian Railways and will undoubtedly be tried out on material which promises good results.

It is understood that European practice still favors oil-quenched and tempered forgings for locomotive driving axles, in spite of the fact that much trouble has been experienced in the United States and Canada from such treatment, particularly on driving axles. Can the author give some information regarding the composition of steel so treated in Europe, particularly regarding the alloys used, if any.

The author mentions that the quench and temper treatments on steel castings will give considerably higher figures than those mentioned in his paper. Some time ago our foundry quenched 20 tons of low-carbon nickel-steel castings in water at 120 deg. fahr. and drew them back at 900 deg. fahr. The average of many tests on the attached coupons was as follows:

Yield point, lb. per sq. in.	62,000
Tensile strength, lb. per sq. in.	92,300
Elongation in 2 in., per cent	23
Reduction of area, per cent	59

All castings were subjected to a drop test afterward to determine if any quenching cracks had developed, but none were found. The results show that low-carbon alloy-steel castings, even if of intricate design, can be water-quenched without much fear of cracking.

The writer is interested in the author's statements regarding low-carbon alloy steels, as our foundry has cooperated in considerable development work in this respect for the Canadian Railroads. Izod-impact values on double heat-treated low-carbon nickel-steel castings, on account of being so much higher than those obtained on other grades of alloy-steel castings we have made, have considerably influenced our railroads in regarding the adoption of this grade of steel for locomotive castings, particularly main sideframes.

W. H. Winterrowd.[7] This paper is timely and contains much valuable information, and particularly interesting is the discussion, which will prove equally valuable. Regarding the discussed difficulty of a railroad keeping track of alloy-steel parts, it is felt that this difficulty can be eliminated by simple systematic methods and proper supervision.

As this paper will be read with a great deal of interest by many railroad men who have had some experience with alloy steel or who are experimenting with it, the writer thinks that it would be of value and interest if the author would explain why it is possible for different billets from separate sources or sometimes from the same source to have such different or varying characteristics even though the billets have passed widely accepted specifications and have been subjected to exactly the same methods of heat treatment.

A. W. Minuse.[8] The paper accurately sums up the alloy-steel situation in the railroad field today. Alloy forgings, which are so generally used in the automotive industry, have not been so extensively used on locomotives for several reasons. Heat-treating such large sections requires care and good equipment, and the careless application of heat to some part of a treated forging in making repairs destroys the structure given by heat treatment, and failure of the part is the inevitable result.

Air quenching, or normalizing, followed by a draw is the most favored treatment, as quenching in oil or water, especially on very large sections, does not seem to be advisable at the present time. Unfortunately this means that one must take lower

[8] Central Alloy Steel Corporation.

physical properties than are obtainable, to insure freedom from cracks and internal stresses, a condition which does not embarrass the automotive field. Locomotive designers have not, except in rare instances, taken advantage of the higher physicals of alloy steels to reduce sections and weight, but have in most cases been satisfied to use the higher physicals on the same sections, striving for longer service life of the part. Undoubtedly with the increasing tendency toward wider application of alloy steels the railroads will in the near future begin to utilize their higher physical properties to obtain sufficient strength on lighter sections. A better understanding of these steels and better heat-treating equipment in the railroad shops will follow, and the future will see oil- and water-quenched alloy-steel forgings being extensively used.

As the author points out, higher steam pressures and their resulting higher boiler temperatures will require greater strength in boiler plate, if the boiler is to be held to the same weight. This situation has been successfully met by the use of a 3 per cent nickel steel. Under actual operating tests plates of this analysis have also proved to be of great value in firebox construction. In this connection the 18 per cent chromium irons have been used as inside firebox sheets and have proved conclusively that in spite of the high cost of this material its use is economically justified. This material is stainless, and after two years' service in this application was clean and free from scale. Its real value lies in the fact that its brittle temperature range is far higher than any temperature it can attain in service, while the higher pressure boilers raise the temperature of carbon-steel firebox plates into the brittle range of this material. Fatigue of these carbon plates is very rapid with the metal in this condition, and many failures are directly due to this cause. Several engines are at present being equipped with fireboxes and siphons made entirely of this chromium iron.

Nitralloy is being tested by many railroads. These intensely hard surface steels, with their ductile heat-treated cores, can be expected to fill a long-felt want where friction and its resulting wear have caused trouble. The case of these steels retains it hardness at temperatures exceeding 1200 deg. fahr.

The author has accurately stated that this material should not be used where impact stresses are a factor. However, Nitralloy analyses and nitriding treatments have recently been improved to such an extent that the cases are much more ductile than formerly without appreciable loss of hardness, and it is entirely safe to use these materials under any impact stresses that may be applied safely to case-hardened materials.

E. E. Thum.[9] The paper is hardly broad enough to cover the ground indicated in the title, since the author confines himself to locomotive parts and makes no mention of alloy steels used for rails. Furthermore, while he mentions many alloys used for various locomotives, he dwells particularly upon nickel steels and irons.

He is to be commended especially for emphasizing the fact that metallurgy has become so highly specialized that railway mechanical engineers should consult steel experts before they go very far in designing a locomotive that is to use heat-treated steels.

Further emphasis should be given to the fundamental difference between the application of heat-treated steels to automobiles and to locomotives. A locomotive requires steel in very much heavier cross-sections than does an automobile, and in handling such heavy forgings due regard must be paid to what metallurgists know as the "mass effect in heat treatment." Suppose one has a $^3/_4$-in. bar and a 3-in. bar of a certain steel (identical except for size) and gives them identical heat treatments. He then cuts the bars up into standard test pieces, and he will find that the properties of the 3-in. bar are not uniform, surface to center, and do not in general correspond to those of the test piece cut from the heat-treated small bar. This is a practical exposition of the "mass effect," and the reason for it is easily understandable when it is appreciated that the properties of a quenched and tempered piece of steel depend fundamentally on the state of dispersion of the hardening carbides in the iron itself, and from a practical standpoint the dispersion of hardeners depends upon the speed at which the metal is carried through the "critical" range. In a very bulky mass of steel it is obvious that the exterior surface will cool at a faster rate than the metal in the very interior; these differences are intensified when a bulky piece is drastically quenched, as in cold brine, with correspondingly great differences in the physical properties at different depths below the surface. Seasoned experience and sound judgment alike indicate that such a heterogeneous mass of steel is not as reliable as it might otherwise be.

The most practicable way to avoid this trouble in heat-treated heavy forgings is to make them of those alloy steels that are known as "air hardening." An air-hardening steel is one that does not require a rapid and drastic quenching in order to keep the hardening carbides in a properly dispersed condition. In other words, the rather slow and deliberate cooling which a hot piece of metal would experience when merely exposed to quiet air at room temperature is sufficient to retail the microscopic constituents of a good air-hardening steel in such a condition that the metallic aggregate at the end has enhanced physical properties.

It is therefore important that railroad engineers should be informed about those steels which show this air-hardening property to the optimum extent. Attention should be called to the nickel-chromium-molybdenum steel which has been so successfully used for heavy ordnance for the last 15 years, especially in England. These steels have probably not yet been made into railroad forgings, but their properties are so good that this neglect must only be due to the fact that mechanical engineers generally are not well enough informed about this type of alloy steels.

A recent report (No. 67) from the research department, Woolwich Arsenal, England, describes extensive experience and tests with these steels, the production of which is characterized by them as being "one of the most important metallurgical achievements of recent years." A typical composition for a large forging (such as a 12-in. gun tube), having a high yield point and relative absence of mass effect, is as follows:

	Per cent
Carbon	0.30
Silicon	0.15
Manganese	0.50
Nickel	2.50
Chromium	0.75
Molybdenum	0.50

Tests taken from one such heat-treated forging, 10-in. thick (to quote only one), and at various depths below the surface, fall within the following very narrow limits:

Ultimate strength, lb. per sq. in.	149,000 to 153,000
Yield point, lb. per sq. in.	126,000 to 137,000
Elastic limit, lb. per sq. in.	105,000 to 110,000
Elongation, per cent	17 to 19
Reduction in area, per cent	37 to 50
Brinell hardness	314 to 324
Toughness (Izod-impact number), ft-lb.	19 to 32

It will be noted that the maximum variation in hardness, surface to center, of such a large forging is only 10 points, whereas a nickel-chromium steel gun tube would be expected to have as much as 60 points difference in Brinell hardness, surface to

[9] Associate Editor, *The Iron Age*, New York, N. Y.

center. (Brinell hardness has a direct relationship to tensile strength.) The heat treatment given to this particular forging consisted of an anneal at 1600 deg. fahr., an oil hardening from 1550 deg. fahr., and a final tempering at 1200 deg. fahr. While this heat treatment is doubtless more extensive than locomotive constructors would like to give to engine parts, it should be remembered that this particular analysis of steel will respond properly to heat treatment when the rate of cooling through the critical range is as low as 5 deg. per min. This fact, of course, is responsible for the uniform properties of the material in such heavy sections, and excellent uniform strength and toughness may be expected from such low-alloy steels after a single heating and air cooling. Furthermore, a reheating, such as would be given from a hot box in service, would not destroy the physical properties, if the part were permitted to cool naturally in the air.

H. A. F. Campbell.[10] The writer has read the paper with interest. In fact, he has read it several times, and it has been a pleasure, because the paper is clear, concise, to the point, and above all very readable.

The writer recently rode from Washington to New York for the whole 236 miles on the pilot of the locomotive of the B. & O.'s fastest train. On the New York Division we were surely hitting some high spots as to speed. There is nothing very unusual about this, but here is the point—to ride on the front of a locomotive making 350 r.p.m. and watch the running gear, main rod, siderods, crosshead, and valve gear thrashing around one would probably feel that he did not quite see why any of it holds together at all. It has never failed to impress upon the writer the necessity for the most skilful design, finest material, perfect workmanship, constant and close upkeep of these very fast moving parts of a locomotive.

Now in regard to nickel steel for the running gear of a locomotive, the writer can speak with some amount of background and experience with nickel steels. In 1915 there was built by the Baldwin Locomotive Works a lot of 15 high-speed Pacific-type locomotives for the C., B. & Q. Railroad. These engines had 27 × 28 × 180/74. The siderods, main rod, main pins, main stub straps, and piston rods were made of nickel-chrome steel. The crossheads were very light and of special cast steel. The nickel-chrome steel was as follows:

Carbon	0.40
Manganese	0.70
Phosphorus	0.010
Sulphur	0.030
Nickel	1.50
Chrome	0.60
Ultimate strength	95,000
Elastic limit	65,000
Elongation, per cent	23
Reduction, per cent	60

Quenched in oil and drawn.

The greatest care was given to the design, the first materials the making of the steel, the forging of the parts, the machining of each piece, and the line-up and set-up in the final erecting. This set of running parts still ranks among the very lightest, for the loads carried, of any in America. It must be fankly stated that this was a special job. It was made just as near as possible 100 per cent throughout each and every process or operation. It was an experiment to show what could be done with very light parts and very high-grade steel. These 15 engines have been in high-speed service for 14 years. There have been some failures, of course, especially of the piston rods; but if these piston rods and crossheads had never had to be cut, without the slightest doubt the original piston rods would still be in service. Some of the original sets of main rods and side-rods are still running and all the sets gave ten years' service with practically no failures. Remember, these running parts were very light. Their history and service represent what can be done with a fine steel, if there is the desire, the determination, and the knowledge to do it. And today we can make an even better steel and forging. Much has been learned and developed since 1915.

[10] Baldwin Locomotive Works, Philadelphia, Pa.

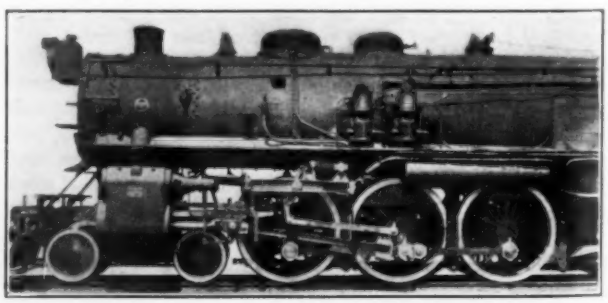
The author has referred to three steels that are normalized and drawn or air-quenched and drawn:

Carbon Vanadium

Carbon	0.40–0.50
Manganese	0.75–0.90
Vanadium	Not less than 0.18
Ultimate strength	90–100,000
Yield point	60–70,000
Elongation in 2 in., per cent	22–28
Reduction, per cent	40–45

Carbon Nickel

Carbon	0.24
Nickel	2.58
Ultimate strength	83,000
Yield point	60,300
Elongation in 2 in., per cent	31
Reduction, per cent	60



Carbon

Carbon	0.45–0.50
Manganese	0.50–0.85
Silicon	0.30
Ultimate strength	85–90,000
Yield point	50–55,000
Elongation in 2 in., per cent	22–24
Reduction, per cent	34

These three steels all are good. Actually there is not a great amount of difference between them.

Wristpins, piston rods, main rods, etc., have to withstand direct tension or compression, bending repeated and reversed, and impact loads, and all of these separately or combined. The steel is under constant fatigue stresses. Some of these parts get the initial crack—that is, the start of a fracture in compression or shear, not in tension at all. Elaborate tests are made for the tension qualities of a steel, when actually one should also study and know its compressive and shear qualities.

It is becoming recognized that the fatigue range, the endurance limit under various combinations of strains, is a function of the

ultimate strength of the steel, and to a much less extent to the elastic limit, elongation, and reduction of area.

That being so was the reason for the previous statement that the three steels are all equally good, one with the other. It is doubtful if the carbon-nickel steel has a fatigue range or endurance limit as good as the carbon-vanadium and carbon steels.

In this connection the writer has had some experience with locomotive wristpins and piston rods of a grade of steels with ultimate strengths very much higher than any of the steels considered by the author.

It might be mentioned that two of the hardest worked parts on a locomotive are the driving springs and the wheel tires. Both are higher carbon steels, with high ultimate strength and reduced elongation or reduction.

The first Norfolk & Western electric locomotives in 1915 produced jackshaft, main pin and siderod loads the like of which had never been dreamed of in nearly 90 years of steam-locomotive operation. It was a truly desperate situation. Unique methods were used to overcome and make these locomotives into working machines.

New jackshaft disks and driving wheel centers with much enlarged hubs were made. The main wristpin in the jackshaft disk, and the wristpins in the front and back drivers were made larger. Special high-carbon forged steel, oil-quenched and drawn, was used. This was a special steel from its inception to its finish, stock, casting, blooming, forging, heat-treating, and fina machining—a 100 per cent job. This forged steel was as follows:

Carbon	0.72
Manganese	0.65
Silicon	0.30
Ultimate strength	140,000
Elastic limit	90,000
Elongation, per cent	12
Reduction, per cent	20

Oil-quenched at 1450 deg., drawn at 1100 deg.

Shortly after the application of these new pins, they were slightly turned down and mild-steel hardened bushings were forced on. This was to avoid returning these pins at later dates.

An exact record of each of these pins is not available. However, they worked; they helped to make these locomotives a working proposition. After fourteen years, certainly, very many of these wristpins, if not perhaps every one of them, are still in service. They were of very high tensile steel, 140,000 lb. ultimate strength, elongation 12 per cent. And bear in mind, these pins were always subjected to the most terrific punishment.

Also, consider two sets of ten each of very high tensile locomotive piston rods now running on the Santa Fe Railroad, as follows:

Piston rods of carbon manganese steel

Carbon	0.51
Manganese	2.0
Silicon	0.33
Ultimate strength	140,000
Elastic limit	100,000
Elongation, per cent	14
Reduction, per cent	34

Oil-quenched and drawn.

Piston rods of nickel-chrome steel

Carbon	0.34
Manganese	0.60
Nickel	2.8
Chrome	0.79
Ultimate strength	131,000
Elastic limit	100,000
Elongation, per cent	15½
Reduction, per cent	31

Oil-quenched and drawn.

In regard to locomotive running-gear parts, it is best to keep one or two general points in mind. There is talk about repeated stresses and fatigue of metal in a rather loose way, 1,000,000 repetitions of a stress, and so on. In locomotive work that is a mere warming up.

The piston rod or crosshead key of a high-speed locomotive in making the one run of 236 miles between New York and Washington has 120,000 repetitions of stress, of varying intensity, put on them in the one trip. In ten days this is 1,200,000 repetitions; in 300 days it is 36,000,000 repetitions.

Therefore, for the modern steam or electric locomotive, the writer would say to go just as far as one can with these three moderate tensile steels with about 90,000 lb. ultimate strength.

But when a change from this class of steel has to be made, then it must be a real change, made whole-heartedly, not worrying about a few cents per pound in price or whether this or that shop can handle the new class of steel. It must be handled, that is all; organize to do it. We do not expect to or try to replace or retreat a driving-spring plate at every roundhouse on the road. It is done at one base shop. Also what in the world has price to do with absolute safety for a locomotive running at 90 m.p.h.? A few cents more per pound for the steel for the running gear for a locomotive costing a total of $110,000 is a small extra cost in comparison to security and safety.

Very high-tensile steels are going to be used more and more for locomotive running gear, and for the very best reason in the world—because they have to be.

The writer's company has to help to design a main rod, and to do all the making of it, to withstand an initial normal piston load of 210,000 lb. Just what would one make the design, the steel, and the manufacture of such a rod? It is a nice problem and something to think about.

G. M. Eaton.[11] There is a real need for a complete and authoritative analysis of Damascus sword blades. It has been known for many years that they contained molybdenum, and now it is learned that they also had a nickel content. It seems unfair to exclude vanadium, tungsten, titanium, and other alloying elements from this roll of honor.

After hearing Mr. Campbell's discussion, the writer takes occasion to congratulate industry at large on the existence of a machine in which the design, material, treatment, fabrication, performance, etc., are all absolutely 100 per cent. This is the only instance which has come to our attention where this goal was achieved in any single one of the particulars noted.

In connection with the reference to "endurance limit," the writer would call attention to the fact that all the fatigue-test results published in this country and which have come to our attention are based on test pieces so small that residual stress is largely removed in the machining operation. Furthermore these test pieces are provided with a surface polish far beyond that usually given to structural elements.

Recent English publications give endurance limits for test pieces carrying the surface as finished by hot rolling operations. These results are just about half the values we have been using in this country. One must emphasize strongly the need of caution in using endurance-limit values. It should be known how well the conditions surrounding the test and the preparation of the test piece represent the preparation and service of the actual article.

Work is now under way in this country on fatigue testing, not only with hot-rolled surfaces, but also on large sizes and with a variety of thermal treatments.

We concur with the conviction that where carbon steel is delivering the goods its use is to be preferred to the use of alloy steel. When carbon steel fails in an epidemic manner, recourse to alloy steel is often the best solution, but there are the difficulties such as the demand for careful thermal treatments, records of what parts are of alloy steel, etc.

The writer finds that the proper psychological set-up exists when the railroad comes to the alloy industry for help. The alloy-steel installation is then removed from the orphan class

[11] Commercial Engineer, Molybdenum Corporation of America, Pittsburgh, Pa. Mem. A.S.M.E.

and becomes a member of the family, and its success is far more assured than when the trial is made without the enthusiasm of those in a position to devise and enforce the precautions essential to success.

Referring to nitrided journals on main driving axles, the writer is opposed to any driving axle, at least on passenger power, in which a brittle surface exists on the main body of the axle. A beautiful solution exists, however, when the axle design is modified in a manner which permits the shrinking of a nitrided bushing over the journal face. This gives all the advantage of the nitrided journal surface, together with a properly ductile axle as a foundation.

The railroads are turning to alloy steel here and there where they have gone as far as they can with carbon steel. This is a healthy condition, and as the procedure evolves itself alloy steels will find their logical railroad applications.

Dr. A. Giesl-Gieslingen.[12] America is far in the lead in the use of alloy steels in locomotive construction. Austria got

along entirely without them until two years ago, when the most powerful European passenger locomotive of the inverted Mountain or 2–8–4 wheel arrangement was developed. The main rod of this engine, for example, represented quite an interesting problem. It was originally planned to work upon the second pair of drivers with a conventional length of rod, but investigations on the effect of the vertical component of the piston thrust upon the rails revealed excessive increases over the wheel load at certain crank positions. These investigations suggest, by the way, the probable reason for the unexpectedly high track maintenance with some existing three-cylinder designs, and led to the adoption of a two-axle drive, like in American practice, in the latest experimental three-cylinder locomotive for the Austrian Federal Railways. In the case of the 2–8–4 two-cylinder engine with 107,000 lb. piston thrust, the use of the second pair as main drivers would have resulted in a fluctuation of wheel load between 80 and 180 per cent of the weight on these drivers during half a revolution, hammering upon the rails five

times per second when the engine is pulling heavy trains up the maximum grade at 35 miles per hour. Working upon the third pair of drivers cut these variations exactly in half and made this heavy engine easier on the track than some of its lighter predecessors. This necessitated a 14-ft. main rod, the longest in the world, and the use of alloy steel in this rod seemed imperative. It was designed with extremely light sections, weighing only 850 lb. without brasses. At 75 miles per hour the rod swings about $\frac{1}{2}$ in. vertically, deviating $\frac{1}{4}$ in. from its geometric center line. Here the question of fatigue enters, but this rod has a greater safety than many others in service.

It will pay to study locomotive designs from this viewpoint to reduce track maintenance, and there is one of the cases where high-grade alloy steel will help to effect considerable economy.

Author's Closure

In the discussion it has been twice remarked that the scope of this paper was not broad enough and, specifically, did not include rails or springs. The field of the paper was very definitely indicated and limited by the committee, and the author simply followed with bucolic contentment the paths outlined.

It has been asked what is the European practice in regard to the use of alloy steel. From necessarily brief observations the author would say that at present the railroads in Europe do not use alloy steel to the same extent that they are used on this continent. Alloy steels are just beginning to be used for boilers. The recent high-pressure locomotive built in England employs nickel steel for the boiler. Very little alloy steel is used for frames, as the frames in European practice are usually built up from rolled plates. When alloy steels are used for forgings, such as axles, piston rods, main rods, and siderods, they are more often than not quenched and tempered, although the tendency is, as in this country, toward the normalized steel. The types of alloy steels most used are nickel, nickel-chrome, and nickel-chrome-molybdenum; in fact, all that came to attention were one of these three types. The nickel-chrome-molybdenum has been used to some extent for railway forgings in England in the quenched and tempered state. This steel has the advantage of giving very nice tensile properties, together with

[12] Vienna, Austria.

depth hardness and freedom from temper brittleness. As far as is known, it has not been largely used in the normalized state, but would seem to be a very good steel.

The most striking difference in European practice was that of lubrication, as there the tendency is all toward forced and automatic oil lubrication in place of our generally unsatisfactory hard-grease lubrication.

Mr. Norris cites data which tend to show that the figures given in the paper are too low. It was the intention in quoting specifications and tensile results to give an adequate picture of what might be obtained by using alloy steels, and the results quoted are not to be considered by any means the ultima thule. Case after case could have been quoted where higher results had been obtained. It should be particularly noted in connection with the figures on low-carbon nickel steel that the highest possible tensile strength is deliberately sacrificed in order to obtain maximum toughness, ductility, and impact resistance. If strength alone were the criterion, it would have been possible by a slight readjustment of the elements in this steel, such as carbon, to far exceed any figures quoted in the discussion. In this connection, the data given by Mr. Pascoe on water-quenched low-carbon nickel steel are extremely interesting and merit attention.

Mr. Winterrowd by his query introduces a very wide subject. The variation from billet to billet of steels made to the same specification, or even from the same heat, involves the history of the steel from the time it was melted in the furnace until the time it was finally finished-machined. These differences may arise from improper teeming into the mold, from "ingotism" or large crystal structure in the ingot, from cracking of the ingot, from improper cooling, from irregularities in the mechanical working, from inequalities of heat treatment, and from a number of other sources. Variations of this sort bring into prominence the quality factor which has been referred to in the paper.

The Stug System of Pulverized-Fuel Firing on Locomotives

By R. ROOSEN,[1] KASSEL, GERMANY

The object of the system described in this paper is to solve the problem of firing locomotives with coal dust of any description. The author tells of the advantages that can reasonably be expected from use of such a system and of some of the difficulties that make pulverized-fuel firing for locomotives a severe problem.

Test results with lignite fuel are given and the methods and equipment used by the German State Railways are described. Particular emphasis is laid on the economical side of using pulverized fuel in engines.

THE numerous advantages which pulverized-fuel firing had given in stationary plants strongly suggested its extension to locomotives, considering that a number of advantages in railway operation and economics were to be expected. Among those aimed at, the following are particularly worthy of mention:

(1) Cutting down the fuel bill, which result is achieved by:

(*a*) The possibility of using low-grade, cheap fuel, particularly such as would not be suitable for grate firing

(*b*) Reducing the quantity of fuel consumed, as pulverized-fuel firing permits of controlling the fire according to the actual output of the locomotive

(*c*) Reduction of standby losses to a minimum and thus avoiding blowing off of safety valves

(*d*) Better utilization of fuel, owing to improved boiler efficiency.

(2) Savings in the roundhouse, owing to considerably reduced wage bill for cleaning ashpan, smokebox, and pits.

(3) Quicker readiness for service, as boiler will be steamed in considerably less time.

(4) No obstructions to draft by clinker as on the grate of standard engines, and consequently increased locomotive mileage.

(5) Possibility of firing very large quantities of fuel in a more economical way than with any other type of mechanical stoking; fireman fatigue completely eliminated.

(6) No sparking at all, avoiding danger of conflagration; no smoke annoyance.

These advantages have instigated considerable experimenting with a view to applying pulverized-fuel firing to locomotives. The attempts made in the United States and elsewhere, such as in Brazil, Sweden, and England, are too well known to need a résumé. In all these cases, however, difficulties more or less prevented the adoption of pulverized-fuel firing on a large scale. Such difficulties were due to the fact that locomotive boilers with their small furnaces present less favorable conditions than stationary boilers or furnaces. In order to ensure sufficient steaming, the locomotive furnace must be stressed to about 10 times what was usual in stationary plants. Either the requisite firebox stress was not attained or the result was the formation of slag on the tube sheet, which soon caused a decrease in steam generation. This may have been due to the fact that stationary-boiler practice with pulverized-fuel firing was applied to locomotive boilers without due consideration being given to their peculiar conditions of service. Either the types of burners employed or the method of supplying air did not prove suitable for generating in the relatively small firebox the amount of heat necessary to develop the requisite quantity of steam or to ensure combustion under such conditions as would preclude trouble with the slag. Any departure from the normal firebox, however, was not advisable, because it was very important, in order to introduce pulverized-fuel firing without considerable initial cost, to abide by the approved pattern, with a view to the easy conversion of existing locomotives into dust-fired engines.

Moreover, the form of the firebox brick lining, which was deemed necessary in a too close imitation of stationary practice, was a delicate problem. The very high temperatures in the firebox resulting from excessive lining, combined with the action of the long, sharp pin flames produced by the types of burners employed, caused a progressive destruction of the brickwork. The complicated design of the lining also made it very apt to crumble and break down under the influence of running shocks. All this entailed continuous and expensive repair work.

Another problem to be faced was the limited space on the locomotive and tender available for the pulverized-fuel equipment, which of course must be arranged so as to combine reliability with economy.

The aforementioned difficulties made pulverized-fuel firing on locomotives a very difficult problem with which to cope. On the other hand, there was sufficient incitement to tackle it anew and bring about definitely satisfactory results. It was with this object in mind that the Stug (Studiengesellschaft für Kohlenstaubfeuerung auf Lokomotiven) was formed when after the war economical considerations in Germany urged the use of low-grade fuel for locomotive firing, particularly lignite, which was available in abundance. The Stug includes the following firms:

---

[1] Chief Engineer, Henschel & Sohn A. G. The author was born in Hamburg on October 13, 1901. He studied machine building at the Dresden Technische Hochschule. In 1925 he joined the firm of Messrs. Henschel & Sohn A. G., of Kassel, where he was put in charge of new locomotive design and tests, chiefly in connection with turbine, Diesel, and coal-dust fired engines. In 1929, Messrs. Henschel & Sohn appointed him chief engineer in charge of the Research Department. At the same time he was selected to superintend the activities of the "Studiengesellschaft für Kohlenstaubfeuerung auf Lokomotiven" (Research Society for Pulverized-Fuel Firing on Locomotives) and, in 1930, of the "Stug Patentverwertung G.m.b.H." (Stug Patents Exploitation, Ltd.). Mr. Roosen's duties in connection with the "Stug" have taken him several times into foreign countries; thus he delivered a lecture on pulverized-fuel firing before the Institution of Locomotive Engineers at the Glasgow meeting in 1929.

Contributed by the Railroad Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Hanomag, Hannover-Linden
Henschel & Sohn A.G., Kassel
Fried. Krupp A.G., Essen (Ruhr)
Berliner Maschinenbau A.G., vorm. L. Schwartzkopff, Berlin,

as well as the German coal and lignite syndicates:

Mitteldeutsches Braunkohlensyndikat, Leipzig
Ostelbisches Braunkohlensyndikat, Berlin
Rheinisches Braunkohlensyndikat, Köln am Rhein
Rheinisch-Westfälisches Kohlensyndikat, Essen (Ruhr)
Oberschlesisches Steinkohlen-Syndikat, Gleiwitz.

These are in cooperation with the German State Railways, the offices being at Kassel on the premises of Henschel & Sohn A.G., where the study and research work were carried out. It was the Stug's aim to solve the problem of firing coal dust of any description in locomotives, stationary plants being included later on.

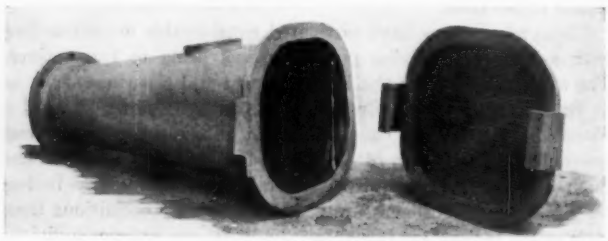

FIG. 1 STUG BURNER, NEW DESIGN

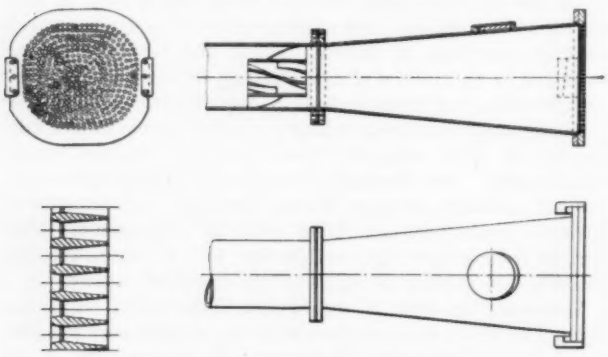

FIG. 2 ARRANGEMENT OF BURNER

As far as locomotives were concerned, the experiments were to evolve a system which would combine the following features:

A rate of evaporation of 12.3 lb. of steam per square foot of heating surface per hour
Variation of burner output within the wide range between maximum stress and minimum stress
High boiler efficiency and prevention of honeycombing so as to ensure continuous operation without trouble due to slag deposits
Simple and highly resistive brick lining
Utmost working reliability of the whole equipment.

The work was systematically carried out on the largest possible scale, since there was a clear understanding that real success could be attained only by making a sound combination of theoretical investigation and experimental work.

In order to avoid from the inception the shortcomings of earlier experiments, two principal requirements had to be fulfilled in the first place:

(1) Shaping the flame so as to fill the whole firebox and avoiding the pin flames which deteriorate the tube sheet or brick lining.

(2) Obtaining a high specific intensity of combustion for peak loads of about 230,000 B.t.u. per cu. ft. of firebox volume, and even more in particular cases, i.e., about 10 times the amount obtained in stationary plants.

Experimentation, properly speaking, commenced after thorough preparatory work. The main task was to develop a type of burner suitable for the combustion of pulverized fuel in a locomotive firebox. The result was, after some simplifications of the shape, a burner such as is illustrated in Fig. 1, which shows the definite form. This burner, on account of its action, is called a "spray burner," and it is based on the Stug's principle of subdividing the injected mixture to the largest possible extent. It consists essentially of a truncated hollow cone, the front end of which is closed by a plate having a very large number of nozzle-shaped holes, whereas the small rear end joins a mixing device for the coal dust and air mixture entering at this point (Fig. 2). The dust and air mixture is thus spread into a considerable number of individual jets which are ignited almost immediately in front of the burner plate, and this causes the formation of a diffused, ball-shaped flame. Clogging of the numerous holes by dust was never experienced. The burner or burners, which are thus constructed in a very simple manner, are so arranged that the spray plates come nearly flush with the firebox back plate, while the burner bodies are outside. The burner bodies therefore remain cold when in operation; the spray plate, which is exposed to radiating heat, being cooled by the coal dust and air mixture. Special cooling of the burners can thus be dispensed with. If one of the burners is out of operation, it is cooled during that time by a small current of pure air. That this system of air cooling is entirely sufficient, is illustrated by Fig. 3, the burners shown having been taken out of a locomotive boiler after having stood a very large number of tests.

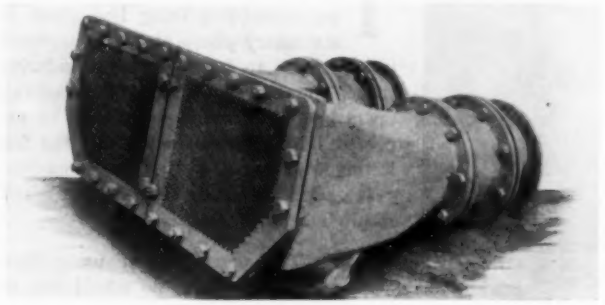

FIG. 3 STUG BURNER, OLD DESIGN

In order to achieve correct design of the burner and furnace, a large number of questions had to be studied, such as the process of combustion, the intensity of combustion, influence of the shape and dimensions of the brick lining on combustion, etc. Thus, the intensity of combustion, expressed in thermal units per cubic foot of firebox volume, is inversely proportional to the gas volume developed during the time of combustion of the dust. The latter must not remain in the firebox for less time than it takes for complete combustion, and the gas speed in the firebox, therefore, must not exceed the velocity of combustion of a dust grain. The gas volume developed during the time of combustion must consequently remain in the firebox until combustion of the dust grain is completed. The gas volume, however, increases with increasing temperature, i.e., lowering the temperature would permit of increasing the intensity of combustion, and this can be effected by reducing the brick lining.

Firebox capacity, cu. ft.	144.7

$$\frac{\text{Free heating surface in firebox (sq. ft.)}}{\text{total heating surface (sq. ft.)}} = \frac{100.3}{967.7} = \frac{1}{9.65}$$

$$\frac{\text{Firebox capacity (cu. ft.)}}{\text{total heating surface (sq. ft.)}} = \frac{144.7}{967.7} = \frac{1}{6.68}$$

been equaled by any other type of stoking on locomotives (Table 2). Indeed, this is more than a locomotive boiler would continuously stand. On analysis the flue gases were found to contain 13.5 per cent carbon dioxide and 5 per cent oxygen. The smoke emitted from the chimney was transparent and showed a grayish hue. The fuel was a commercial quality of lignite dust developing about 9000 B.t.u. per lb. when ground to about 20 per cent residue on a 170-mesh screen.

After these excellent results

$$\frac{\text{Free heating surface in firebox (sq. ft.)}}{\text{total heating surface (sq. ft.)}} = \frac{139.9}{2085.0} = \frac{1}{14.9}$$

$$\frac{\text{Firebox capacity (cu. ft.)}}{\text{total heating surface (sq. ft.)}} = \frac{222.5}{2085.0} = \frac{1}{9.36}$$

Shortening the combustion period of the dust grain has the same effect. It can be obtained, besides, by proper mixture of the dust and air in the burners, as mentioned before, by increasing the fineness of milling of the coal. This process, however, if pushed beyond commercial practice, may become uneconomical, so that the use of this method is curtailed. Thus the Stug uses a degree of fineness of about 15 to 25 per cent residues on a 170-mesh sieve for lignite and about 10 to 20 per cent for coal containing a low percentage of volatiles. All this investigation work required a large number of tests. Under these conditions the Stug obtained, as early as 1925, in a locomotive boiler of 967.7 sq. ft. heating surface, an evaporation from cold feedwater of 14.3 lb. of steam per square foot of heating surface, combustion being entirely satisfactory (Table 1).

When the German State Railways, on the strength of these results, called upon the Stug to obtain a rate of evaporation of 12.3 lb. of steam per square foot of heating surface per hour in the G-12 boiler, the desired result was obtained only after further experimental work. The difficulty was that this boiler has a firebox considerably smaller in relation to the heating surface than the boiler tested in the first place (ratio 1 to 9.65 as against 1 to 14.9). It thus became necessary to raise the intensity of combustion to more than 237,000 B.t.u. per cu. ft. per hour. The brick lining was actually reduced to a minimum, and was just sufficient for the heat from the incandescent lining below the brick arch to be radiated back to the burner, and to protect the casing which has taken the place of the ashpan. Under these conditions the Stug even succeeded in intermittently raising the intensity to about 316,000 B.t.u. per cu. ft. per hour and the steam generation to well above 20.5 lb. per sq. ft. of heating surface per hour, which result, to the author's knowledge, has never were obtained, the German State Railways placed an order with Henschel & Sohn, one of the members of the Stug, to fit a coal-dust burning apparatus on two heavy 2-10-0 type superheated freight engines of the G-12 class.

Fig. 4 gives a general idea of the pulverized-fuel burning equipment of these engines. The German State Railways G-12 class is a three-cylinder engine with a heating surface of 2100 sq. ft. and a grate area of 42.0 sq. ft. The tender is of the six-wheeled type, and when converted retained the existing frame. Two burners of the type previously described are arranged below the firebox back plate, the spray plate having about 1900 holes and allowing the passage of about 3300 lb. per burner per hour. The ashpan is replaced by a casing suspended from the foundation ring. This casing is lined all over with firebrick, which radiate the heat stored in them back to the burners and thus assist in igniting the coal dust and air mixture. The brick lining of the wall opposite to the burners, below the brick arch, serves the same purpose. Apart from this, the firebox walls, nearly down to the foundation ring, are without any lining. This arrangement makes the whole of the surface in contact with the water highly evaporative and further affords easy observation of the staybolts. In the bottom of the casting a small auxiliary burner is provided, the operation of which is independent from the main burners. The front part of the casing is fitted with a bottom slide, worked from the fireman's side of the cab. Apart from this, the locomotives have not undergone any noteworthy modifications.

As mentioned before, the tender frame with wheels and axles remains unchanged. The water tank, of 3.740 gal. capacity, is of the horseshoe type. The usual coal bunker is replaced by the pulverized-fuel reservoir having a capacity of about 6.4 tons

and is constructed as a perfectly closed container with sloping sides. This shape is preferable to a cylindrical container, because it makes for a steady flow of the coal dust and does not allow it to rest in the lower portion of the container. For the same reason the container is welded and not riveted, so as to avoid projecting edges. In addition, stirring nozzles are provided in the container sides. The container is supported on the water tank at four points, and can easily be lifted as a unit. It is provided with three filling apertures in the top, which also give access for occasional inspection. As a rule, one of these openings is sufficient for filling purposes.

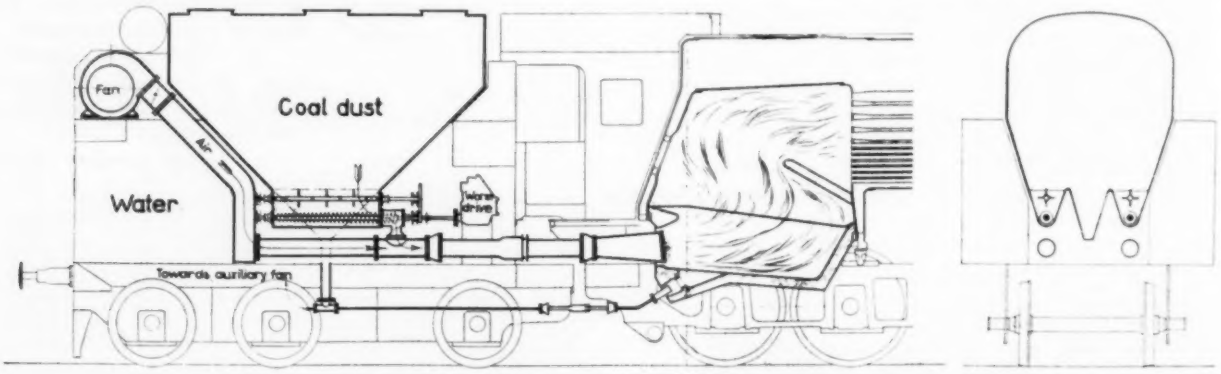

FIG. 4 LAYOUT OF A STUG LOCOMOTIVE, ORIGINAL DESIGN

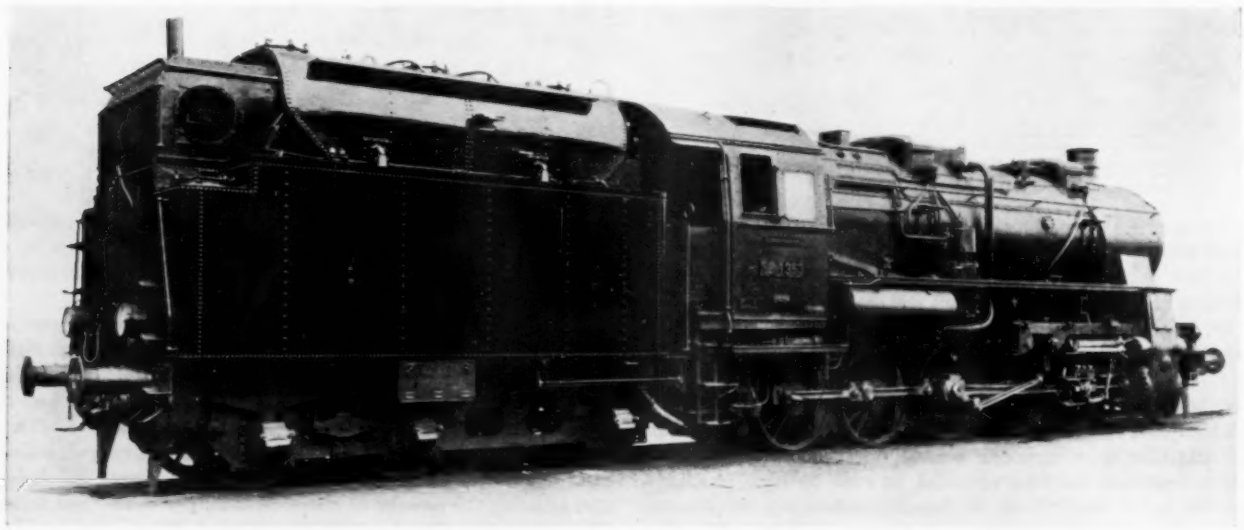

FIG. 5 COAL-DUST FIRED ENGINE NO. 58-1353

At the base of the container are three trough-shaped feedways, those on the outside housing the conveyor worms for the two main burners, while the conveyor screw for the auxiliary burner is lodged in the small central trough. These worms convey the coal dust toward an opening, through which it pours down into the air stream from the blowers. These worms can be clutched and declutched separately.

At the rear end of the water tank is the blower which supplies the air for combustion, and it should be noted that in this first lot of locomotives all of the air necessary for combustion is furnished by the blowers. This method keeps the excess of air in the firebox down to a minimum and ensures maximum boiler efficiency. The blowers are coupled to the turbine shaft, which revolves at a maximum speed of 4500 r.p.m. and operates on saturated steam taken from the dome of the boiler. From the blower the air flows through two separate pipes toward each burner, and on its way mixes with the coal dust conveyed by the worms. The air pipes, which terminate at the burners on the locomotive, are made flexible between the engine and tender by means of ball joints and stuffing boxes, and this arrangement has stood perfectly the test of actual service. The air speed in the pipes varies between 50 and 150 ft. per sec., more or less, according to the output of the locomotive.

The conveyor screws are driven by a small fast-running steam engine, which also operates on saturated steam. It is of the three-cylinder uniflow type, with inside admission piston valves, its speed being controlled by varying the degree of cut-off. A governor prevents the maximum speed from exceeding 500 r.p.m. The steam engine is geared to a small fan which supplies the combustion air to the auxiliary burner.

Admission of fuel to the main burners is controlled by varying the number of revolutions of the steam motor (within a speed range of about 1 to 5), and consequently the worm speed and the quantity of fuel conveyed by the worms. The same applies to the supply of air, which is regulated by varying the number of revolutions of the blower or throttling the admission of air. All of the controls are so interlocked as to make them foolproof. Thus the worms cannot be started before the blowers are set to work, and vice versa, so that clogging of the tubes with coal

FIG. 6 STUG G-12 LOCOMOTIVE, WITH DYNAMOMETER TRAIN

dust can never occur. When the locomotive is worked at less than half its full output, one of the burners is cut out. The nozzle plate of the idle burner is kept cool by a small air current being allowed to pass through it.

Both engines (Fig. 5) were first tried on several runs on the German State Railways' lines near Kassel. Thus schedule freight trains were hauled on the section from Kassel to Eichenberg, which has numerous curves and long inclines of 1 in 100. The weight of these trains was about 1200 to 1300 tons. On level track it was generally possible to run with only one burner in action, while on the heavy gradients, when both burners had to be operated, the engine was working at its full output of about 1400 hp. at the tender drawbar.

These trial runs fully demonstrated that the engines came up to all expectations as to their adaptability to running conditions, simplicity of operation, and reliability of the pulverized-fuel burning equipment. Full steam pressure could easily be maintained, and there was no difficulty in preventing steam from blowing off when passing from gradients to level or down grades. When running down steep gradients, both of the burners could be cut out, so that the auxiliary burner alone was in operation. When restarting the main burners, ignition was readily made by the auxiliary burner flame.

These trial runs were carried out on lignite dust developing about 9000 B.t.u. per lb. Combustion of the dust was perfect, the flue gases emitted through the chimney were colorless, and even on night runs no sparking was observed. Even while the engine was running very slowly, so that the exhaust puffs succeeded each other at relatively long intervals, there was an unimpeded flow of the flue gases.

On the strength of these results, one of these engines was assigned in May, 1929, to the Halle district of the German State Railways, where it has been in service ever since, with a considerable saving of fuel and furnishing a valuable occasion for collecting road experience. Particulars in this respect will be given in connection with other G-12 class engines adapted for the Stug system later on and likewise assigned to the Halle district. The economical success achieved will also be dealt with.

The other of these two engines was submitted to a series of thorough trial runs by the German State Railways' testing department at Grunewald (near Berlin), during the summer and fall of 1929. On such trial runs, the engine is coupled to a dynamometer car with a brake locomotive in the rear. The brake locomotive compresses air in its cylinders, which is exhausted through the chimney, so that the resistance can be adjusted to any desired amount. The engine under trial can therefore be examined with constant output and for any distance, independent of road conditions. All factors of interest, such as fuel and water consumption, boiler efficiency, temperature, and composition of flue gases, can thus be checked at various speeds and compared with each other. The runs were made under conditions varying from no-load to top boiler stress of 12.3 lb. per sq. ft. per hour. The dust consumption is determined by weighing the tender before and after the run.

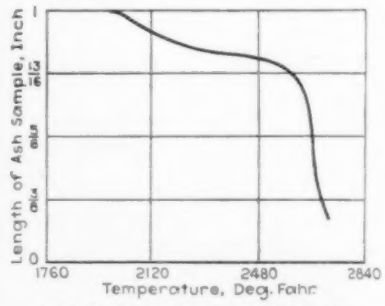

FIG. 7 SLAG MELTING DIAGRAM

The rate of coal-dust consumption and the boiler efficiency gave entirely satisfactory results. In all of these runs, the whole of the air required for combustion was injected through the burners (primary air supply), an improvement of the boiler efficiency being expected as against drawing part of the air direct through the ashpan into the firebox (secondary air supply). It was indeed possible to reduce the excess of air in combustion to about 20 per cent, corresponding to a CO_2 content of about 15 per cent, combustion being very satisfactory. It appeared, however, that with varying loads as experienced in actual service the advantage of introducing 100 per cent of the air for combustion as primary did not amount to much. Therefore, simultaneously with the trials of the first two engines by the State Railways, the Stug proceeded with a series of experiments on its test stand at Kassel, during which part of the air was blown through the burners and the remainder was drawn in through the ashpan. This method was necessary for the burning of hard-coal dust, which was then under trial at Kassel, and it furnished conclusive results also with lignite dust. On the basis

of these results obtained at Kassel, the Grunewald engine was submitted to another series of tests with part of the air drawn in through the ashpan (Fig. 6). The results were nearly the same as in the former series of tests, that is, entirely satisfactory. In order to furnish a basis for comparison with a conventional type engine, a normal grate-fired class G-12 engine was put to test under the same conditions. The boiler efficiency of the coal-dust fired engine was around 78 per cent under all loads, which, in the case of top load, was about 9 per cent above the grate-fired engine, while with small loads there was less difference. The heat expenditure in the fuel, related to the drawbar horsepower, was accordingly 9 per cent lower with peak loads. The steam consumption of the auxiliary machines on the tender is of course included. It amounted to about 5 per cent of the steam generation of the boiler. The combustion of the dust was complete. The composition of the flue gases will be seen from Table 3, which gives figures obtained in the course of trials made with the Stug system under loads as applied during the Grunewald runs.

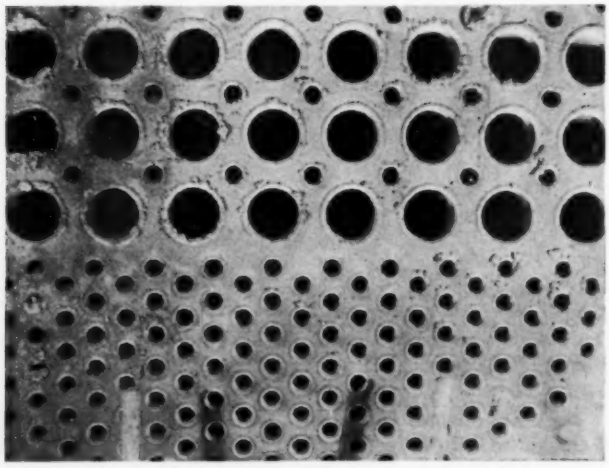

FIG. 8 TUBE SHEET AFTER HARD-COAL DUST TEST

After these tests had been carried out to entire satisfaction, the Grunewald engine was also assigned to the Halle district for regular service.

While the two aforementioned engines were undergoing trials by the State Railways, experiments on the test stand at Kassel were continued. The aim was to ascertain to what extent manufacturing could be simplified and cheapened. The tests chiefly bore on the possibility of driving the blowers and conveyor worms by one turbine, thus eliminating the steam motor which had been provided at the State Railways' request for the worm drive. It appeared that this simplified drive succeeded well if the air and dust supply were regulated so as to give a correct proportion at any turbine speed. Control of the furnace output from top load to minimum load (a range of about 1 to 8) was also obtained by just varying the turbine speed, one burner being cut out in the case of smaller loads. The auxiliary burner worm and blower, too, could be dispensed with in this way, since no-load performance of the engine could be maintained with one main burner in gear at reduced turbine speed. The equipment was thus greatly simplified.

$$\frac{\text{Freeheating surface in firebox (sq. ft.)}}{\text{total heating surface (sq. ft.)}} = \frac{131.6}{2076.7} = \frac{1}{15.8}$$

$$\frac{\text{Firebox capacity (cu. ft.)}}{\text{total heating surface (sq. ft.)}} = \frac{211.9}{2076.7} = \frac{1}{9.79}$$

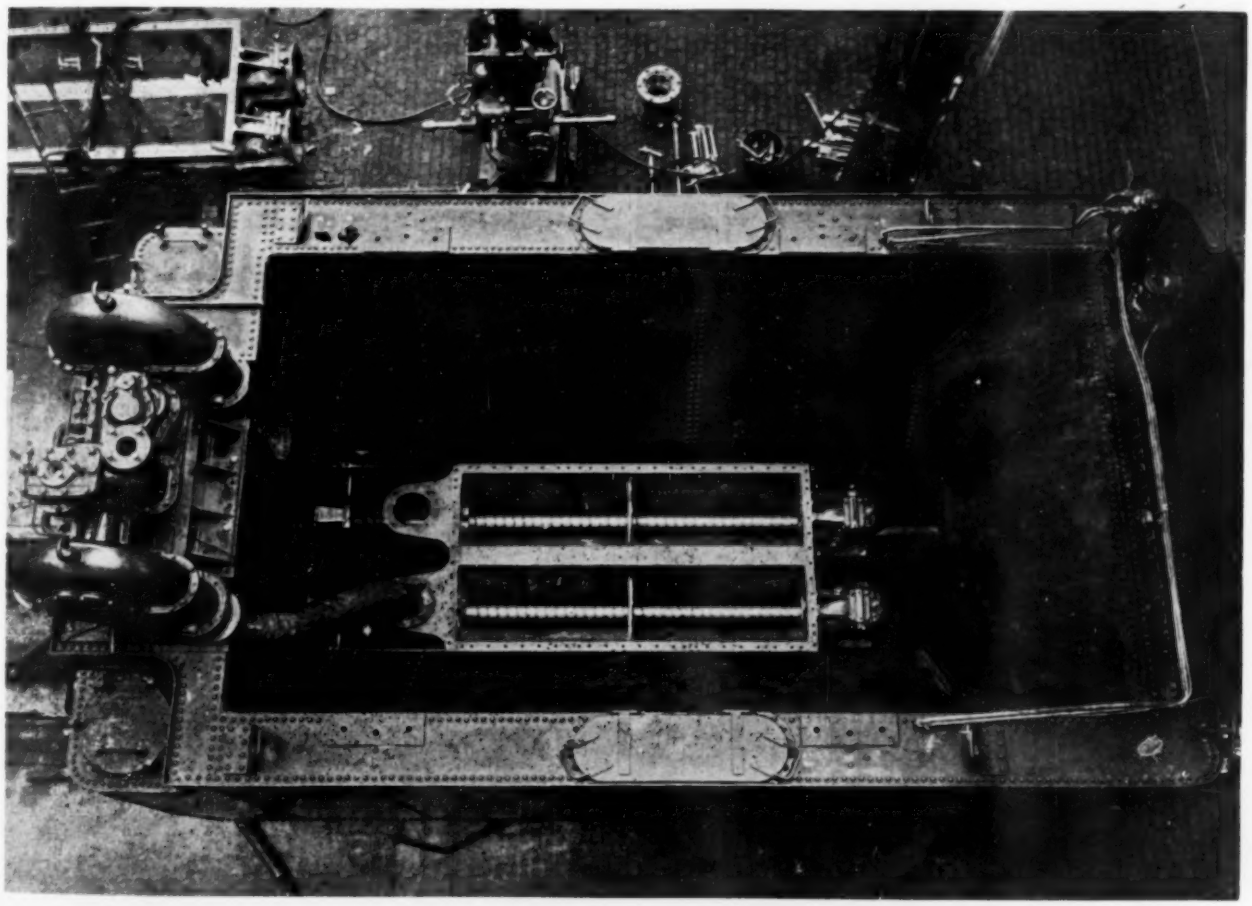

FIG. 11 WATER TANK, BLOWERS, AND DUST-BIN BOTTOM, LOOKING DOWN

obtaining greater simplicity, the behavior of the ash was given further attention. It is known that the larger part of the ash is carried away through the chimney, the remainder, however, remaining in the ashpan. A perfect pulverized-fuel firing system must avoid the formation of troublesome honeycombing on the tube sheet. This important problem, therefore, may be given more detailed consideration.

The tendency of the ash to form deposits depends on the temperature at which it will begin to soften and fuse. The combustion in the furnace, therefore, must be accelerated so that the ash will have cooled down below these temperatures before it hits the tube sheet. The temperature limit for this purpose lies between 900 and 1200 deg. cent. for most types of coal (Fig. 7). As it appeared from the tests, such acceleration is obtained by using dust ground to a sufficient degree of fineness, ensuring a perfect mixture of the dust and primary air, adequately timing the air supply to the firebox, a perfect mixture of the gases with the secondary air, and in the case of coal with little volatile constituents a certain preheating of the primary air by exhaust steam from the tender turbine. In this way

the Stug succeeded in avoiding honeycombing totally, or at least to such an extent that no trouble was experienced with it. It is noteworthy that these results were obtained in the very small firebox of the German State Railways' G-12 class engine in which a firebox stress of 235,000 B.t.u. per cu. ft. is produced with top loads. It is obvious that conditions must be more favorable with American engines having a larger firebox volume and very often a combustion chamber. With such designs, temperatures can be kept so low that the inconvenience of honeycombing is easily avoided. How good the results obtained by Stug were, will be seen from the photo (Fig. 8) showing the tube sheet after a peak-load performance on hard coal of several hours.

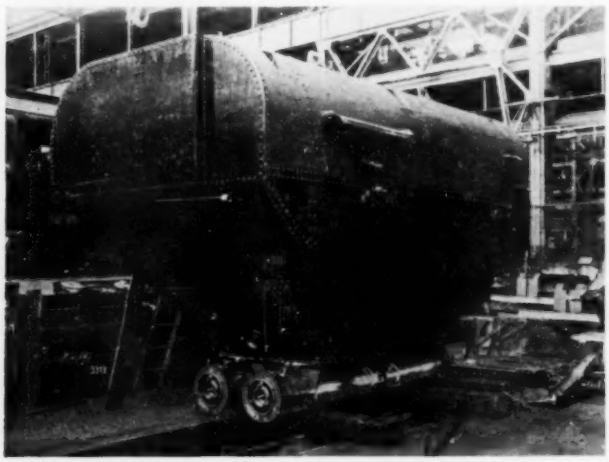

FIG. 12 DUST BIN

These investigations were instrumental in proving that hard coal and many types of foreign coal, such as Brazilian, Austrian, and Russian, which may be available for pulverized-fuel firing, can be fired to full advantage, the preceding Stug tests having demonstrated that the problem was solved in every respect so far as lignite dust was concerned. (See Table 4, referring to tests with hard coal.) In these hard-coal tests, the burner head was slightly modified where it joins the firebox, and the primary air was preheated to about 200 deg. fahr. by exhaust steam from the turbine. The hard coal used had no more than about 20 per cent of volatile constituents.

Similar results were obtained in burning dust from low-temperature lignite coke having only about 10 per cent volatile constituents.

As mentioned before, these tests, the purpose of which was the extension of pulverized-fuel firing to types of coal other than lignite, were carried out simultaneously with the trial runs of the first two lignite-dust-fired Stug locomotives on the German State Railways' lines. The experience collected by these further tests made at Kassel, and in particular the simplifications of equipment described, were of course taken advantage of in the construction of the further engines which were adapted for coal-dust firing by Henschel & Sohn on the German State Railways order, on the strength of the good results they had obtained with the two first ones.

These further State Railways' engines again were of the G-12 class, it being required to increase the bunker capacity of the tender while maintaining the original tender frame. This increase, from 6.4 to 11 tons, was achieved by suppressing the steam-motor and auxiliary-burner equipment. Fig. 9 shows the general layout of these engines and Fig. 10 the photo. The

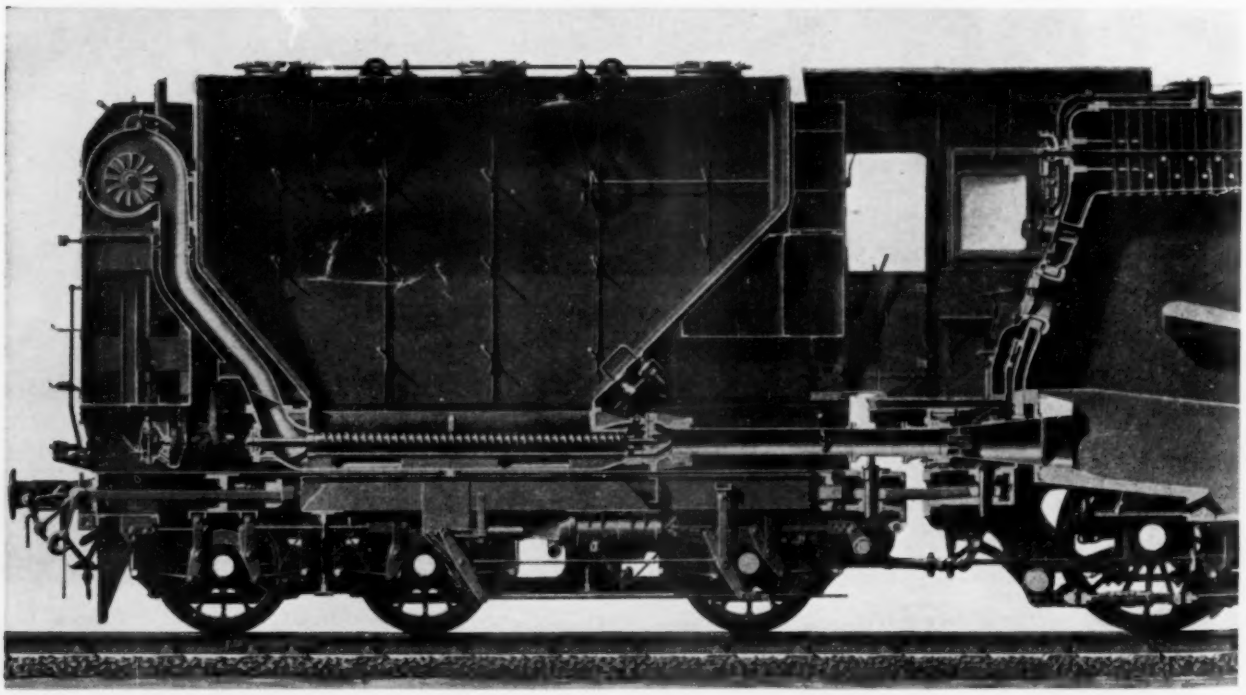

FIG. 14 LONGITUDINAL SECTION

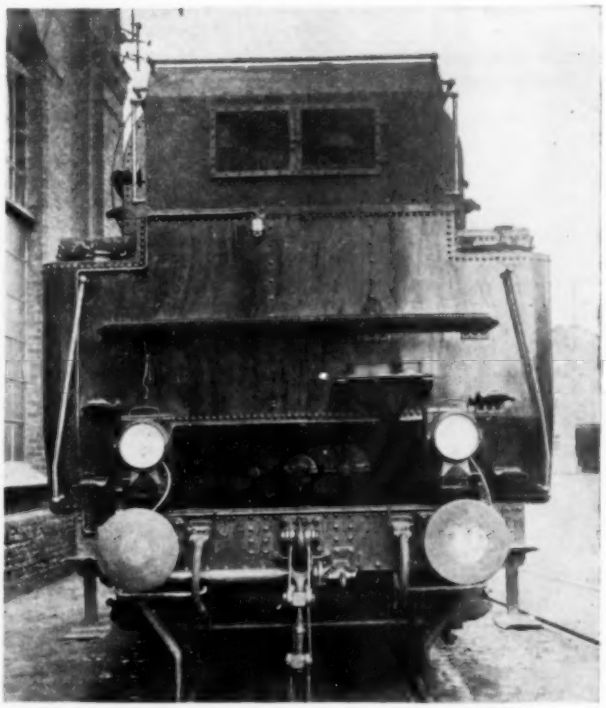
water tank encloses the coal bunker in horseshoe fashion, as in the previous engines. The blowers supplying the primary air are arranged on top of the water tank at the rear end of the engine (Fig. 11). The blower casing is cast solid with the turbine casing, which ensures sturdy construction. The turbine shaft, by means of a worm gear, drives a vertical shaft extending

downward through the water tank, the latter shaft operating the two dust conveyor worms by a bevel and spur wheel gear. The gearing reduction is about 1 to 30, the conveyor worms rotating at a maximum of 150 r.p.m. The worms are located in two trough-shaped castings forming the bottom of the bunker and affording perfect alignment of the worm bearings (Fig. 12). The air current from the blowers encloses the trough in three-quarters of a circle and picks up the dust at the worm outlet, whence it is conveyed toward the burners through two pipe couplings with ball joints and stuffing boxes. The burners are again located below the firebox back plate. The ashpan casing is fitted with inlets for giving access to the secondary air. The size and number of these inlets depend on the type of coal used, one slot below the brick arch being quite sufficient for lignite. The brick arch extends inward to about one-half of the firebox length, thus producing an S-shaped flame. In order to remove such deposits as may form on the tube sheet owing to an occasional supply of inferior or too coarse-grained dust, an ash-blower is provided in the firebox back plate. It will be useful for cleaning the boiler in such cases and also can be operated on the run if necessary. Otherwise the engines have not been modified as against the conventional G-12 class, there being only the addition of a steam connection at the dome for the turbine on the tender. Of course, the blast pipe was adjusted so as to produce sufficient draft for drawing the secondary air supply into the firebox, a pressure of 4.2 lb. per sq. in. of the exhaust steam in the blast pipe deing the maximum required at top output.

The control of the engine is exceedingly simple. The fireman has but to regulate the supply of steam to the tender turbine by turning a single handwheel, thus varying the quantity of fuel and primary air. The ingress of secondary air is controlled by a valve in the ashpan. This clearly demonstrates the enormous relief to the fireman as against grate-fired engines. The dust conveyor worms are clutched and declutched by two ratchet levers conveniently arranged on the fireman's side. The air and dust supply systems are again so interlocked as to make them absolutely foolproof; i.e., it is impossible to start the conveyor worms without first producing an air current to carry the dust into the firebox (Fig. 13).

These engines, a general layout of which is given in Fig. 14,



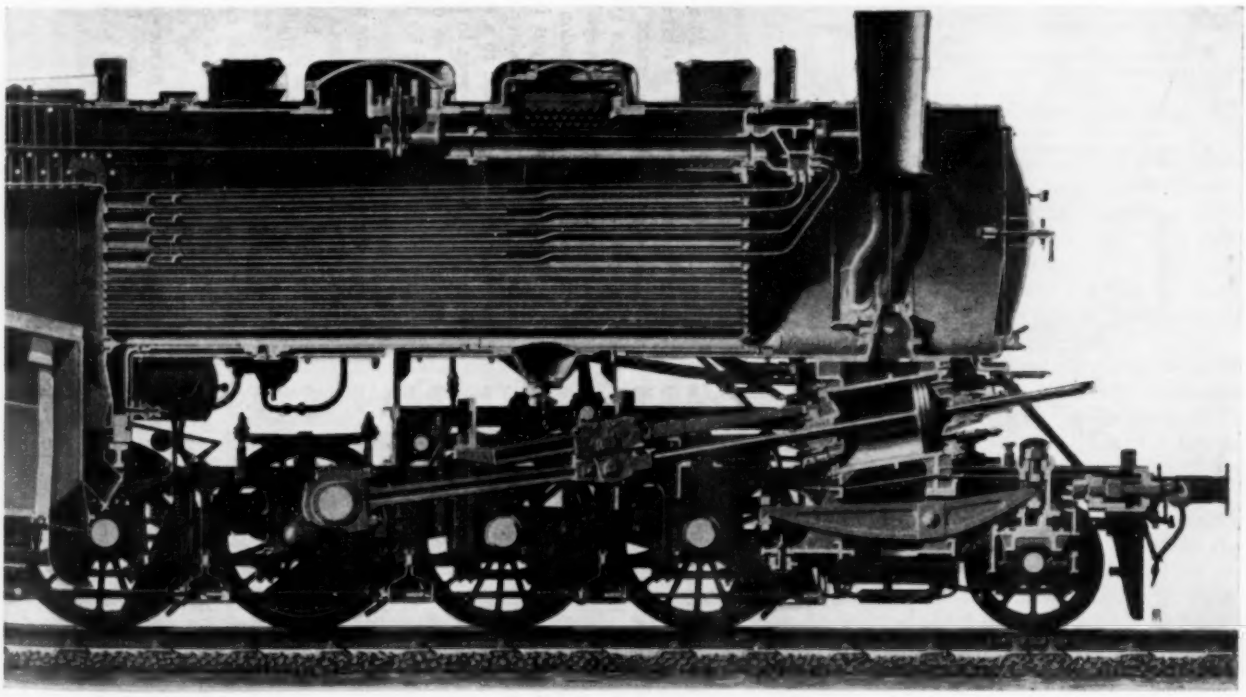


FIG. 13 REAR VIEW OF STUG ENGINE TENDER

OF NEW LOCOMOTIVE AND TENDER

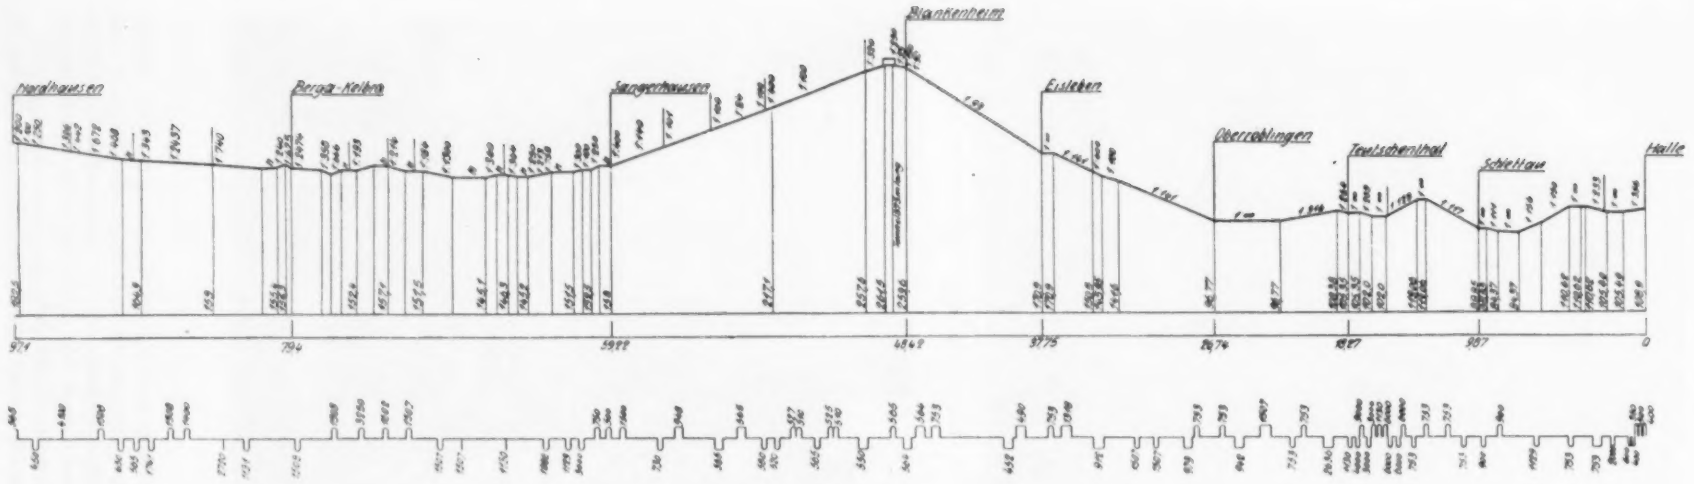

FIG. 15 PROFILE OF HALLE-NORDHAUSEN SECTION

were delivered to the German State Railways in the spring of 1930. After a few successful trial runs in the vicinity of Kassel, one of them was immediately assigned to the Halle district, where it has given excellent service ever since. The other engine was exhibited by the German State Railways at the occasion of the Second World Power Conference in Berlin. The visitors thus had an opportunity to closely view this engine, while the State Railways had arranged for them to participate in demonstration runs of one of the Stug pulverized-fuel-fired G-12 engines between Berlin and Magdeburg (about 100 miles). After the conference, the exhibit was turned over to the Grunewald Testing Department for thorough examination. The trial runs are now being carried out.

It will now be of interest to deal more explicitly with the coal-dust fired engines in actual service in the Halle district. These engines are running on various lines having long gradients and numerous curves (Fig. 15), hauling loads up to 1600 tons (the tractive weight being 81 tons).

Fig. 16 shows one of the various Stug engines on the road. During the last two years the engines were operated on dust coming from the separators of lignite briquet works in Central Germany. The dust can be used as it comes from the separators, no milling being necessary. It contains about 8 to 15 per cent ash, about 40 per cent volatile constituents, 10 to 15 per cent moisture, and has about 20 to 25 per cent residue on a 170-mesh screen. It is conveyed to the Halle locomotive depot, over a distance of 30 miles, in container cars owned by the lignite syndicates. From the container cars the dust is conveyed into the tender bin by compressed air, which operation takes about 15 minutes. The quantity of dust put into the tender is ascertained by weighing the container car on a track scale. The filling pipe is connected to a central opening on the tender bin fitted with a screen to retain foreign matter. Two further openings provide an outlet for the air and indicate the end of the filling by the small dust clouds rising from them.

The contents of the tender are generally sufficient for a round trip, more distant stations being at present supplied by container cars. It is, however, planned to install bunkers for refueling at Halle and some more distant points in the near future. The bunkers are so designed, as a result of thorough experiments conducted by Stug, as to ensure filling of the tender within a few minutes. Provision is made to obtain complete filling of the tender bin, which incidentally is also the case with the method now in use. For lignite-dust firing the stationary bunkers are to be supplied by railway-owned container cars, whereas for hard-coal-dust firing the bunkers are to be filled from mills erected on the site and working slack from the collieries.

Careful investigations have been made by Stug with a view to ascertaining whether it would be advisable to grind the fuel on the tender. The result, however, was that at present serious difficulties would be experienced in trying to design a mill to combine light weight, reduced volume, economy, and reliability to such an extent as would be required in view of the limited space on the tender and the considerable variation in locomotive output.

Further details from road experience will certainly be interestedly awaited.

It is noteworthy that during the whole running period there was not a single case of self-ignition or spontaneous combustion. There is, however, every reason to believe that, even if such an occurrence should come to pass in the tender bin, there would be no danger, as the glowing dust could be blown into the firebox.

Caking of the fuel in the tender bin was not experienced. In order to counteract arching of the dust, some upturned whirling nozzles in the sloping sides of the bin were provided. It was, however, hardly necessary to resort to them.

In lighting up a coal-dust-fired engine from cold, steam of 75 to 85 lb. per sq. in. pressure is taken either from a pipe line in the shed or from another engine under steam, the connection being made through the steam-heating pipes of the locomotive. This will start the tender turbine and set the blower ring on the exhaust pipe of the engine to work, the dust and fuel mixture

entering the firebox being ignited by a wood or cotton-waste fire. Once the steam pressure in the locomotive boiler has risen to about 80 lb., it will furnish the supply for further steam raising, and the outside source can be dispensed with. The time for thus steaming a pulverized-fuel burning engine is considerably shorter than in the case of a grate-fired locomotive.

It will be interesting to note that all of the auxiliary machines have acquitted themselves very well in nearly two years' road service. The conveyor screws were never clogged up. A fact deserving particular mention is that the holes in the burner plates were neither clogged nor worn by the impact of the dust and that the air cooling has been entirely sufficient as provided.

FIG. 16 STUG G-12 LOCOMOTIVE HAULING FREIGHT TRAIN

Experience with the brick lining was satisfactory, only little repair work being necessary.

While working safety was thus always on a very high level, it may yet be permitted to inquire as to what happens if one of the worms or burners fails. In this case the locomotive can be operated at reduced performance on the other burner. The risk in this respect is, however, no greater than that of the two boiler-feed devices of a locomotive failing simultaneously. How seldom this happens is well known.

Particular importance must of course be attached to the economical side. In the Halle district, the fact that pulverized-fuel-fired engines are running on an alternating schedule with grate-fired engines of the same class furnishes an excellent basis for comparison. The local conditions here are greatly in favor of pulverized-fuel firing, there being an abundance of lignite, whereas the principal hard-coal mining centers are about 250 miles away. Thus, lignite is not only basically cheaper, but also offers the advantage of considerably lower freight rates. This carries the cost of lump coal at Halle to about 28 reichsmark per ton, whereas lignite dust is 12 to 14 reichsmark delivered free onto the tender. The latter amount applies to lignite dust from separators, but mill dust can be had at the same price, in which about 3 reichsmark per ton for drying (raw lignite dust having 50 to 60 per cent moisture) and milling are included. This enables a large saving to be obtained in the fuel bill, as will be seen from Fig. 17. Curve *a* gives the amortization of a standard grate-fired engine over a period of 15 years; curve *b* showing that the dust-fired engine, in spite of a slightly higher prime cost, will pay in considerably less time, i.e., about 9.6 years, on account of the annual saving in its fuel bill. On the basis of equal life, therefore, the dust-fired engine will have produced a saving of $40,000, i.e., about its own value.

It thus appears that the use of pulverized-fuel-fired engines effects a considerable economy, which, with their reliability

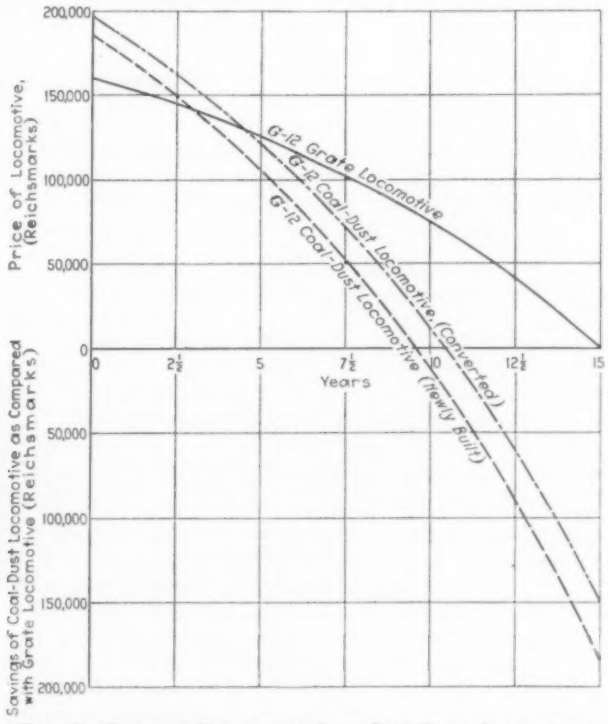

FIG. 17 ECONOMY DIAGRAM OF STUG G-12 CLASS LOCOMOTIVE

proved in actual service, strongly encourages its adoption on a large scale in the near future.

The Stug's research work has established that slack dust, too, has a bright outlook in Germany on account of the difference in price between lump coal and slack. This justifies a favorable forecast also in respect to engines fired with slack dust. This will be particularly appreciated for application to high-pressure locomotives, toward which there is a strong tendency, and which, on account of their small water spaces, make an easily adjustable fire control desirable.

Before closing this paper, some information should be given as to applications of the Stug system to stationary plants and ships. As was to be expected, the spray burner designed for heavy locomotive work has given good results in flue boilers, a boiler efficiency of 84 per cent having been obtained with lignite. The Stug system also has proved its applicability to hardening and melting furnaces. Very good results were obtained in cement and nitrate kilns, combustion being complete and economical in all these cases. Trials with marine boilers are now being carried out. A number of large stationary water-tube boilers were supplied by one of the members, the Hanomag concern.

It is a subject for investigation and discussion to consider the possibilities of the Stug system of pulverized-fuel firing in the United States. There is no doubt that its numerous advantages will go a long way in arousing interest conducive to its adoption.

Research Relating to the Action of 4-Wheel Freight-Car Trucks

By T. H. SYMINGTON,[1] BALTIMORE, MD.

This paper includes a study of operating and maintenance problems of car trucks that have resulted from increased weights, greater rigidity, and high speeds. The author discusses the 4-wheel truck as a whole, and includes such features of design as cross-equalization, swiveling resistance, self-squaring, car roll and nosing, guard-rail shocks, lateral motion, and four-point suspension.

Harmonic truck-spring action is discussed at considerable length. It is felt that excessive harmonic spring oscillation at critical train speeds may be caused by eccentricity of wheels. Tests will be made to determine this, and the author outlines various tests for determining unknown factors.

THE vital parts of freight cars are the trucks. We are using today the same fundamental principles in freight-car-truck design that have been in use for 75 years.

Modern heavy cars, some of great rigidity, operating at very high speeds, have brought with them many operating and maintenance problems. A scientific study of these problems and means for their solution are discussed in this paper.

There being no equipment in existence with which to make a proper study of the various problems involved, it was necessary to build two standard freight cars and equip them with much special apparatus of great exactness. Each car is also equipped with 12 water tanks to provide any desired load. The two cars were necessary in order continually to have a yardstick with which to compare the performance of different appliances. These cars are now very generally known and are shown in Fig. 1.

An accurate superimposed record is made on the recording table in car No. 1 of the following actions on each car:

1 Speed in miles per hour.
2 All car-body roll in relation to the constant plane of Sperry gyroscopes.
3 All truck-spring movements on both sides of the leading trucks.
4 All vertical movements of the center line of each car.
5 All lateral movements between the car body and one side frame.
6 All movements, at right angles to the journals, between the journal-box wedge and the roof of the journal box.

A telemeter record is made of the magnitude and frequency of all transverse forces and of the forces of vertical acceleration resulting from spring oscillation or end shock.

Each car is also equipped with an accurate spring dynamometer with which to measure the force of vertical acceleration resulting from end shock and a Kreuger-cell instrument with which to measure both the force of vertical acceleration resulting from end shock and the same maximum force of vertical acceleration resulting from spring oscillation.

Both cars are equipped with large periscopes through which to see and study all truck actions from inside the cars.

An idea of the accuracy of the equipment may be obtained from Fig. 1. Typical sections of the records obtained are shown in Appendix No. 2. Actually, the records of the performance of the two cars are made in different-colored inks. For easy reproduction, Appendix No. 2 was traced in full and dotted lines from actual records.

This research work naturally divides itself into four general headings, viz.: Safety, Damage to Lading, Train Resistance, and Maintenance Costs. These are all so interrelated that it is thought best to discuss the truck as a whole and then in detail.

The 4-Wheel Truck as a Whole

We have known for 50 years that, on any curve, there is always an essential sliding of three wheels on the rails. This cannot be avoided and constitutes the major part of constant-radius curving resistance.

Oiling the wheel flanges materially reduces this curving resistance, and also reduces rail wear on the gage side of the rail.

Nothing can be done to reduce the resistance and wear resulting from sliding between the treads of the wheels and the top of the rails.

Wheel sliding can be prevented only by having both axles always radial to the curve. This has never been accomplished in a simple, efficient 4-wheel truck design. The only truck yet produced where the axles are always radial to the curve is the Boyden six-wheel freight-car truck, discussed in Appendix No. 1.

This wheel sliding always necessitates, on any curve, a continuous high flange pressure against the rail of the outside leading wheel. No derailment on curves will result from this particular

[1] T. H. Symington & Son., Inc. Mr. Symington was born in Baltimore, Md., in 1869, and received his early education in the schools of that city. In 1887 he entered the Baltimore & Ohio Railroad shops, as machinist's apprentice, and served four years. He then went to Lehigh University, where he took a four-year course in two years, and received the degree of Mechanical Engineer. Following this he was with the Richmond Locomotive Works from 1893 to 1898, leaving there as assistant superintendent to become superintendent of motive power for the Atlantic Coast Line Railroad. In 1901 he organized the T. H. Symington Company and continued as its chief executive until the company was sold in 1925. During the war, he organized, owned, and operated six large companies in Rochester, N. Y., and Chicago, Ill., for the production of special machinery, ordnance, and artillery ammunition. Toward its close he was appointed Assistant Chief of Ordnance, in charge of the entire U. S. artillery ammunition program.

Mr. Symington originated and built the draft-gear test plant on which the United States Government made the first comprehensive draft-gear tests. He also originated and carried to completion research on cast-steel side frames that has resulted in the modern frame. Since 1925, he has been executive head of T. H. Symington & Son, Inc., and actively engaged in the research work covered by this paper.

Contributed by the Railroad Division and presented at the Annual Meeting, New York, N. Y., Dec. 1 to 5, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

flange pressure unless the weight on this wheel is unduly reduced.

Cross-Equalization. With flexible cars, the only cause of reduced weight on this leading outside wheel is excessive car roll that may put one-half of the entire body weight on one side bearing. With rigid-body cars and reduced side bearing clearance, track warp may also put the entire weight of one-half the car body on one side bearing 25 in. from the center. Only 15 per cent of the load is then on one side of the truck, and this sometimes is not sufficient to keep the wheel on this side from mounting the outside rail. With large side bearing clearance, excessive car roll also may result in derailments on approach curves, whether the car is flexible or rigid, because of insufficient cross-equalization of load and increased swiveling resistance resulting from excessive weight on one side bearing.

If the load on one truck never can be more than 16 in. from the center, the minimum proportion of the load on one side of the truck is about 30 per cent, which always is sufficient to keep a wheel from mounting the rail on curves from flange pressure.

Figs. 2 and 3 illustrate the two conditions—with and without cross-equalization. The desirability for increased cross-equalization of the load on all cars is obvious in the interest of safety.

When the load is so cross-equalized, there must be an auxiliary support at least 25 in. from the center in order to prevent any possibility of the car body rolling off the truck from centrifugal force when the car hits a curve at high speed.

Some truck designers have thought that equalization in line with the rail is desirable on 4-wheel trucks. Careful research has demonstrated that, while this equalization does no harm, it performs no desirable operating function.

A derailing condition results from warp in the track between truck centers and not from the warp between wheel centers on one truck. By "warp" is meant the amount that one point on the rails is out of the plane of the three other rectangular points on the rails.

The flexibility of the A.R.A. standard truck is always sufficient to permit one truck wheel to go down into a maximum-depth low

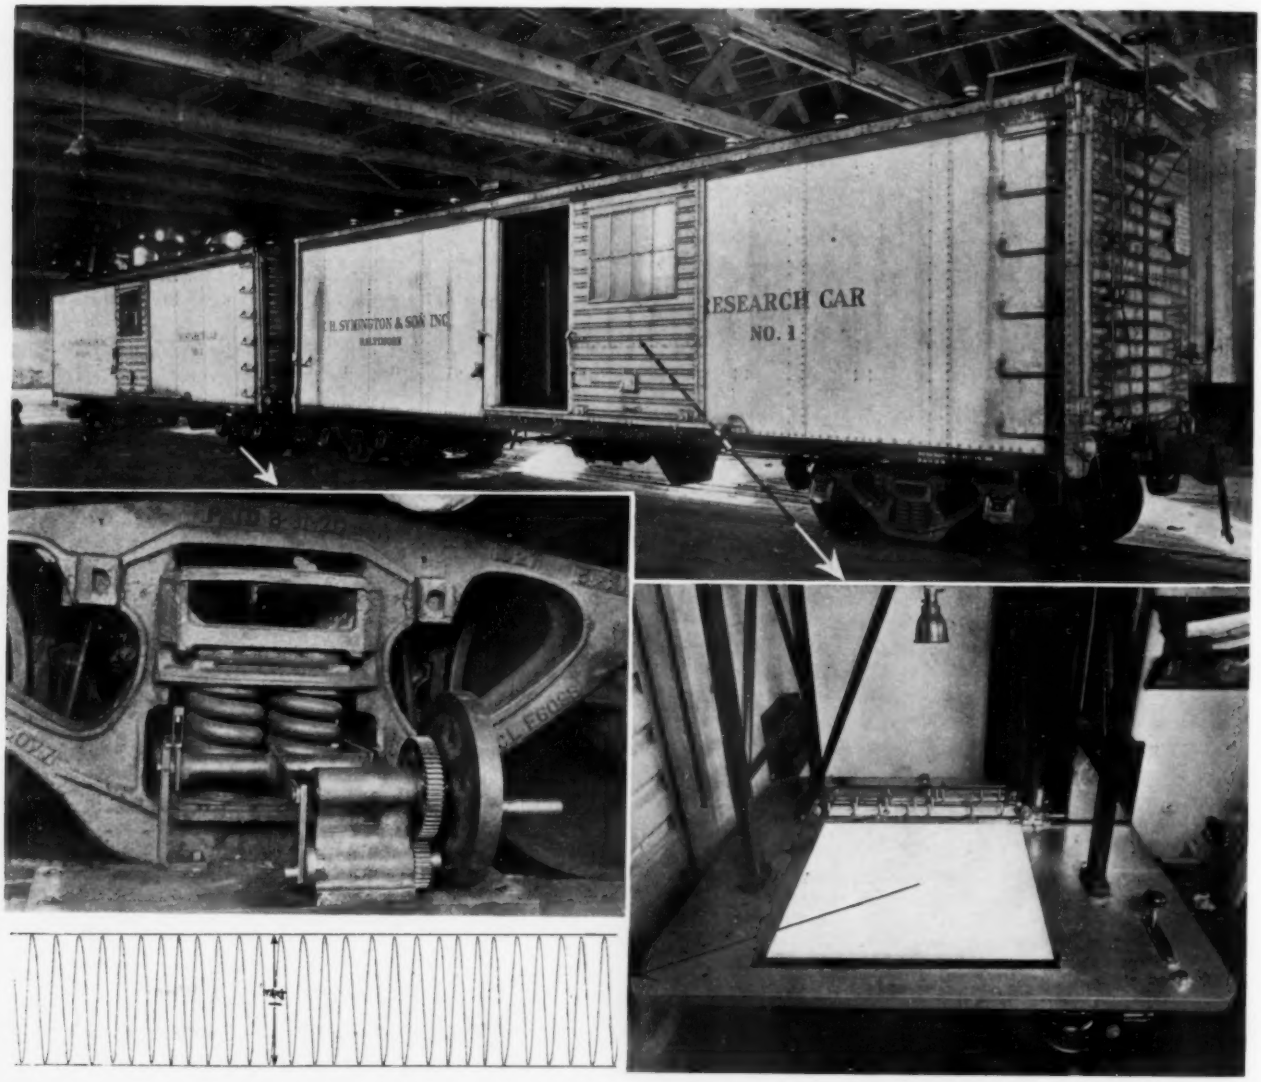

FIG. 1 CARS USED IN RESEARCH ON THE ACTION OF 4-WHEEL FREIGHT-CAR TRUCKS

(Crank throw at truck of Car No. 2 produced the equivalent of 1¾ in. of truck-spring movement. Diagram at bottom left was produced on recording table in Car No. 1 with 240 cycles of equivalent spring movement per minute. Paper roll moved by hand. Record showed exactly 1¾ in. of pen travel at this and all less number of cycles of movement per minute.)

TABLE 1 SWIVELING RESISTANCE. PRESSURE REQUIRED AT WHEEL FLANGE TO SWIVEL ONE A.R.A. STANDARD TRUCK OF A FULLY LOADED 55-TON BOX CAR WITH THE WEIGHT CONCENTRATED ON ONE SIDE BEARING

	Pressure, lb.
With friction side bearing	20,870
With roller side bearing	5,820
With T. H. Symington bolster	270

joint without losing its share of the load on this side of the truck.

Swiveling Resistance. There is no swiveling resistance between the trucks and the car body except on approach curves with changing radius. Table 1 gives the results of tests to determine the maximum swiveling resistance under various truck conditions, with the track warped 3 in. between truck centers to put excessive loads on one side bearing. It is realized that this excessively warped track is found only occasionally in industrial yards, but the identical swiveling resistance is often encountered on main-line approach curves when the car body has rolled over on to one side bearing.

Derailments. Most freight-car derailments occur when entering or leaving curves because, at these points on the line, the curve radius is changing and we have the combination of high flange pressure against the outside rail and minimum weight on the derailing wheel. On entering a curve, it is the rear truck that usually derails, and on leaving a curve, it is the leading truck that usually derails. The total flange pressure on approach curves is made up from:

a The pressure necessary to slide three truck wheels
b The pressure necessary to swivel the truck
c The lateral component of car-body roll.

When the car body rolls toward the outside rail, there is a maximum flange pressure because all three factors of pressure—*a*, *b*, and *c*—are involved. This pressure may spread the track, break the wheel flange or shear off the journal-box-brass lugs, but never causes a derailment because, with standard cars, 85 per cent of the body weight is then on this side of the truck.

When the car body rolls toward the inside rail, only factors of pressure *a* and *b* are involved, but the outside wheel will sometimes derail because then only 15 per cent of the body weight is on this side of the truck.

Table 2 gives the results of tests to determine the derailing tendency on approach curves with different trucks on warped track representing a soft spot at the outside rail, when the load was on the side bearing adjacent to the inner rail. Here, also, only factors of pressure *a* and *b* are involved.

Self-Squaring. It is obvious that, on tangents, minimum train resistance and flange wear result when the trucks are square and the flanges do not drag on the rails. Any design that will square a 4-wheel truck after coming out of a curve and keep it square is worth considering.

Any truck that will prevent the wheel flanges from exerting high pressure, first against one rail and then against the other, is worth considering, because both train resistance and flange wear are involved.

This surging results from either car roll or car nosing. If side-bearing clearance is large, cars are apt to roll excessively. If too small, cars with standard trucks will nose.

Observation and careful study of the action of the two research cars shown in Fig. 1, under varying speed, truck, and load conditions, lead to definite conclusions.

Car Roll and Nosing. Car roll results at certain speeds from a synchronous coordination of small rail-joint depressions, the inverted pendulum action of the car body, and the truck springs. Excessive car roll will sometimes result in lifting the wheels off the rails, first on one side of the truck and then on the other.

If the synchronous impulses from the rail joints are not sufficient to cause objectionable car roll, the truck will see-saw on its

center plate, when there is sufficient side-bearing clearance, and not disturb seriously the mass of the car body.

If side-bearing clearance is a minimum or at zero, these vertical rail-joint impulses directly affect the car body mass with resulting nosing.

This nosing originates from the car body. If side-bearing clearance is lacking, the truck cannot rock independently of the car body, and synchronous impulses from the rail joints will alternately compress the truck springs on opposite sides of the car. The lateral component of this action causes the car body to swing first to one side and then the other. This action occurs on all passenger cars. Without an easy lateral float of

the car body on the trucks, the lateral movement of the car body will cause the trucks to surge first against one rail and then against the other and result in rapid end wear on brasses and journals. This nosing has the same period as car roll, and can therefore be identified with the synchronous timing of the rail joints at certain definite train speeds, often about 17 miles per hour.

Car roll can be reduced by reducing side-bearing clearance and by increasing the stiffness of the truck springs.

Car nosing can be eliminated by increasing the side-bearing clearance or, with minimum side-bearing clearance, by providing a very soft, easy lateral motion.

Either construction will break up any objectionable synchronous nosing action of the car body and truck in tune with the rail joints.

Safety. We have taken adequate care to prevent accidents resulting from the trucks by providing ample strength in the side frames and bolsters and by providing safety supports for the brake beams. We have done nothing to the trucks to eliminate derailments and to solve the broken-wheel-flange problem. An analysis of these problems indicates the need for better cross-equalization to prevent derailments and an adequate lateral motion on all freight-car trucks to minimize lateral shocks.

Guard-Rail Shocks. Car roll, or car nosing, will often take up all lateral clearances between the car body and the collar of one journal. If, at this instant, the opposite wheel flange strikes a guard rail at speed, something must yield in the line of force from the blow at the guard rail to the body mass, namely:

1 The guard rail
2 The wheel flange
3 The journal collar
4 The stop lugs on the brass
5 The side frame
6 The bolster
7 The car body.

If the blow is taken by the opposite journal shoulder, the force must pass through the top flange on the brass, and through the wedge to the roof stop lugs on the box on the same side of the truck as the offending guard rail.

This is nothing but a force of lateral acceleration. The kinetic energy is proportional to MV^2, where M is the mass that is laterally accelerated and V is the velocity involved in this lateral acceleration.

If we consider the weight on the rails of one truck of a fully loaded 55-ton car as 100, the body weight on one truck is 90 and the truck weight is 10. With adequate lateral motion, the mass to be laterally accelerated at one instant is the truck only, or 10, and the velocity of the lateral acceleration of one wheel is in direct proportion to the speed of the train and the entering angle of the guard rail. If we consider that, for a certain speed and guard rail, this lateral wheel velocity is 2, the lateral velocity of the center of gravity of the truck mass is 1. Then MV^2 for the truck = 10.

With a similar car, without lateral motion, we must add the force to laterally accelerate one-half of the car body with load. In this case the body mass equals 90 and the lateral velocity is 1, because, at any one instant, this lateral velocity of one-half of the car body is one-half of the lateral velocity of the wheel striking the guard rail. Then MV^2 for the car body equals 90 and the sum of the two equals 100.

There are several factors of correction, namely: the lateral yield in the truck structure, the force needed to compress slightly the truck springs because of the small lifting angle of any lateral motion, and because the lateral force on the car body is applied at the center plate some distance below the center of gravity of the car body. We are certain, however, that the force of lateral acceleration at the guard rail without lateral motion is many times this force when we have adequate lateral motion.

The same advantages accrue from adequate lateral motion when the dynamic shock comes on the throat of the wheel flange.

If we can, with suitable lateral motion, greatly reduce this dynamic force, we automatically increase the factor of safety for the wheel flange many times and therefore largely eliminate broken wheel flanges.

If the wheel flange is strong enough to stand the shock, the brass is sometimes broken.

It would seem essential, therefore, that any lateral motion provide sufficient travel and gravity resistance so that there is *always* an ample reserve of yield to insure the minimum shock to the wheel flange.

It is fortunately a rather rare coincidence when a wheel flange strikes a guard rail at speed at the instant when all lateral clearances are absorbed in the opposite direction.

There is no doubt about the fact that there are many lateral shocks that are not sufficient to break a wheel flange or shear off the brass lugs, but are sufficient to break down the oil film on the journal collar, or shoulder, with resulting rapid end wear on brasses and journals.

Lateral Motion

An adequate lateral motion must accomplish two separate important functions:

1 The floating action at the center must be very easy in order to prevent nosing when side bearing clearance is at a minimum
2 There must be sufficient travel and gravity resistance to insure lateral yield under all operating conditions and to prevent the bolster from striking the side frame.

This subject can be studied best with the swing-hanger construction used on all passenger cars, which operate with little or no side-bearing clearance. These hangers vary in length from $28^1/_4$ in., spread $8^3/_4$ in. at the bottom, to the equivalent of $6^1/_2$ in. parallel hangers.

No matter what design is used, it is always a compromise to give the best results to eliminate nosing and provide sufficient yield and resistance.

With angular hangers, the bottom spread must be small to eliminate nosing and increased to give sufficient lateral resistance.

If parallel hangers are used, they must be long enough to eliminate nosing and short enough to provide sufficient resistance in the usual travel of $2^1/_4$ in.

It is good practice on a straight railroad to provide best against nosing, and on a crooked railroad to consider lateral resistance as of first importance.

Pullman cars that operate on all sorts of railroads probably offer the greatest difficulty in this compromise between nosing and needed resistance.

An ideal hanger for all passenger cars would seem to provide a compound lift curve to produce a very easy float at the center and ample lift toward the end of the motion.

Fig. 4 shows full-size lift curves:

(*a*) With the longest angular hangers in general service
(*b*) With the shortest angular hangers in general service
(*c*) With the shortest equivalent parallel hangers in service today
(*d*) With the Barber lateral motion, and
(*e*) An ideal lift curve that has no compromise.

Lift curve (*e*) can be produced either with compound swing hangers or with compression rockers.

It has been demonstrated that $6^1/_2$-in. parallel hangers will induce little nosing on passenger cars with no side-bearing clearance. The reason is that combined helical and elliptic springs have a very flat load curve, and therefore largely absorb the effect of track irregularities without disturbing the car body.

On freight cars, with only helical springs, track irregularities are more readily conveyed to the car body, and an easier lateral motion at the center than on passenger cars is required to prevent the car-body swing from carrying the trucks with it. Curve (*e*) has therefore been found best for freight cars.

One objection to all swing hangers is that the lateral motion is continuous and the millions of movements necessitate a periodic renewal of pins and bushings in the hangers on account of wear.

With properly designed rockers, there is no sliding friction and the parts will last, with no deterioration, for the life of the car.

When rockers, or rollers, are used for lateral motion, experience has shown that the car should be equally stable with the weight evenly distributed on the bolster, or concentrated on one rocker, which often occurs with rigid-body cars. This means that one rocker should give equal lift each way from central position. It is also important that the rocker-wear factor, viz., the product of its diameter by its length, be sufficient to insure long life with ordinary steel rocker bearings.

Four-Point Suspension. There has been much discussion about 3-point and 4-point suspensions. When cars are supported on 4 rockers, there is an even 4-point support only on level track with rigid-body cars. Often the rigid-body car is supported on 3 rockers, and, on unusual track, the main supports may be 2 diagonal rockers instead of 2 diagonal side bearings, as on standard cars.

Many attempts have been made in the past to carry a freight car on 4 rocker side bearings in order to minimize swiveling friction and reduce weight.

The only well-known cars of this construction in service are five hundred 100-ton coal cars on the Norfolk & Western Railroad. They were designed for great flexibility, as a rigid-body car of this construction would not stay on the rails because there is no cross-equalization of the load.

With rigid-body cars, the rocker supports must be sufficiently close together to provide the essential cross-equalization of weight necessary always to maintain 30 per cent of the body weight on the light-loaded wheels and thereby prevent derailments.

If the rockers are not of conical form, provision also must be made to take care of the angular movement between the truck and body bolsters, or the mechanism will lock and derail the truck on a curve.

The only reason for increased swiveling resistance with roller side bearings (see Table 1) when the weight is largely on one side bearing, is that the rollers are not of conical form, and therefore must slide a little on their bearings because of the angular movement between the bolsters.

When 4 rockers are used to support a car body, it would certainly seem desirable to arrange for gravity to square the truck when coming out of a curve. It is believed that this failure of the truck to square itself is responsible for increased train resistance and wheel-flange wear.

Barber Lateral Motion. The only lateral motion in general service on freight cars in this country is the well-known Barber lateral motion. This motion is the equivalent of parallel hangers $4^3/_8$ in. long. With such short hangers, cars will nose if there is little or no side-bearing clearance. The travel of $1^1/_8$ in., with a lift of $^3/_{16}$ in., may not provide sufficient travel and resistance always to insure lateral yield. The makers of this device advise that, if desired, they can increase the travel and lift, which would give better action to prevent nosing and to provide needed travel and resistance to avoid lateral shocks.

The Truck Springs

With the large masses and high speeds of modern freight cars, the cumulative harmonic vibration of helical truck springs is responsible for a number of our operating problems.

Because of the small available space, freight-car truck springs

are made in helical or coiled form, and also because the same springs must be suitable for empty or fully loaded cars and there must be no excessive variation in coupler height.

Harmonic Spring Oscillation. All helical springs have definite periods of vibration dependent upon the springs themselves, the mass supported by them and the speed. This vibration, without pendulum action of the car body, is in tune with the intermittent forces from the rail joints in the track at speeds of from 35 to 60 miles per hour.

The resulting cumulative spring oscillation is probably the largest factor in damage to perishable freight and to truck springs. This oscillation is also a large factor in velocity train resistance and, in the author's opinion, for the initiation of transverse rail fissures when the springs go solid.

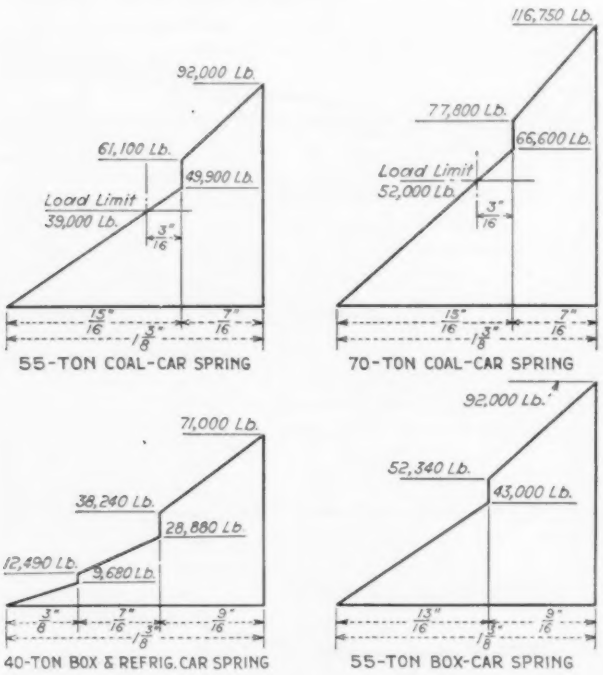

FIG. 5 NON-HARMONIC SPRING CURVES

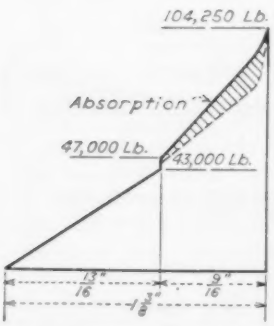

FIG. 6 SPRING CURVE OF 55-TON BOX-CAR SPRING WITH ONE SNUBBED EDGEWATER UNIT

We have frequently recorded spring oscillation that closes solid A.R.A. spring groups of 40 and 55 tons capacity at the rate of 3 to 4 times per second.

All cars are subject to spring oscillation at certain particular speeds. We often identify one type of car as jumping when other cars are not jumping. This is because the critical speed for the other cars was not attained during the time of our observation.

Few railroad men realize that the shock inside a freight car from spring oscillation may cause a man to crash through an ordinary chair to the floor of the car. When once experienced, one can easily understand why so much beef is found on the floors of refrigerator cars; why fat cattle lose from 10 to 15 per cent in weight in a long shipment to the stockyards; why certain fruits must be picked so green, in order to stand shipment, that they never reach perfection at a distant market; why we have so many spring failures on cars loaded to the rail limit; why such loaded cars do so much damage to rails.

The breaking up of harmonic truck-spring action will automatically solve all of the above problems.

The first moves to stop the failures of truck springs under harmonic action were to increase the static capacity of the coils and then to add more A.R.A. standard coils and increase the static capacity of the spring group. Both actions materially helped to diminish spring failures, but had no effect in reducing harmonic spring action, except to increase the critical speed for this action. All such heavier-capacity groups will go solid under harmonic action when the track, the lading, and the train speeds are favorable to such action.

Concentrated effort is now being made by many railroads to break up this harmonic truck-spring action by the use of various means to introduce friction in the spring action so that the compression curve of the spring will vary materially from the release curve.

Excessive harmonic truck-spring action can be prevented by constructing spring nests that have irregular compression curves as illustrated in Fig. 5.

The best general performance of springs was had with a spring group having the curve represented in Fig. 6. In this spring group, an Edgewater ring spring was under sufficient initial compression so that it was inoperative except under harmonic spring action. It is evident that any harmonic action tends to be broken up both by the sudden change of direction in the combined spring curve and by work absorption.

A great advantage in this spring-group construction is that the friction elements are only working in an emergency, and can therefore be relied upon for a long life.

It is believed that a snubbed Frost spring in the same group would give approximately the same results.

The first essential for any truck spring would seem to be to prevent its ever going solid under vertical oscillation. The fiber stress then, at some point in a coil, might easily go to 250,000 lb. per sq. in., when there would be a certain failure.

If one coil in a nest is broken, the spring group will thereafter go solid much more readily, with resulting destructive shocks to lading and to the rails.

It is believed by many engineers that excessive harmonic spring oscillation at critical train speeds may be caused by eccentricity of the wheels. Tests will be made to determine what, if any, reduction in harmonic spring oscillation can be effected with wheel treads ground concentric with the journals.

Some efficient and durable means will certainly be found to break up this destructive harmonic spring action, and it is believed that the subject can be studied scientifically in the simplest way with the two research cars for which the author is responsible. These cars being identical, the action of any two types of spring can be recorded accurately and compared under identical service conditions. It is of course necessary to record the action of any type of spring at all speeds up to, say, 60 miles per hour, and with, say, one-quarter, one-half, three-quarters, and full lading.

MEASURING THE FORCE OF VERTICAL ACCELERATION

Fig. 7 shows the spring dynamometer and Kreuger-cell instrument installed at Station A in each car to measure the force of vertical acceleration resulting from the vertical component of end shock. The dynamometer instrument is of 1000 lb. capacity and the suspended weight is 50 lb.

We know that the actual force of vertical acceleration is greater than the dynamometer indicates because of the slight

yield in the spring, but the readings in the two cars are entirely comparable.

These dynamometer instruments can be depended upon only when subjected to a single force of acceleration, and will not properly measure forces of acceleration of high frequency such as result from spring oscillations.

They have been successfully used to record the force of vertical acceleration resulting from end shock.

A 55-ton loaded coal car was drifted into Car No. 1, which was backed up against a string of cars and brakes set on Car No. 2. Readings were taken at five points in Car No. 1, as shown in Fig. 8, and compared with the reading of the fixed instrument at *A*.

It will be noted that, in this car, with this type of loading, the highest recorded force of vertical acceleration was at Station 2. At 3 miles per hour, the dynamometer at Station 2 recorded 1000 lb.

Tests were then made with one horizontal dynamometer in-

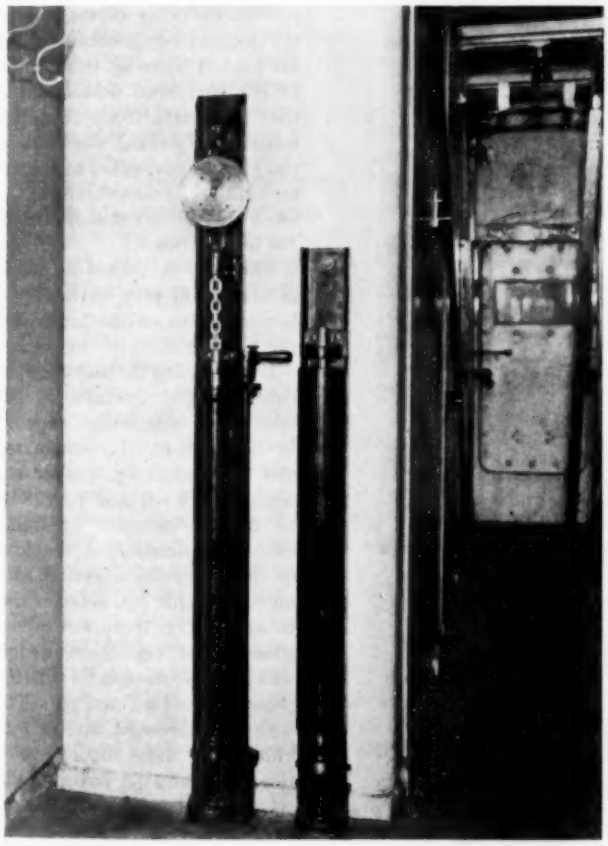

FIG. 7 SPRING DYNAMOMETER AND KREUGER-CELL INSTRUMENT INSTALLED AT STATION A IN EACH OF THE CARS SHOWN IN FIG. 1

strument fastened to the car floor at Station 2, opposite the vertical instrument at Station A, and the recorded force of vertical acceleration at Station A was from 5 to 6 times the force of longitudinal acceleration at Station 2, dependent on the speed of impact. Table 3 gives the results of three impacts.

It is believed that, for all brittle ladings, end shock is far more destructive than spring jump. These high forces of vertical acceleration are dependent on the efficiency of the draft gear.

It would help materially to provide yield between the lading and the car body which would function like the spring-cushion seat in an automobile.

TABLE 3 COMPARATIVE FORCES OF HORIZONTAL AND VERTICAL ACCELERATION RESULTING FROM END SHOCK

(Comparative readings taken with two identical spring dynamometers.)

	Horizontal	Vertical
First shock	150	970
Second shock	180	840
Third shock	90	400

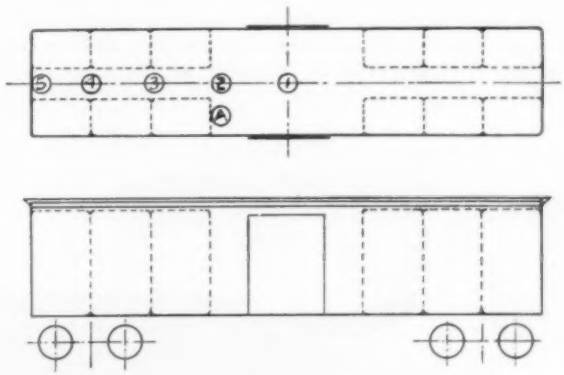

FIG. 8 LOCATIONS OF DYNAMOMETERS IN RESEARCH CAR IN END-SHOCK TESTS. LOAD IN CAR, 18 TONS

[One dynamometer permanently located at *A*. For end-shock tests an identical dynamometer was placed at points (1) to (5). Readings compared between the two instruments for each end shock gave the following percentages: *A* = 1.00; (1) = 0.28; (2) = 1.00; (3) = 0.765; (4) = 0.104; (5) = 0.071. For comparison of longitudinal and vertical acceleration the extra instrument was placed in horizontal position at (2).]

It is probable that excessive spring oscillation at the rate of 3 to 4 times per second is responsible for the shaking down of perishable fruits and vegetables.

The Kreuger-Cell Instrument. This instrument, named after its inventor, a Swedish professor, is considered by our Bureau of Standards as equal to the telemeter in accuracy for measuring dynamic forces. It will, however, only measure the maximum applied force.

With this instrument, the compression, within its elastic limit, of a section of a ball is measured. The radius of the ball is 10 in., which is suitable for this range of pressures. The ball's surface is in contact with a piece of flat hardened steel, ground and polished. The flat surface is covered with a very thin coating of camphor smoke, and any applied force will produce a definite circular impression in the smoke. The diameter of this circle is then measured with a microscope, the instrument having been previously calibrated in a static testing machine. This instrument is far more dependable for recording impact pressures than any Brinell instrument, and is entirely suitable to check the accelerometer record of maximum forces of vertical acceleration resulting either from end shock or from spring oscillation.

The Telemeter. This instrument, in the present application, operates as follows: The force to be measured passes through a piece of chrome-vanadium steel, properly heat treated, which force must not exceed the elastic limit of the section. Within this piece of steel, and subject to the same elastic compression under load, there is placed a highly refined carbon pile, the electric resistance of which varies directly with the pressure on the pile. This changing electric current produces an unbalance in a Wheatstone-bridge circuit that is exactly proportional to the pressure on the pile. The unbalance in the Wheatstone bridge causes the twisting of a pair of tungsten wires. On these wires there is a tiny mirror. This mirror reflects a beam of light upon a moving photographic film. After the instrument is calibrated, this record of force is very accurate.

The recording instrument is called an oscillograph. For this particular work, where the oscillograph is placed in a vibrating freight car, it had to be redesigned as follows:

1 The tungsten element is shortened from 4 in. to 2 in.
2 The tungsten element, with mirror attached, is immersed in oil to eliminate any vibratory action of the mirror.
3 The oscillograph is supported in all directions on sponge rubber.

In connection with the telemeter in this installation, an accelerometer is placed over the rear truck in each car for measuring the forces of vertical acceleration resulting from spring oscillation. The accelerometer operates on the same principle as the telemeter, and a record of the vertical acceleration in each car is made on the moving photographic film in the oscillograph in Car No. 1.

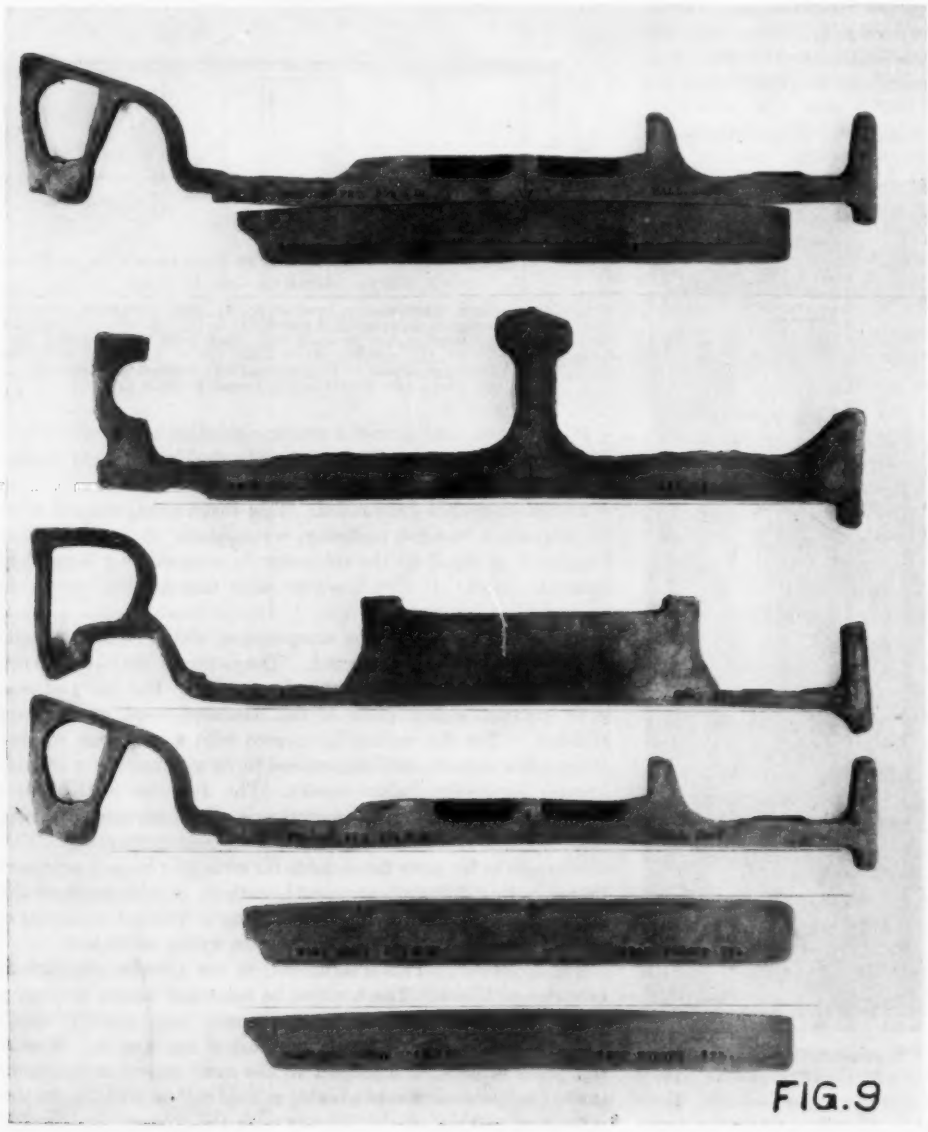

FIG. 9 WEAR BETWEEN TOP OF JOURNAL-BOX WEDGE AND ROOF OF JOURNAL BOX

THE JOURNAL-BOX WEDGE

A number of railroads are having difficulty with the wear between the top of the journal-box wedge and the roof of the journal box. If the wedge is harder than the box, the wear occurs in the roof of the box. If the box is harder than the wedge, the 78-in. radius on top of the wedge is worn flat. Fig. 9 shows a photograph of actual conditions as they exist.

This is a very serious matter, because, with loss of proper equalization on top of the wedge, there may result an excessive load at the front or back end of the journal that will cause a hot box.

Journal bearings often wear tapered, and if this tapered wear is coincident with loss of equalization on the wedge, a new brass will certainly have a concentrated load near the shoulder or the collar of that journal. A study of this matter on the research cars has established the fact that all of this wear, resulting in loss of equalization, is caused by the wedge's sliding on the roof of the box at right angles to the journal.

It has been demonstrated that all journal brasses are normally against the outer center lugs in the journal boxes because they are pushed there by the brakes. It has also been demonstrated that there is a frequent movement of the journal and brass in the journal box, often to the extent of the clearance between the brass and the center stop lugs in the journal box.

This play is always in excess of the lateral play between the beveled faces of the brass and the beveled faces of the wedge.

By increasing the play between these beveled surfaces, it has been found that wedge slippage in the box is entirely eliminated and the radius on top of the wedge can be reduced from 78 in. to 24 in., thereby providing better equalization of the load on the center of the journal, with no loss of this equalization due to wear. Fig. 10 shows the construction of this new wedge, which is interchangeable with the present standard wedge. The wedge is hardened and is provided with three small beveled tits that gradually imbed themselves into the roof of the journal box.

One blow from the journal shoulder drives this wedge against the front roof stop lugs in the journal box, and thereafter it never shifts in the box. There is ample bearing surface to permit, without wear, transverse sliding and sliding in line with the journal between the flat bottom of the wedge and the flat top of the brass. It will be noted that provision is made to prevent any possibility of the standard brass upsetting in the journal box should there be a seizure between the brass and the journal.

SPRING PLANKS

A study of the action of the A.R.A. spring plank on standard

trucks has led to the theoretical conclusion that it performs no important function. The function of the spring plank is to hold the truck square; that is, to keep one side of the truck from getting ahead of the other. An exhaustive investigation of the actual fits of the four bosses of the A.R.A. side frame in the four holes in the spring plank has shown the manufacturing necessity for sloppy fits, which permit an initial large angular movement between the side frame and the spring plank. It is believed that if the bearings between the side frames and bolster are sufficiently long and close fitting, the bolster can be utilized to maintain essential squareness of the truck. The spring plank can then be dispensed with entirely and the truck weight thereby reduced about 600 lb. on each 70-ton car. When the spring plank is eliminated, it is a simple matter to arrange the truck so that the cost of changing wheels is largely reduced.

It is not considered sound from a purely engineering angle to tie the side frames together at the bottom to a fixed dimension when the tops of the side frames are not similarly controlled.

The bolster applies all lateral forces to the side frames, and, without a spring plank, we are certain that the reaction points are at the tops of the journals. Secondary lateral stresses in the side frames are thereby minimized.

Service tests are in progress to demonstrate the efficiency of this type of truck construction.

Side Frames and Bolsters

Cast-steel side frames and bolsters have been vastly improved in design in the past few years. Further improvement can be made. The ideal ultimate standards will have essential strength, minimum weight, and maximum wearing surfaces to insure long service life.

This will be accomplished by designs that minimize secondary stresses and prevent a concentration of such stresses at any points in the structure. Metal that is never adequately working also should be eliminated. It is believed that future specifications for these parts will be based largely on elastic limits.

There are today a very large number of designs in current use that are not interchangeable and require a multitude of patterns and coreboxes. Brake-hanger brackets are also of various designs and degrees of efficiency and ultimately will be standardized.

Manufacturing tolerances permit quite a difference in the lengths of side frames, and the practice will soon become general of mating side frames in the same truck as now holds in mating wheels on the same axle.

As the normal position of each brass is against the outer center stop lug in the box, it would seem proper to mate side frames on the basis of the distance between the faces of the outer center stop lugs and not from center to center of journal boxes.

Additional Research

When the writing of this paper was undertaken, it was believed that this entire research could be completed in time to tabulate all the results. Unforeseen delays have made this impossible.

It is considered premature to comment on truck-spring performance at this time. We first must get the record of performance of all types of truck springs at all speeds up to 60 miles per hour and with various ladings.

No tests have yet been made to measure the magnitude and frequency of lateral forces or of the effect of vertical spring oscillation on perishable freight.

An exhaustive program for joint freight-car-truck research has, at this writing, October 1, been arranged between several of the larger manufacturers of trucks and springs and one of our important railroads. The results of this work cannot be included in this paper, but will, at a later date, be made public.

Appendix No. 1

THE BOYDEN TRUCK

The Boyden 6-wheel freight car truck is a splendid example of how *not* to introduce a new device on a railroad. It was prematurely put in service.

One 120-ton car on the Virginian Railroad was equipped with Boyden 6-wheel trucks many years ago. On the first run, improper weight distribution and excessive car-body roll caused a truck to derail and the car turned over. The truck was then redesigned by a competent truck engineer to distribute better the load on the wheels, and essential stops were provided to limit the body roll. As far as possible, old patterns were used and no refinement of design for reducing weight was made. This car has since been in continual successful operation for five years and has made about 75,000 miles with the original steel wheels that have never been out from under the car.

Fig. 10 Showing Construction of New Wedge Which Is Interchangeable With Present Standard Wedge

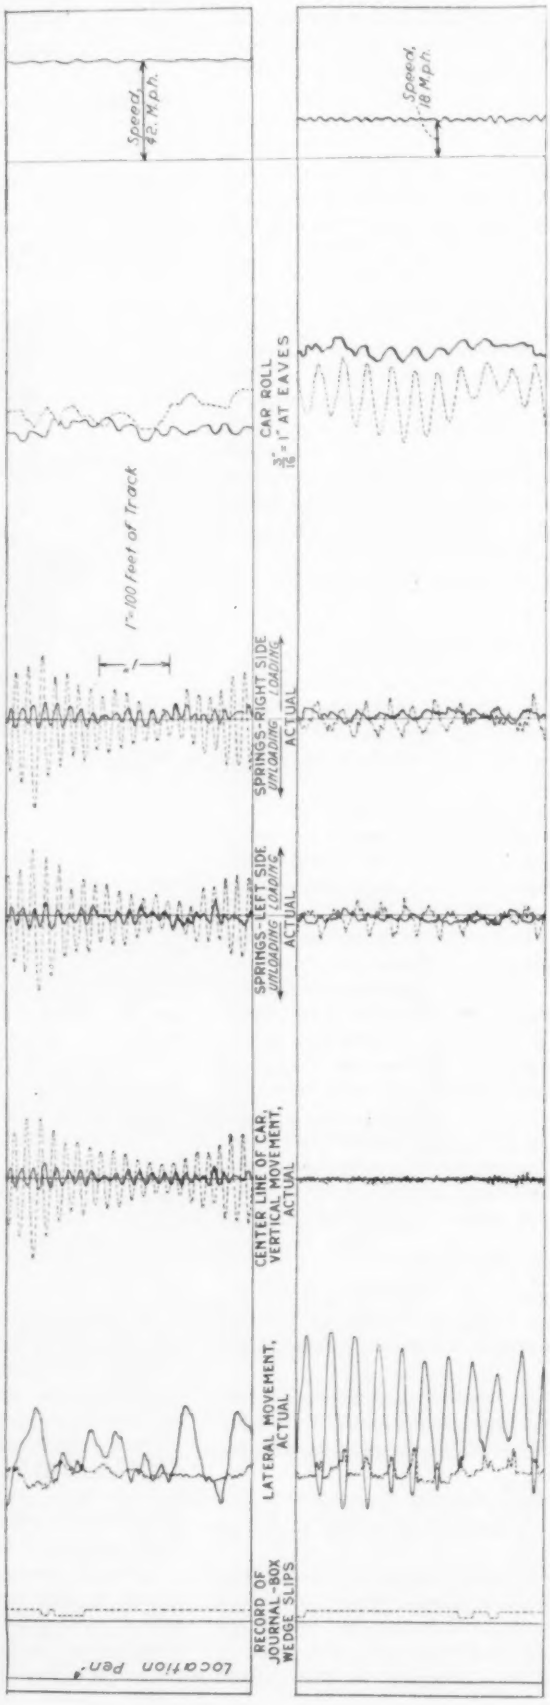
This truck was built without regard to weight and is too heavy. Any good truck designer can bring the weight down in line with other 6-wheel trucks.

It is believed that, with 100 cars equipped with this truck in refined form to eliminate superfluous weight, a dynamometer car would show a very large reduction in train resistance. This, coupled with a much longer average life for steel wheels and rails, might easily result in the economic replacement of other 6-wheel trucks now in service.

The Boyden principle can easily be adapted to 6-wheel passenger-car or locomotive-tender trucks with equally satisfactory results.

* * *

In presenting his paper the author said that when a loaded high-gravity car with any existing trucks rolled excessively on an approach curve, nothing could insure against a derailment. It had been proved that car roll could now be eliminated.



When a rigid body car with any existing trucks and with small side bearing clearance encountered a soft spot on an approach curve, nothing could insure against a derailment. It had been proved that freight-car trucks could now be made safe on curves with a run-off of $1^1/_2$ in. in 10 ft.

Harmonic spring action on loaded cars, with any coiled truck springs, at their critical train speed sometimes resulted in the springs going solid at the rate of 3 to 4 times per second, and these hammer blows on the rail, in the author's opinion, initiated transverse rail fissures. It had been proved that harmonic truck-

Appendix No. 2

SPECIMENS OF RESEARCH-CAR RECORD WITH 40-TON SPRINGS IN EACH CAR. SPRING-NEST LOAD, 17,350 LB.

Full Lines: Car No. 1 with non-harmonic springs (Fig. 5), full lateral motion [Curve (*e*), Fig. 4], and non-slip journal-box wedges.
Broken Lines: Car No. 2 with A.R.A. springs, no lateral motion, and standard journal-box wedges. Records reduced in size for publication. Original length, 23⅞ in.

spring action could now be broken up so that the springs would never go solid.

All the evidence indicated that damage to perishable freight could be largely reduced by the use of non-harmonic truck springs.

The lateral forces with standard trucks were sometimes responsible for spread track and usually responsible for broken wheel flanges. It had been proved that the magnitude of these lateral forces could now be reduced many times.

All the evidence indicated that train resistance could be largely reduced with perfected trucks that would minimize friction, oscillation, and concussion. The dynamometer car alone would establish this fact.

All the evidence indicated that maintenance costs on track, wheels and axles, all truck parts and car roofs and framing could be largely reduced with perfected trucks. Time alone would definitely establish this fact. Any improved truck must be so designed as to insure a very long life.

Some railroads figured that it costs 5 cents per pound per year to pull around excess dead weight. Then 500 pounds surplus weight was $25 per car per annum.

Research of this character must, of necessity, be undertaken by private interests. It would receive railroad endorsement only if it was scientifically sound and if its purpose clearly led to definite economic advancement.

While those present might not agree with the conclusions so far reached in this truck research, he was confident that they would have difficulty in finding fault with the methods employed to establish the facts in connection with the very intricate and vital mechanical problems involved.

Discussion

F. H. Clark.[2] The paper does not give details of the author's truck, but the writer assumes that the present-day center plates disappear and that the car body will be carried on rockers placed between the body and truck bolsters.

The author presents what amounts to a protest against the inaccurate construction that has always prevailed in this country in assembling freight-car trucks. He mentions three points; first, the spring plant connections to the side frames—and the writer is inclined to agree with him that the spring plank might well be dispensed with. The best spring plank that the writer ever saw was one which had no rigid connection to the side frames. The suggestion that side frames be mated for length is one that also meets with the writer's approval.

As to journal boxes and contained parts, the only improvements made in over forty years that the writer now recalls are in the substitution of malleable iron or cast steel for cast iron in the box itself and the application of close-fitting lids.

The journal bearing and wedges and the roof of the box against which the wedge bears are still rough and loosely placed, which may in a way be an advantage when we consider the fact that side frames are not mated and that the spring plank may put the truck permanently out of square instead of squaring it as intended.

These are all matters of detail and might apply to any truck. As to the relation of the truck to the track, the reduced wear of wheels and rails on curves and the lessening of derailments are important points and it looks as though much might be done in this direction.

F. J. Herter.[3] The method of supporting the car body used in the Symington bolster is apparently unique, in that it reduces swiveling resistance, so that it becomes practically negligible as is shown in Table 1. This should reduce train resistance to a large extent on curves at points where the radius changes.

It seems that the function of the rocker to prevent derailment does not have much advantage over other types of side bearings, provided that the other types are placed the same distance from the center of the car with the added protection of a support outside of the side bearing to keep the car from overturning under severe conditions. However, there is one decided advantage in the use of this bolster—no side-bearing clearance exists to permit the car body to attain a large initial velocity laterally to produce car roll. The function of the rocker to provide lateral motion is very effective in reducing high stresses due to shocks resulting from flange impact with rails, including guard rails. In summing up all the advantage of the Symington bolster, it must be admitted that it accomplishes much to be desired.

It might be questioned whether or not the car body would overturn on the rocker in the event something should lodge on the rocker seat and restrict the rocker action. This would, in effect, be the same as placing a rigid side bearing much nearer the center of car.

The discussion on truck springs brings out the necessity of overcoming excessive spring oscillations. It has been said that the oscillation of springs under stock cars has broken the legs of hogs. This does not seem unreasonable in view of the statement made in the paper that the shock inside of a freight car from spring oscillation may cause a man to crash through an ordinary chair.

From the experiments made by the use of the spring dynamometer to determine vertical acceleration due to end shock, it may be found that this is much more serious as it affects lading than spring oscillations, and should be overcome, if possible. The author refers to this vertical acceleration as the result of the vertical component of end shock. It seems to the writer that it might be better to say that the vertical acceleration is due to the tendency of the center sills to buckle upward under end shock.

An analysis of the results shown under Fig. 8 seems to indicate that the vertical acceleration must be due to the fact that the center of draft is below the center of gravity of the center sill section. This is on the assumption that the test cars are of the A.R.A. underframe construction, in which case there is an eccentricity of 1 in. or more. Under these conditions, if the center sills were free, we should expect the greatest vertical acceleration at the center of the car. The reason this is only 0.28 as against higher readings between the center of the car and the end of the car, seems to be due to the resistance to upward deflection at this point offered by the two cross-bearers located at the door posts.

It would be interesting to make similar experiments with a fish-belly center-sill car, from which we should not expect much upward deflection at the center of the car, but perhaps should expect some at the bolster.

If these conclusions are correct, the solution would require the center of draft to coincide with the center of gravity of the center sill section.

The writer questions the advisability of decreasing the radius of the back of the journal-box wedge from 78 in. to 24 in., unless it has been found that the force is not sufficiently concentrated to crush the material in the roof of the box.

Until tests prove otherwise, it seems that the loaded spring plank will keep the side frame from rocking due to lateral forces applied by the bolster, and in this way prevent concentrated loads at the shoulder or collar of the journal. It must be remembered that to dispense with the spring plank also removes a convenient means of attaching brake-beam supports or guards.

ALAN N. LUKENS.[4] Years of study on the question of improved springs for freight cars and the examination of many ingenious inventions in this line have shown that some very basic principles have been overlooked or ignored in most of such schemes and designs, including the present well-known A.R.A. standard bolster springs.

The first of these basic principles is that any spring used, regardless of such appliances as may be introduced, should be designed by the best modern methods so that the stresses developed at all critical points may be accurately known and maintained within the limits proved to be the best by life tests and practical experience. Most of the springs in use, including the A.R.A. standards, were designed many years ago before scientific research had shown beyond doubt that the stresses in them were far higher than anticipated. The A.R.A. springs were designed for a stress of 80,000 lb. per sq. in. at the solid height, while modern methods applied to them show they actually develop 93,000 lb. per sq. in. at that point. Furthermore, while the stress developed by their rated loads is not far from reasonable, the modern practice of our railroads of loading cars up to axle capacity regardless of the springs simply subjects the springs to stresses far beyond the reasonable limit.

The second basic principle has been the subject of the author's investigation, namely, the prevention of vertical harmonic vibration. Elliptical springs during movement generate considerable friction between the leaves. This friction if properly utilized prevents the starting of harmonic vibrations, which fact has led to many attempts to add some friction or other elements to helical springs that they too may prevent the vibrations. As early as 1882 United States patents were granted for the so-called "graduated" bolster spring. This consisted of several rather small springs of normal bolster-spring length grouped around a very large, stiff spring of shorter length. It was hoped when compression of the smaller springs encountered this short, stiff spring, vibrations would be broken up or prevented, though the expression harmonic vibrations was not then used—ease of riding being used in their claims. Then followed in 1899 the McCord dampener and in 1901 the Shea controller, both of which added a little friction, and for which many claims were made for great reduction in the number and extent of vibrations. Neither succeeded in accomplishing very much, and excessive wear soon removed them from the market. Then followed a period of inaction in this field until in recent years attempts have been made to secure results by the use of stronger and stiffer springs or simply by using a greater number of the standard springs without any attempt to control the vibrations.

When the author conceived the idea of his snubbed spring he at once stepped so far beyond his predecessors that nothing short of scientific research and the accumulation of sufficient data could render sound judgment of his accomplishment.

Observation of the action of his snubbed springs demonstrated very clearly the vast improvement such springs make over the standard groups. While the charts in the paper speak for themselves, a most dramatic picture of this improvement can be obtained in a very simple way. When the train is running at a speed over 35 miles per hour, stand in the safe passage provided between the cars with one foot resting on the platform of either car. In this position one foot will receive but slight jolts without repetition of sequence while the other foot is doing a regular tattoo jig step so rapid and violent that it will be impossible to keep that foot down on the platform even with the knee loosely flexed.

Without a doubt these snubbed springs effect a remarkable reduction in the rapidity and severity of the vibrations and the author is to be congratulated on his excellent work and on his accomplishments thus far.

The writer believes a still further gain in checking vibration can be secured by the use of springs meeting the terms of the first basic principle outlined above, even to the full extent of eliminating all harmonic vibration throughout the full range of present or future train speeds, and suggest that full trials be made of such springs, particularly in combination with some of the known friction devices not mentioned in the paper. The writer would also suggest that in all new designs of trucks consideration be given to providing increased space for springs. Room should be provided for groups 12 in. wide instead of the present standard of 11 in., together with an inch or more in height. Much good can be accomplished on existing trucks with their restricted space, but the full advantage can only be gained by providing more space in future trucks.

L. K. SILLCOX.[5] The author has pointed out that the minimum proportion of the load on one side of the truck sufficient to keep a wheel from mounting the rail on curves due to flange pressure is 30 per cent if the load on one truck is not more than 16 in. from the center. It is not clear just what is meant by the load on the truck, that is, whether it is the light weight of the car body or the weight of the car body plus the lading. If we take, for example, a 50-ton car as being typical, having a light weight of 45,000 lb. weight of trucks 5000 lb. and maximum lading of 124,000 lb., we find that the light weight on trucks is only 40,000 lb., while the loaded weight on trucks amounts to 164,000 lb. and the weights on one truck (cars with 2 trucks) are 20,000 lb. and 82,000 lb. for light and loaded cars, respectively. With 30 per cent of the load on one side of the truck as the minimum requirement to keep the wheels from mounting the rail on curved track, the loads on one truck of the same car are 6000 lb. and 24,600 lb., respectively, for light and loaded car. Theoretically speaking, the wheel-flange pressure, or rather the reaction of the rail against the wheel to overcome the centrifugal force imparted to the truck in rounding a curve, is in direct proportion to the weight on the truck. However, this is only true when a car is running at a certain speed on a curve having superelevation to suit that speed, so that the car body is normal to the track. Such conditions do not obtain in actual railway practice and a question is raised as to whether or not the derailment tendency of cars on curves is also a function of the weight of the car besides the weight distribution on both sides of trucks as pointed out in the paper.

It is stated that the track warp between truck centers, rather than the warp between wheels on one truck, results in a derailing condition based on the contention that there is enough flexibility in A.R.A. standard trucks to permit one wheel to go down the maximum depth of depressed rail joint without losing its share of the load on this side of the truck. Following the same reasoning, it would appear that a longer truck-centers distance as compared to the wheel-centers distance would also obviate any such unequal distribution as to set up a derailing condition.

Car-body roll or nosing induced by harmonic spring vibrations is a common source of trouble resulting in damage to the lading, particularly of live stock and perishable freight. There is still another serious objection to such harmonic vibration when the periods of spring vibration coincide with the bridge vibration. In this case an unduly high stress is set up in the bridge structure and further experiments on truck springs might well take this feature into consideration.

[4] Mechanical Engineer, Railway Steel Spring Company, New York. Mem. A.S.M.E. Committee on Mechanical Springs and A.S.T.M. Spring Committee.

[5] Vice-President, New York Air Brake Co., New York, N. Y. Mem. A.S.M.E.

As to the damaging effect resulting from end shocks, it would appear that this is not within the province of proper truck design, and only suitable draft-gear construction may well overcome or minimize this feature.

The truck spring planks as employed on A.R.A. standard trucks are the only rigid cross-tie between the two sides of the truck, and may be relied upon to square the truck on entering tangent-track curves. Some modification in construction rather than its entire elimination would appear to be more desirable.

W. P. BORLAND.[6] Whether or not the author's conclusions as set forth in the paper are fully substantiated, the writer is not in position to say. He is convinced, however, that the author has accumulated a mass of fundamental data concerning the behavior of car trucks under the varied conditions of actual service which should be of far-reaching importance and value in improving the design and construction of equipment of this character to meet the severe requirements of present-day freight-car service.

The accident records of the Interstate Commerce Commission reflect the very great need for measures to correct the causes and reduce the number of derailments. A comparison of these for the first and last 10-year periods for which statistics have been compiled, namely, the period 1902 to 1911, inclusive, and the period 1920 to 1929, inclusive, shows that during the first period there were 61,329 collisions and 56,136 derailments; during the second period there were 57,382 collisions and 136,758 derailments, a decrease of 3947 collisions and an increase of 80,622 derailments. The property damage from collisions for the first period was $48,235,952 and for the second period $57,450,943, an increase of less than $10,000,000; from derailments $48,965,656 for the first period and $159,635,736 for the second period, an increase of more than $110,000,000. It should be borne in mind that these amounts refer only to damage to railway property and do not include amounts paid for lost or damaged lading, personal injuries, or other claims growing out of such accidents.

These figures show the very marked upward trend in the number of derailments, whereas the number of collisions has been kept within less extreme limits. A great deal of thought and effort and large expenditures have been directed toward the prevention of collisions. During the period covered by these accident statistics the commission has prescribed specifications for automatic train-stop and train-control devices and has required their installation on a considerable number of railroads. During this period extensive additions to and improvements in signaling and interlocking have been made. While these improvements in operating conditions and practices were being effected there has also been development of power which has resulted in increase in the length and speed of trains and reduction in the number of trains operated, a condition which tends to reduce the danger of collisions, but which may contribute materially to the causes of derailments.

Examination in detail of the accident record for the year 1929 discloses that of the total of 9871 derailments reported, 4510 were due to defects in or failures of equipment, while only 2080 were due to defects in or improper maintenance of way and structures. There were 6643 train accidents due to defects in or failures of equipment, of which 1342 were attributed to trucks and 1867 to wheels and axles.

In considering all of these statistics the fact should be borne in mind that they include only those accidents which resulted in death, personal injury, or property damage amounting to $150 or more. It is a matter of common knowledge that there are a large number of similar accidents not sufficiently disastrous to be included in these statistics but which are a constant source of delay and expense to the railroads and of trouble and worry on the part of railroad operating officials.

Research work of the character conducted by the author is therefore directed along lines which should be productive of important results. It is of direct interest to the Bureau of Safety of the Interstate Commerce Commission, and should certainly enlist the active support of railroad officials who are responsible for the design, construction and maintenance of cars and for safe, efficient, and economical operation of the railroads.

J. A. PILCHER.[7] Since the paper indicates that, in a measure, the reason for the main car troubles is lack of uniform surface of the track when under load, brought about largely by the influence of the rail joints, it may not be amiss to call attention to the method of track construction as discussed by W. B. Potter, Engineer, Railway Engineering Department, General Electric Company, in the *Railway Age* of February 17, 1923, page 423, in which he discusses a method of track laying which he terms "asymmetrical," and which will give the lateral strength and all of the advantages of the almost universal practice of diagonal track laying, at the same time doing away largely with the tendency for oscillation of the car when the speed is such that this oscillation synchronizes with the low joints. The claim is that the irregularity of the rail joints, one side as compared to the other, would, in a measure, break up the oscillation. The article does not say that this experiment has ever been carried out, but reads as follows:

> The writer suggests that it might be possible to secure the advantage of diagonal joints in respect to track maintenance and the steadier running quality of square joints by laying the track with joints asymmetrically spaced; that is, instead of overlapping a half rail length, to overlap between one-quarter and one-third, preferably a length of lap that would not be an even fraction of the rail length.

With the longer rails that are now being used, viz., 39-ft., there would seem to be no particular disadvantage in this suggested arrangement.

The question really to be determined is whether the advantages to be gained, either with the change in the track or change in the springs, are sufficient to warrant the possible expense.

G. M. EATON.[8] Hope has been held out that alloy steel might solve the epidemic breakage of freight-car springs. In an intermittently prosecuted development program extending over a good many years a persistent effort was made to develop a high-grade alloy-steel spring for heavy fatigue service which would give a life better than the standard carbon-steel spring.

About twenty different high-grade alloy steels were tried. On fatigue test the best individual spring of alloy steel failed at about half the average number of cycles achieved by carbon steel.

It was found comparatively recently that the reason for the early failure of the alloy steels lay in the condition of the surface. The mill-finished surface of most high-grade alloy-steel bars, of a type and size apparently adaptable for freight-car springs, is less well adapted to coiling and quenching operations than the corresponding surface of carbon-steel spring stock. The two major types of surface inferiority are decarbonization and seaminess. Often this surface inferiority of the alloy steel cannot be recognized by the naked eye, but a deep etch is most revealing for seams.

[6] Director Bureau of Safety, Interstate Commerce Commission, Washington, D. C.

[7] M. E., Norfolk & Western Railway Co., Roanoke, Va. Mem. A.S.M.E.

[8] Spang, Chalfant & Co., Inc., Ambridge, Pa. Mem. A.S.M.E.

The only commercial way known to date of capitalizing on the merits resident in high-grade alloy steel for heavy helical springs in fatigue service, is to remove the inferior mill-finished surface. This may be done commercially by centerless grinding or turning. When this is done we are justified in looking for longer spring life in existing freight cars. But it is most doubtful whether we can expect permanent springs in this service due to the excessive stress to which attention has been called.

In connection with this comparatively recent discovery that the stress on the heavy standard freight-car spring is 60 per cent higher than intended when the spring was designed, we can have a little comfort from the fact that the nominal working stress is not $80{,}000 \times 1.60 = 128{,}000$ lb. per sq. in.

This equation overlooks the fact that when the as-rolled free height of the spring is reduced by the setting operation, the material of the spring on the inside of the coils is stressed far beyond the elastic limit and flows plastically. When the setting load is removed and the spring assumes its final free height, this material at the inside of the coils is in a state of negative stress of fairly high degree. As working load is increased this stress passes through zero and then builds up as a positive stress that is too high for permanent endurance.

The comfort we can gather is only to the effect that the working stress is less than 128,000 lb. per sq. in. The springs still break from overstress.

There is a further improvement of springs that is theoretically possible, and in the writer's judgment entirely practical.

Many of the commercial coil-spring quenching rigs cool the inside of the coil material more slowly than the material at the outside of the coils. This results in the anomaly of a spring which is weak in the regions of maximum stress and strong in the regions of minimum stress. It is entirely possible and practical to arrange a quenching rig which reverses this condition and results in a spring whose strength is distributed in the same general manner as its working stress. This is not being done today in any commercial quench with which the writer is acquainted. In any research looking toward the development of low-maintenance freight-car trucks, this method of quenching is well worth developing to a practical production stage.

W. E. Symons.[9] The paper is of especial interest to the writer since the author's conclusions fully confirm some similar findings reached several years ago following quite extensive service tests, although the writer's methods of procedure were different in many respects.

Several years ago two Western trunk lines built some 6000 modern refrigerator cars for the California fruit traffic, but when placed in service derailments were so frequent as to interfere with all traffic.

After much correspondence and considerable controversy, the writer as a neutral expert was employed to ascertain the cause and apply proper remedies.

After a careful study, one car was fitted with an adjustable center plate so that the writer could not only observe, but actually measure the force of lateral energy of car body delivered to the wheel flanges at the rail. To facilitate this work a platform box was built extending from end of car under the truck axles, and when riding in this box in a semi-recumbent position, one could not only clearly observe the behavior of car body and trucks, but take readings, make notes, etc. of all important factors.

In this observation box only a few inches from the rear wheel, the writer often noted the car body rolling to such an extent as to lift the wheels up from the rail far in excess of the flange depth, while on entering or leaving double-S curves, due to rigidity of the car-body superstructure and defective track, the car body would rest on the forward and rear diagonally opposite side bearings, not infrequently being clear of one or both center bearings.

It was also found that cars which rolled violently at a certain speed, would cease rolling at a higher or lower rate of speed, wheelbase, rate of speed, and track conditions being the governing factors, while side-bearing location and clearance were considered.

After very extensive road tests on heavy gradients with sharp curves in a mountainous country it was decided to replace the M.C.B. center plates with the concave and convex type, sometimes called the ball-and-socket type, and provide lateral play to truck bolster by using the Barber rollers.

With the two above changes in car design and proper repairs to the track as to surface and alignment, the derailments and wrecks ceased, as this equipment was then safe for movement at all permissible speeds.

The author's findings not only coincide with those of the writer, but his views on the problem in general gives the latter courage to speak in detail on a subject that for years has been sadly neglected.

We now come to the financial feature of the problem. As there are about 2,300,000 freight-train cars, there would be about 4,600,000 trucks to replace or exchange. The items of maintenance expense involved by this exchange would be as follows:

Freight-train car repairs	$335,000,000
Proportions of track and bridge repairs	415,000,000
Total	$750,000,000

It would be interesting, if in connection with this splendid analysis, the author could give some estimate of the costs involved and economies that might be expected to result therefrom.

George G. Floyd.[10] The work done by the author with his research cars has developed the fact that springs are a very important item in the make-up of the average freight-car truck.

One of the distressing characteristics of a coil spring is that certain speeds even on reasonably good track may cause the car to vibrate violently vertically with disastrous results to the car loading. With equipment of the average capacity and weight of today, this critical speed for vertical oscillations of the springs of the car body is around thirty-five to forty-five miles per hour, depending upon the weight of the car body and its load. Therefore, until just recently, with the slower freight-train speeds of years ago, this question of vertical oscillations of the car and its load did not enter into the problem because the speeds at which this occurred were not reached.

From a reading of the paper it would seem that the ordinary four-wheel truck of today is a reprehensible device. The four-wheel truck, of course, like all other mechanical devices has certain inherent bad qualities; but, considering the service that it has given for the last fifty years, it is probably not entirely to blame for all the ills and ails and difficulties in the operation of freight cars. A six-wheel truck is probably better, but it is too expensive for the average freight car. Two wheels would be cheaper than four, but while our friends abroad have been more or less successful with a two-wheel truck, it has never been popular in this country.

I object somewhat to condemning the four-wheel truck and putting on it the entire burden as there are other parts of the entire railroad system that are not entirely without blame. The track has something to do with the question, the air brakes are not entirely blameless, and the locomotive engineers are not entirely without fault. I protest against the apparent disposition today to make the four-wheel truck carry the entire burden. Some years ago the writer participated in an investigation of

[9] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

[10] Mechanical Assistant to President, American Steel Foundries, Chicago, Ill.

a series of approximately two hundred derailments. These derailments were on a single division of the road and there were twelve engineers involved in handling all the trains on this division. As he remembers it, fifty per cent of the derailments were chargeable to two engineers. There were four engineers who had no derailments and the balance of fifty per cent of derailments were charged against another four engineers.

One of the difficulties was the particular manner in which brake applications were made; while the track and the equipment, of course, had a contributory value, the fact remained that improper handling of brakes produced derailments and proper handling of brakes avoided derailments.

In another investigation of something like fifty derailments of long trains, the car that went off the track was invariably within five cars of being in the middle of the train. The cause of these derailments was a combination of air brakes, speed, and track conditions, each probably equally important. It would therefore seem the proper manipulation of the air brake system in stopping the train plays quite an important part in the matter of derailments.

An arrangement has been made whereby the author has turned over his research cars and equipment to a committee of manufacturers who in connection with his own research engineers will conduct a more or less elaborate series of experiments along the line already indicated in the paper. This committee hopes eventually to secure the cooperation of representatives of the railroads in the use of this research equipment to carry on an investigation that will be of great benefit to all concerned, and the author is to be congratulated upon the spirit with which he has entered into this arrangement.

Author's Closure

Mr. Clark calls attention to the fact that the details of the author's improved truck designs are not discussed. The reply to this is that the paper has to do with general research on the subject, applicable to all trucks and to no one truck in particular.

Regarding his statement that "the spring plank may put the truck permanently out of square instead of squaring it as intended"—the writer assumes that, in this connection, Mr. Clark refers to the possibility of the spring plank holding the bottoms of the side frames apart a different amount than they are held apart at the top by the bolster. We are all familiar with the fact that many cast-steel side frames and bolsters have been in operation for over twenty years without any appreciable wear between the side frames and the bolster, and we also know that, on some similar trucks, this wear is very excessive after one or two years' service. It seems to the author that there is no explanation for the latter case except the fact that these rapid-wearing trucks are held permanently out of square across the rails by the spring plank.

On one lot of 2500 cars built in the last few years, inspection showed that a large number of trucks were as much as 1 in. farther apart at the top of the side frames than at the bottom of the side frames. This came about from the following causes:

1 Allowance for shrinkage in cooling was not made in the dies for punching the spring planks hot, and therefore the spring planks were all short between the pressed holes for side-frame bosses.

2 The bolsters ran to maximum length.

3 The distance from the center of the spring-plank bosses on the side frame to the inside of the columns of the side frame was entirely too great due to error in the side-frame pattern and to a lifting of the spring-seat core of the side frame in the mold.

So far as the author knows, no railroad or steel company gages the distance between the center of the bosses on the spring seat of the side frame to the inside of the columns on the side frame. Certainly we shall have less wear if the side frames can adjust themselves to give uniform spring load over the entire spring seat, and, in the author's opinion, the elimination of the spring plank will help this condition.

This particular wear, resulting from the two side frames not being parallel, comes on the inside or outside faces of the frame columns and on the column guides on the bolster.

If the center plate bearing on the bolster, the spring seats on the bolster, and the spring seats on the side frame are not in parallel planes, there is a resulting rapid wear between the bolster and the frame columns. If the truck gets out of square by having one frame go ahead of the other, there is also a resulting rapid wear between the bolster and the frame columns.

It is readily seen that the breakage of any coil in a spring group may result in a lack of normal adjustment between the bolster and the side frames, which is another reason for the desired elimination of spring breakages. Under all of the non-adjusted conditions mentioned, harmonic spring oscillation results in rapid wear.

Where lateral motion is obtained by the continuous relative material motion between the bolster and the side frame, rapid wear can result, even without harmonic truck-spring oscillation.

Mr. Herter apparently overlooks the fact that, with standard trucks supported on the center plate, it is not practical to bring the side bearings close together in order to prevent the car body from overturning under severe conditions, because the outside supports would have to be so far separated on the body and truck bolsters that they would not be effective. For complete safety, the tilting action between the body and truck bolsters must be sufficient to permit the body bolster to come down on top of the side frame in an emergency, and the fulcrum for this tilting action must be much closer than 25 in. from the center of the rails. The outside bolster support on the author's truck does not function at all unless and until lateral motion materially moves the body bolster in relation to the truck bolster.

Regarding the possibility of something lodging on the rocker seat on the truck, we have done our utmost to find some way in which this could be accomplished with the trucks under the cars, but have been unable to find any way in which the truck could be disabled.

These research cars have U.S.R.A. center-plate height and the center line of draft is on the center line of the sills so that there is no eccentricity of sill loading from end shock. The load in these cars under these end-shock tests consisted simply of twelve water tanks weighing about 18 tons per car. It will be noted from Fig. 8 how this load is distributed in the cars. It has seemed to the author that end shock would tend to rotate the load mass in each end of the car around its own center of gravity, which would seem to account for the upward buckling of the car frame under end shock.

Regarding reducing the radius on the back of the wedge from 78 in. to 24 in., the author would call Mr. Herter's attention to the fact that five hundred 100-ton coal cars have been operating on the Norfolk & Western Railroad for over ten years, with the entire body load supported on four rockers. The product of the length by the mean diameter of each of these rockers gives a wear factor of 156, and there has been no evidence of crushing of the material in the rockers or in the rocker bearings. With a 24-in. radius on top of the wedge, there is a similar wear factor of 336, and as there are eight wedges per truck, as against two rockers per truck, it is evident that there is more than four times the wear factor on a 70-ton car than has been found entirely efficient and satisfactory on a 100-ton car.

The author is unable to see Mr. Herter's point in reference to the spring plank keeping the side frame from rocking due to

lateral forces applied by the bolster. These lateral forces must be resisted by the two journal collars or shoulders, and the nearer these reaction points can be held in line with the point of application of the load, which is the bolster, the better it will be.

Regarding the attachment of the brake-beam safety supports to the spring plank, the author would call Mr. Herter's attention to the fact that a large number of Verona cast-steel trucks have been in service for a great many years. These trucks have no spring planks and the brake-beam safety supports are fastened to the bolster. A careful investigation has indicated that there has never been a failure of this type of safety support.

Referring to Mr. Lukens' theoretical discussion on truck springs, the author thinks he is right, in that truck springs develop a higher fiber stress at closure than the old formulas indicated. However, the author is strongly of the opinion that these slightly higher stresses at closure can be entirely overlooked if we eliminate harmonic spring vibration and car roll so that the springs will never close.

Regarding Mr. Lukens' statement that the friction generated by elliptic springs, if properly utilized, "prevents the starting of harmonic vibration," the author is inclined to the opinion that the absence of harmonic vibration on passenger-car springs is due more to the very flat load curve of these springs than to friction. The flatter the load curve, the slower is the critical speed for harmonic vibration. This critical speed for passenger cars, to produce harmonic vibration, is so slow that this velocity factor in harmonics is negligible and somewhat similar to the harmonics in a well-designed automobile spring with long travel, which is not objectionable.

The snubbed springs that Mr. Lukens refers to do actually break up excessive harmonics, and the springs will never go solid under any conditions. There is, however, one objection to the snubbed spring, and that is, under harmonic vibration, when the bolster hits the snub, it can be definitely felt in the car and it is objectionable. Experiments are now under way to definitely break up this harmonic vibration with what might be termed yielding snubs to obviate this objection.

The author is sure that, if Mr. Sillcox will read the paper over again, he will see that, in all discussions of cross-equalization of the load, the author refers entirely to the load above the truck bolster and it is immaterial whether the car is light or loaded. In the analysis of what proportion of the load of one end of the car body is on one rail and what proportion is on the other rail, this is a simple matter of leverages. If this load is concentrated at 25 in. from the center of the rails, the body load on one rail is 15 per cent and on the other rail it is 85 per cent. If the body load is concentrated at $15^1/_2$ in. from the center, the percentage of this body load on one rail is 30 and on the other rail, 70.

The author cannot agree with Mr. Sillcox in his analysis of the effect of centrifugal force in connection with derailments. As a rule, the superelevation on a railroad curve is higher than is needed for freight service and lower than is theoretically correct for high-speed passenger service. For this reason, the author does not believe that we ever have a high flange pressure against the outside rail due to centrifugal force from the truck mass. The centrifugal force on the car body tends to throw this mass toward the outside rail and the principal reaction is downward on the outside rail, although there is a lateral component of this action toward the outside rail. It seems to the author impossible for this action to ever cause a derailment because, with standard trucks, under this condition, 85 per cent of the body load is then on the outside rail. Centrifugal force is, the author thinks, contributory to derailments only because it results in an initial roll of the car body toward the outside rail, with a quick return of the car-body roll to the inside rail, and it is under this condition that the car will sometimes derail, because then only 15 per cent of the load is on the outside rail. This is true whether the car is loaded or whether it is light.

Regarding the derailing condition from track warp, this is, in the author's opinion, a function of the resulting warp between the four side bearings, and if the car body is sufficiently flexible, no derailment will result from track warp. Increasing the distance between truck centers, it seems to him, would only help to the extent that a longer car would have greater flexibility than a shorter car of the same construction. It must not be overlooked, however, that if the warp in the track results from superelevation to level, the warp between truck centers will increase in exactly the same proportion as the cars lengthen. Mr. Sillcox is right that truck design has nothing to do with damage from end shocks, but with these research cars this very important subject can be scientifically studied in connection with both longitudinal and vertical shocks to perishable ladings.

The author cannot agree with Mr. Sillcox that "the spring plank provides a rigid cross-tie between the two side frames of the truck and may be relied upon to square the truck on entering tangent track curves." If the spring plank was riveted to each side frame, this effect would be obtained, but riveted spring planks are no longer used.

Mr. Borland's discussion, giving statistics of railroad operation in this country is, of course, very interesting and particularly so in connection with modern operation. It is very clear that, in spite of all the railroad safety campaigns in this country, freight-car derailments, with loss of life and damage to property, are not decreasing, and the author stands on the flat statement that, in his opinion, any railroad track that is safe for a locomotive should be more than safe for any freight car.

Mr. Pilcher, who is keenly alive to the desirability for eliminating derailments and harmonic spring vibration, suggests a change in the laying of the rails to break up the present synchronization of the rail joints in connection with harmonic spring vibration and car roll. It is possible that, by relaying our track in this manner, something might be accomplished, but it seems to the author that Mr. Pilcher is carrying on the very old practice of mechanical men of "passing the buck" to the maintenance-of-way engineers. In the author's opinion, the mechanical men should exhaust every possible means for making freight cars safe on track as it is. It is perfectly obvious that no cure obtained either by changing the trucks or changing the track will be adopted if the advantages to be gained are not out of all proportion to the expense involved.

Mr. Eaton discusses the freight-car spring from a theoretical angle, not only in connection with the use of alloy steels, but also in connection with the method of manufacture. Railroad men naturally lean toward the cheapest material they can buy, and to a method of manufacture that is not a laboratory proposition, but that will apply to quantity production.

Very recently the truck-spring manufacturers of this country have greatly improved their methods of manufacture and the resulting specifications, and the author is sure they would welcome any offered possibility for increasing the quality of their truck springs, provided the cost of manufacture is not increased beyond the willingness of the purchaser to pay for the added value.

Mr. Symons' personal study of the behavior of freight-car trucks is very interesting. He states that some 6000 modern refrigerator cars could not be kept on the rails, but that the derailments ceased when the cars were equipped with ball-and-socket center plates and with the Barber lateral motion. He also states that, at the same time, proper repairs were made to the track in connection with both surface and alignment. The author does not see how we can draw a definite conclusion, covering this lot of cars, as to whether the derailing conditions were

improved by the changes in the trucks or the improvement in the track. From his own experience the author is unable to see how these particular changes in the trucks could help the derailing condition, and he would conclude that the improvement in the track was responsible.

In regard to Mr. Symons' observation of the lift of the wheels from the rails under the influence of car roll, the author would state that with every truck tested under his research cars, where the side bearings were spaced 50 in. apart, he has seen the wheels lift off the rails from car roll. These research cars are now being equipped with accurate means for measuring the maximum amount of wheel lift from the rail on any run, and to give a continuous record on a chart of all wheel lifts of $^1/_4$ in. or more. With this superimposed record, it will be possible to determine exactly how much roll is necessary to lift the wheels off the rail on any car.

Regarding Mr. Symons' statistics in connection with the financial aspect of this matter, it is impossible in a short time to go into the question of the economies that might be expected to result from perfected trucks. The author's general feeling in this connection is that any railroad is willing, at any time, to make a 50 per cent investment, but they would have to be very sure that the investment of $1.00 would certainly produce a return of 50 cents each and every year.

The author hopes that Mr. Floyd does not feel that he is condemning the 4-wheel truck for freight cars. He thinks it is the only possible truck for freight cars up to 70 tons capacity, but is sure that Mr. Floyd is in entire agreement with him that it is our duty to perfect this 4-wheel truck as far as it is possible, provided, of course, that this can be done economically.

Mr. Floyd refers to an investigation where it was found that out of two hundred derailments on one division of a railroad, two locomotive engineers out of twelve were hauling 50 per cent of the derailed trains. He does not state whether these two locomotive engineers were discharged or disciplined. The author is fully conscious of the human factor in railroading, and it is impossible to have all locomotive engineers 100 per cent efficient. If the delinquencies of these two locomotive engineers only showed in these derailments, it appears to the author that we can do a great service if we make our freight-car trucks so foolproof that we can operate safely with engineers who are not 100 per cent efficient.

This research work is still in progress at Baltimore and will continue until bad weather. It is hoped and believed by our joint committee of truck and spring manufacturers that, by the early summer, we shall have formed very definite conclusions as to what we believe to be the best possible truck construction from every angle, and we shall then be very glad to make a complete demonstration of our findings to any railroad man who is interested.

Progress in Textile Manufacturing

Contributed by the Textile Division

Executive Committee: Edwin H. Marble, *Chairman*, McRea Parker, *Vice-Chairman*, Wm. L. Conrad, *Secretary*, Earle R. Stall, Henry M. Burke, and Paul A. Merriam

THE year 1929 has shown a marked improvement in the attitude of textile-mill owners toward the adoption of better machinery and methods. Consequently, the more progressive manufacturers have been able to improve their product and at the same time reduce their costs, with the result that many are showing profits while the industry in general is considered to be still in a state of depression. At the same time, many mills of proved inefficiency, for want of progressive leadership or capital, have been forced to close. Continuation of this trend will inevitably bring to the front a group which will continue in business and make money, while others will have to go out of business, and the result will be to put the industry in a healthy situation again.

The machinery manufacturers, appreciative of this situation, are bending their efforts to improve their equipment, and those that are successful are taking orders. This improvement is generally shown in the adoption or more general use of anti-friction bearings, cut gears, etc., in an effort to reduce vibration to a minimum.

Demand for Engineers

As a result of this tendency toward improvement in methods within the factory and the machinery developed for the industry, there is an increased demand for trained men from textile and engineering schools. The plant engineer has definitely taken his place in industry, and the more progressive textile concerns are availing themselves of his services. This is resulting in a breakdown of many of the rule-of-thumb methods, and the substitution in their place of machinery and control based on scientific principles.

This interest in scientific methods has created a demand for more and better equipment for the testing of materials at various stages of manufacture. As an example of this, an improved machine has been placed on the market during the year for bursting tests on knitted fabrics which gives more uniform results than previously were obtainable.

Humidity Control

There is a growing appreciation of proper humidity and its accurate control, and this is being applied not only in more mills than formerly, but over a wider range in the individual mill. Numerous installations have been made during the year. Developments in this line will undoubtedly lead to more knowledge of the subject and to improved control.

New Materials for Machinery and Equipment

In the effort to obtain improved operation of machinery, there has been a search for improved materials of construction, and some of the newer materials, such as those embodying artificial resins of the nature of bakelite, have been introduced. These have found their place in bobbins, spools, pickers, etc. In rayon manufacture, alloy metals have to a considerable extent replaced glass where acid-resisting qualities were required.

Rayon

The processes and machinery employed in the manufacture of textiles are fundamentally similar though used on various raw materials. These latter include the so-called "synthetic fibers," generally referred to as rayon, but because this material is a chemical product and relatively new, whereas other textile materials are natural and have long been in use, it appears well to give it separate consideration.

The marked increase in the output of rayon is in itself worthy of note. Factories have continued to spring up in almost mushroom fashion, both in this country and in Europe. Many European concerns are establishing factories in the United States an Canada. As result of this growth, and the concurrent demand for the product, the output of rayon for the calendar year 1929 can be safely estimated at close to 400,000,000 lb. This phenomenal growth is significant, for it brings out the fact that rayon is replacing other materials as well as finding novel uses of its own. Much machinery previously used on other fibers is being converted to the use of rayon, while at the same time new machinery is being designed for its special use. Considerable progress has been made in this direction during 1929.

While rayon is still manufactured under four basic processes, namely, the viscose, acetate, cuprammonium, and nitrocellulose, many modifications have been made in these with the result that a near approach has been made to real silk, both in fineness and appearance. At the same time its other properties have been improved, resulting in greater resistance to heat and better affinity for dyes. Hosiery made entirely of rayon is now a fact, and a rayon sewing thread has been placed on the market during the year.

Preparation of Fibers

In the matter of preparation, which applies in general to all forms of raw textile material, greater attention is being paid to grading and cleaning of the material used. This has been especially true in cotton, because of attempts to use lower grades which are mechanicaly picked and less carefully ginned. This has resulted in radical improvements in machines for opening, blending, cleaning, and picking. Machinery which has been developed for cotton has found application, with some minor alterations, to wool, with substantial results. This dual application has permitted some degree of standardization, with resulting economy in manufacture and sale of this equipment.

Carding

In carding, greater attention is being paid to more uniform webs, with corresponding reduction of variation in counts. To this end, a more accurate weigh box has been introduced during the year and an improvement made on the Scotch feed. This improved feed lays a wider and thinner sliver than previous feeds, permitting a greater degree of overlapping of the sliver, with correspondingly greater smoothness and uniformity in the rovings taken from the card.

Cut rayon stock, too, is being carded with a greater degree of success through the better working knowledge of materials and special arrangements for their proper handling. Proper control of humidity and temperature has played an important part in this improvement.

Advances have been made in the kind and quality of oil supplied the textile trade for the lubrication of the stock. Research has produced oils of mineral bases which are successfully replacing the more expensive vegetable oils. Greater attention is being paid in the mills to the kind and quality of oil used and its method of application, resulting in better working of the stock.

Spinning

Perhaps the outstanding development in spinning is the application of variable speed to the spindles. This permits giving more equal tension to the yarn throughout the spinning cycle. Unequal tension was the result with constant-speed spindles because of the tendency of yarn to become tight where the effective diameter of the bobbins was small, and loose where this diameter was large. Variable speed permits greater production per spindle, as the maximum speed of the spindle is no longer determined by a condition which exists but a fractional part of the working cycle.

Variable speed has been accomplished generally by the use of variable-speed motors directly connected to the individual frames without clutches. In Germany successful experiments are reported in the use of individual motors on fliers.

Another development which is not new but which has received a great deal of attention during the past year is the so-called "mule spinning frame" for spinning woolen yarns from roping taken off a woolen card. This type of machinery has been on the market for several years, but recent improvements have materially altered it so that frames are now available over quite a range of counts. Outstanding among these improvements is the divorcing of the draft rolls from the spindles and driving them independently of each other so that the most productive speed can be assigned to each.

Weaving

Power looms are now designed especially for rayon. These looms are fundamentally the same as the ordinary loom, but have refinements and features which adapt them better to rayon.

The automatic loom has been improved by constructing it heavier and by using anti-friction bearings for the main journals. In addition, more attention has been paid to the kinematics of design, resulting in harness motions of smoother acceleration and head motions freer of variation caused by the picker action. The result is a loom which runs with less vibration and consequently at a higher speed than heretofore has been considered practical.

There is a tendency toward a greater use of the electric types of stop motion since these have been improved over the older electric devices. One of the larger loom manufacturers has conducted successful experiments along this line, and will no doubt offer its improved device to the trade in the near future.

Out of the electric stop motion has grown the idea of complete electric control of the loom. This is accomplished by equipping the loom with an individual motor of the double squirrel-cage type, which is capable of giving a high starting torque when thrown directly across the line. This permits a push-button control of the motor, with resulting facility of starting and stopping the loom from any working position taken by the weaver, which is an obvious advantage.

In the manufacture of rugs there has been a general movement toward looms of greater width in order to meet the demands of the trade. Looms capable of weaving fabrics 15 ft. wide are not uncommon, and equipment for widths up to 20 ft. has been installed. This has involved some very serious problems in design on the part of the machinery builder.

Of passing interest in this connection is a machine capable of making rag rugs by a braiding process. Rag carpeting is now available for the householder of modest means.

Dyeing and Bleaching

With the growing demand for color, new dyes have been introduced which give brighter colors, dye more successfully in neutral baths, and are better able to withstand hard wear. The insistence on fast colors is more general. The use of vat colors has increased on rayon, cotton, and mixed fabrics, also on woolen and worsted fabrics, and to some extent on felts. Dyes have been developed for especial use on rayon with more uniform results. Peroxide bleaching is finding greater use in the bleaching of cotton yarn and piece goods. It is also being used to a greater extent on woolen piece goods to meet the present demand for bleached fabrics in women's wear.

The changing attitude toward technical and automatic control is exemplified in dyeing and bleaching.

Finishing

Marked progress is developing in the direction of grouping finishing-plant machinery in series or ranges. This, among other important advantages, secures elimination of the intermediate handling. Three methods are employed which use, respectively, variable-speed motors, by which variable speed and synchronism are obtained electrically; constant-speed motors or mechanically driven shafts, speed variation being obtained through a mechanical speed changer; and variable-speed steam engines, where control is obtained through the governing mechanism. It is anticipated that this form of operation will eventually be extended to other departments of the industry.

The gradual but certain influence of the cutting-up trade has never been more in evidence than in the past year. Today a wool fabric must be finished, ready for the needle; there must be practically a permanent set not affected by the steam pressing now almost universally used by clothiers, this steam pressing taking the place of the former hand pressing or ironing which the earlier tailors thought necessary. The fabric is subjected to a processing that gives it a clean, even luster, a feel pleasing to the touch, and a set or permanent conditioning that can be depended upon. Several types of machines have been introduced, all embodying the same general principles of steaming the fabric when rolled upon a cylinder, while enclosed in a mantle or wrapper, and exhausting the steam from the body before removing it. This is the system of open steaming, as contrasted to the older closed steaming formerly much in use.

In the cotton trade the changes have been less radical. The use of rayon has brought about a demand for lighter machinery, but of higher speed capacity and capable of closer adjustment. In some types of magazine looms the filling yarns project beyond the selvage and have to be cut off. This has brought into the field shearing machines with nicely adjusted cutting parts and suction devices adapted to bring the projecting ends into the cutting parts, which remove the imperfections without damage to the fabric.

In general, practically all machinery in the finishing departments for all fabrics has had to be redesigned to meet the call for increased speed in the various processes.

Knitting

The production of heavy knitted fabrics closely resembling the woven product has caused no little interest and speculation in the textile field. These fabrics are closely bodied and are finding a ready acceptance for top coatings and heavy overcoating. The fact that a knitting machine produces this fabric many times as fast as a loom could produce its equivalent, has given the weaving trade some food for thought.

Conclusion

This report outlines some of the developments in the textile field during the year. The Committee feels that it is indicative of the greater place which the engineer and engineering methods are taking in the industry. There is need for a freer exchange of ideas among the engineers if the benefits of their practice are to become more general and more pronounced. The textile publications are helping to this end, and it is notable that the leading textile journal of Europe is now publishing an American edition. The Textile Division affords a forum for engineers engaged in the industry. To such extent as textile engineers avail themselves of this opportunity, will they promote the industry to the same healthy basis enjoyed by other industries in this country.

McRea Parker, *Vice-Chairman.*

TEX-52-2

Design and Operation of Range or In-Train Drives for Finishing Plants

By WENDELL S. BROWN,[1] PROVIDENCE, R. I.

Marked progress is being made toward grouping finishing-plant machinery in series or in ranges. This, among other important advantages, eliminates intermediate handling. Range drives may be divided into three classes:

1 Adjustable-speed motors, which include direct-current constant-voltage equipment, direct-current multivoltage equipment, and alternating-current equipment.

2 Constant-speed motors or mechanically driven shafts, speed adjustment being obtained through such a device as the mechanical variator.

3 Adjustable-speed steam-engine drives.

Range drives prove advantageous in many combinations, from cloth in the rope form to cloth in the open form. Examples are given.

The successful operation of finishing machinery in ranges is dependent upon the attainment of certain advantages, such as elimination of in-between losses, improved uniformity and quality of product, saving in power and maintenance expense, and saving in executive work.

There are also certain possible disadvantages, such as the present market tendency toward a multiplicity of small lots and varied styles, and the demand for samples. Range speeds are limited to that of the slowest member, breakdowns tie up production, additional building construction is necessary to accommodate extra length, operating losses due to cloth damage in earlier processes continue unnecessarily through subsequent processes, and there is somewhat greater initial expense.

THE textile industry no longer finds itself exempt from the world-wide demand for more efficient handling of men, machines, and materials. The awakening call here and abroad for organization surveys in all kinds of industries, including the manufacture and the finishing of textiles, is quite apparent, and the necessity for improvement needs no elaboration.

This paper concerns advances in the more efficient handling of machines employed in that particular branch of the textile industry engaged in the art of finishing, which includes bleaching, dyeing, and printing.

Marked progress is being made through grouping certain machines or processes in series or ranges. Range drives may be defined as the successive processing of goods without intermediate handling through separate machines arranged in series, or "in-train," as against the older method of operating individual processes singly. The older methods involve intermediate handling, consisting of packaging, transportation, and storage between machines.

Some of the forms of mechanical range drives are not new, for instance the old rope soaper ranges. Undoubtedly, new combinations, more frequent combinations, and larger groups of machines are now being put into ranges than formerly, and the practice is generally recognized as good. In part, this is due to, and has been the cause of refinements in the development of automatic speed-control equipment. The question now is how much equipment to place in range, the number of machines being limited by economics rather than by mechanics.

[1] Engineer, F. P. Sheldon and Son. Mem. A.S.M.E.

Contributed by the Textile Division and presented at the Annual Meeting, New York, N. Y., December 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Types of Range or In-Train Drives

A range drive includes two or more separately driven units or machines. These separate drives are arranged with intercontrol so designed as to insure the proper degree of synchronism under changing over-all speeds and other varying conditions.

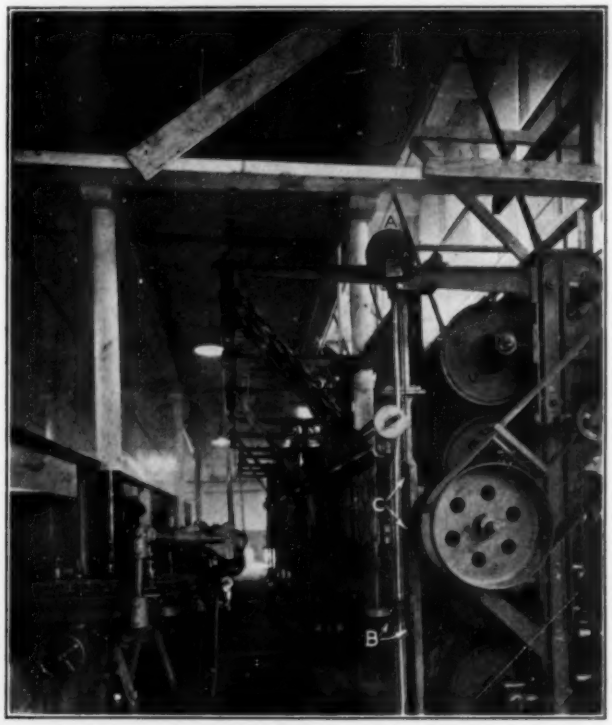

Fig. 1 Installation of Dancer-Roll Control on a Finishing Range Consisting of Mangle, Dry Cans, and Ninety-Foot Tenter

(This automatically maintains proper relations in cloth travel between two different process units operating in tandem, each unit being driven by independent motors operated from a common control. The motors are over 100 ft. apart with no mechanical interconnection. A is the dancer rheostat, B the dancer roll, and C the slot in which the dancer roll travels.)

Range drives may be divided into three classes according to the method adopted for driving the individual units or groups.

Class 1 Adjustable Speed Motors

These are synchronized by rheostatic control for direct-current motors, and usually by brush-shifting elements for alternating-current motors. Synchronizing in some instances is accomplished manually, but is usually most satisfactorily performed by automatic actuation through a "dancer roll" or other mechanism.

A dancer roll (see Fig. 1), also sometimes known as a compensating gate, consists of an idler roll floating upon a fold of cloth

as the latter passes from one machine to another. The vertical movement of this roll is dependent upon the variation in accumulated slackness of the cloth, and is communicated to and operates on the motor-control device. This type of control can be made sufficiently sensitive to act over short distances of roll travel, especially if the control device is of the vernier type, superimposed upon a main regulating device which controls the range as a whole.

Direct-current adjustable-speed ranges are of two types: (A) Constant voltage, using specially designed but now standard motors, with field and armature control, and (B) multivoltage, including the Ward Leonard with standard motors. The former or direct-current variable-speed equipment of the constant-voltage type is very highly developed, and is thoroughly reliable. A typical example of this system of range-control equipment follows:

1 Control from one central push-button station providing the functions of "Inching," "Run" (fast or slow), and "Stop."

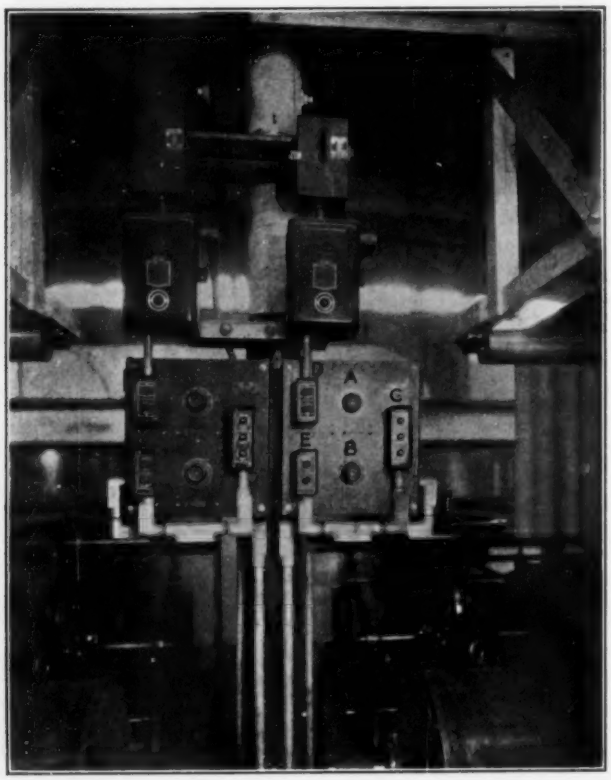

FIG. 2 CONTROL EQUIPMENTS FOR TWIN DRY CANTENTERING RANGES

2 Predetermined speed setting, without necessity of adjusting main rheostat each time, when starting.

3 Automatic time or current-limit acceleration.

4 Dynamic breaking for quick stopping electrically.

5 Interlocked field rheostats for full-field starting.

6 Emergency "Stop" and "Lock-safe" push buttons located where required.

Control is usually accomplished through one main rheostat or a single multiple rheostat, operating in the fields of all motors alike, with fine or vernier individual rheostats for each motor actuated by dancer-roll equipment. There is also the alternative possibility of locating a single main rheostat in each motor field, actuated by the dancer roll, but in this case the follower motor obviously operates in sequence rather than simultaneously with the master equipment.

Typical control equipments for twin dry cantentering ranges are shown in Fig. 2. Each panel makes possible the following centralized control:

Manipulation of rheostat-handle "A" controls the main speed setting of the range drive as a whole. Manipulation of rheostat-handle "B" controls the speed setting of the swing-motion motor from 17 to 51 breaks per minute. Manipulation of push-button station "C" controls all stop, starting, and inching functions of the drive. Manipulation of push-button station "D" starts and stops the swing-motion motor. Manipulation of push-button station "E" controls the operation of the chain-expander motor. With the control equipment are furnished limit switches for preventing over-expansion, or over-contraction beyond permissible limits in the width between chains. There is also furnished a limit switch for automatically centering the swing-motion element of the frames each time at stopping. The motor to drive the tenter frame is 15 hp. with 4:1 ratio. The motor to drive the cans and mangle is $7^1/_2$ hp. with 4:1 ratio operating in tandem with the preceding. A separate 5-hp. motor for independent drive of swing motion is furnished, and also a separate $1^1/_2$-hp. reversing motor for width control between chains.

In some cases the dancer-roll control is omitted altogether in range drives. For instance, in a mercerizing range, when from power or stretch considerations it becomes desirable to get the cloth out of the caustic to the frame in the least possible time, the slack or extra travel required through a dancer roll is considered detrimental to the most efficient processing of the fabric. In such instances where the direct-current constant-voltage system is used, it is not unusual to take the cloth in open form direct from the padder to the frame without going through the dancer roll. In this case, one setting of the vernier rheostat controlling the fine field adjustment on the follower motor is often sufficient for an entire run of goods, regardless of how frequently the range is stopped, the operator doubtless setting the device to produce a slight tension in the cloth, that is, drag on the lead motor to insure against accumulation of slack. When installing a drive for this sort of a range, particular attention should be given to matching up the motors so as to provide similar speed relationships when inching and starting, as well as when running continuously at higher speeds.

As to multivoltage direct-current systems, the Ward Leonard is at present its principal exponent. It utilizes the common, standard, direct-current, shunt-wound, constant-speed motor, but requires, however, an individual direct-current generator for each range, the speed regulation of motors supplied from this generator being obtained by field rheostatic control of the generator, that is, of the impressed voltage itself. Additional vernier rheostats are furnished with the individual motors to obtain, through dancer-roll equipment, the necessary automatic adjustment of synchronism.

This system is also highly developed, its particular field being plants having only a few ranges requiring but a slight amount of direct current. The control wiring is the simplest of all systems.

The alternating-current adjustable-speed drive with continuous operating ratios of 3:1, or greater, is proprietary equipment. One of the primary advantages of this system is that for a plant already equipped only with alternating current it eliminates the capital expenditure for space, fixed charges, and maintenance and some of the energy losses in equipment necessary to convert alternating current to direct current. It also has the further advantage for plants making their own power, but dependent on purchased alternating current for standby service in case of generator failure, that outside service is immediately available without conversion.

A further recent and comparatively expensive development for automatic control without the use of dancer rolls is known as

the differential regulator or rotary field rheostat. This has been used in paper-mill ranges and for pile fabric which latter would be damaged by dancer rolls. It consists of a continuously adjustable rotary field rheostat driven by a synchronous motor, and mechanically operated by the differential movement of a screw and nut, both of which operate continuously in the same direction, the nut forming a part of the rheostat cylinder, and the screw being driven directly from the section motor.

At the present time a continuous operating-speed range of 4:1 with possible slow-down feature for threading-in seems to be the practical alternating current limit, and all that is usually required. It is accomplished by brush-shifting devices. Contrasted with direct-current systems, it is customary for the automatic individual control of each motor to operate over the whole speed change. That is, the governing of the range is effected only by the control of the lead or master motor, the remaining motors coming into step in sequence, as the brush-shifting devices are actuated in turn by their own dancer-roll control, which latter must have sufficient travel to govern its respective motor over its entire speed ratio. These brush-shifting elements may be designed for mechanical operation, or for pilot-motor actuation. The alternating-current system has become highly developed for range operation in the last few years. For example, in one up-to-the-minute arrangement for a three-motor range drive, the scutcher-mangle drier is driven by a 35-hp. motor; a Tommy Dodd by a 15-hp. motor, and the tenter-drier winder by a 15-hp. motor. The 35-hp. lead motor has a pilot motor for brush shifting controlled by a push-button station at the entering end of the range.

The two 15-hp. motors may be operated singly by "Run," "Jog," and "Stop" buttons, and hand speed control, or in range by pressing an additional "Tandem" button in which case they follow the dancer roll to the exclusion of the other buttons. Speed control of the range may be had from either end as when the operator on the entering end on one floor may wish slower speed for splicing, and the operator on the delivery end on another floor wants speed control of drying.

Comparative prices of the three systems line up about as follows for 4:1 ratios and average size motors. The constant-voltage direct-current system including direct-current generator, but not including the alternating-current motor to drive it, seems to run about the same as alternating-current adjustable-speed motor equipment, and about 10 per cent to 20 per cent higher than the Ward Leonard. If, however, direct-current generator capacity is available, or if, to make the comparison fair, alternating-current generator capacity must be added to the alternating-current system, the constant-voltage system would be cheaper. If, on the other hand, allowance must be made for purchasing a motor to drive the direct-current generator for converting alternating to direct current, the latter system will be penalized.

The comparative over-all efficiencies of the three systems are about as follows based upon usual continuous operating speeds, and neglecting starting or slower speeds which are generally of only short duration. Direct-current variable-speed and direct-current Ward Leonard are about equal, and both about 5 per cent superior to adjustable-speed alternating current, provided that direct current is generated directly in the plant. If, however, alternating current only is generated at the plant and must be converted to direct current through a motor-generator set, the alternating-current installation shows an advantage over direct current of perhaps 12 per cent in power consumption. However, the question of efficiency is of little moment in those finishing plants which make their own power, and which also, at the same time, utilize the extra exhaust steam in process work.

Comparative starting torques of the three systems are about as follows:

The direct-current constant-voltage motor is inherently a constant-horsepower motor, whereas the Ward Leonard and adjustable-speed alternating-current motors are constant-torque motors, a reduction in speed causing a corresponding reduction in horsepower. Consequently, in the two latter cases, special attention must often be given in selection of proper rated horsepower to insure sufficient power at the lower speeds.

The comparative power factors of the three systems obviously work out in favor of direct current if no conversion is necessary. Furthermore, if conversion from alternating to direct current is necessary, there is still a difference of a few per cent in favor of direct current based on the use of an induction motor-generator conversion set. However, the necessity for conversion may offer an advantageous opportunity for power-factor correction by using a synchronous motor with over-excited fields to drive the direct-current generator. This often proves a valuable asset in obtaining additional alternating-current capacity, or a better rate for purchased power, the power factor being notably poor in finishing plants.

Comparative Selectivity. When it is desired to provide for operating portions of the range independently, the Ward Leonard system is obviously inferior to either of the others, as its motors are bound up with the varying voltage of the main generator. One important exception however, which is not of infrequent occurrence, is where it is desired to operate the machine to be cut out at considerably higher speed, such for example as with mangle units. This is accomplished by adding manual field control to the particular motors to be operated separately.

Range drives do not always require much speed adjustment. In some instances, as for example, in two-speed mercerizing tenter ranges (threading and continuous operating speeds), two-speed motors may be used in tandem with or without variators. In other instances where 2:1 or lower speed ratios are required, slip-ring alternating-current motors may work out to advantage, although their series and efficiency characteristics tend to make them unsuitable and unstable.

Class 2 Constant-Speed Motors or Mechanically Driven Shafts

With machines or groups driven from constant-speed sources, it, of course, makes no difference whether these sources are mechanically driven or motor-driven shafts. In either event, the individual groups may be synchronized by means of mechanical speed changers based on various principles, including the use of such well-known devices as expanding pulleys, cone pulleys, variators, and more recently the fluid motor known otherwise as the "oil gear" or "hydraulic variable-speed transmission." The latter type of transmission is comparatively expensive, but has been quite highly developed and very successfully used in the paper-making and in the tire and rubber industries. It does not seem as yet to have been adopted widely in finishing plants.

At the present time the mechanical variator is quite extensively used for converting constant speed to adjustable speed. It operates on the principle of varying pulley diameters, and was first developed for manual control only. It is a competitive device, now highly developed, and used in range drives for the automatic synchronization of various groups. This is accomplished usually through the familiar medium of a dancer roll which operates on the variator directly and mechanically, or which, instead, may actuate the variator through a reversible pilot motor.

Variators have the advantage of being applicable to all types of constant-speed drives, whether motor or mechanically driven. In late years they have been much improved as to general design, including space requirements, and maintenance expense. They are, moreover, subject to somewhat less power losses than for direct current obtained by conversion, especially at slow speeds,

but lack some of the refinements of control found in motor drives. This drive, even more so than the direct-current constant-voltage type, is obviously a constant horsepower proposition as far as the motor is concerned, and has therefore the advantage of high starting torque.

The initial cost of the variators with constant-speed motors as compared with the lowest price system of adjustable-speed motors often shows a slight saving in favor of the former.

Class 3 Adjustable-Speed Small Steam Engines

Small adjustable-speed steam engines in range seem to be infrequently used on account, no doubt, of trouble from oil, dirt, etc. Speed control and synchronizing may be accomplished, however, by manual or automatic control of steam supply through the medium of a dancer roll, as for other types of adjustable-speed equipment.

Perhaps it is fair to consider the field of steam engines in range drives limited to moist places unsuited for electrical control equipment, and where exhaust steam may be used for nearby process work.

Applications

Range drives prove advantageous in many combinations from cloth in the rope form to cloth in open form. Examples of two-unit groups are:

A Open soapers and driers, starch mangles, and driers.
B Mangles and dry cans.
C Dry cans and tenters.

Examples of groups containing more than two units are:

A Bleachery washers, souring, piling.
B Singers, mangles, saturators, kiers.
C Mangles, dry cans, calender.
D Mangles, cold tenter, dry cans, calender.
E Mercerizing ranges consisting of padder, mercerizing frame, double washers, etc.
F Scutcher, water mangle, cylinder, drier, Tommy Dodd, cylinder drier, tenter, cooling cans, atomizer, winder.
G Brusher, mangle, tenter, drier, calender.
H Scutcher, water mangle, drier, starch mangle, dry cans, tenter, and winder.
I Open soapers, cylinder driers, starch mangle, cylinder drier, tenter, cooling cans, atomizer, Simpson winder.
J Alternate choice of starch mangle or Tommy Dodd, cylinder drier, tenter, cooling cans, atomizer, Simpson winder.
K Water mangles, weft straighteners, dry cans, guider, tenter, batcher.

Inherent Characteristics of Range Drives in Finishing Plants

The successful operation of finishing machinery in range is dependent upon the attainment of various advantages, and the relative importance of these items varies widely, according to special operating conditions at different plants and the goods being processed. Each case must be analyzed carefully, and the various factors given their proper weight in the total perspective. Often it is possible to utilize much present plant equipment in reorganized range drives, with little additional machinery.

Some possible advantages of range drives are:

1 *Reduction in or elimination of several "in-between" losses.*

a Economy in man-time is often a major item, and it is not unusual for the installation of a large range to reduce the number of operatives from 8 or 10 men to 2 or 3 men. For example, in the old system, each separate machine might require a man, and some machines two men each, whereas in range, one man might be necessary only at the feed end, one man at the discharge end, and one man for miscellaneous duties, such as taking care of mangle making and trucking.

With regard to smaller ranges, one practical bleacher who is an authority on the subject states that an aniline black installation, for example, consisting of padder, cans, and ager, could easily be operated by two men, especially if equipped with a selvage guider, whereas under the old method, three men would be required full time, and a fourth man for at least half time. Again, if arranged to best advantage, two complete soaper ranges with chrome becks, cans, etc., can be operated by three men. Sometimes placing the units, such as soaper ranges, so as to face each other results in substantial reduction of personnel. Such units might consist of open chrome beck, several rope soaping machines, piler, scutcher, water mangle, guider, cans, and folder. Back gray cleaning can often be done at comparatively small cost in ranges. Such a unit might consist of soaping box, string washers, scrays, scutchers, cans, and batcher. Careful inspection of seams and the use of lap seams made on needle machines should insure continuous operation of the range at from 100 to 150 yd. per min.

b Economy in actual machine time. Some plants allow 20 per cent or more idle time for machines when operated singly, due to transferring, threading, etc., and have found this loss reduced to 5 per cent with range drives.

c Economy in storage space may easily be worked out in the drafting room.

d Economy in cloth time accomplished by keeping the cloth on the move promotes customer satisfaction.

e Economy of cloth, that is less damage to cloth ends. With single machine operation there is often an actual loss of several yards at each separate operation due to threading-in, and dirt from handling in the box or roll form.

2 *Improved uniformity and quality of product* resulting in reduction in seconds. This is due to several reasons, as follows:

a Less narrows, due to less frequent threading-in.

b Keeping fabric straight and square as to weft or filling. This has been a baffling problem with some finishers of wide goods, such as sheetings. Range drives eliminate angularity of pull between separate machines, which angularity often causes expensive losses due to crookedness of cloth.

c Less damages due to stoppages. Fabric processed in properly designed, maintained, and operated ranges is subject to the same treatment throughout. In fact, one authority says that for aniline-black installations the padder, cans, and ager must be put in range to secure best results.

d Less damage to cloth ends is more fully explained in 1 *e*.

e Less likelihood of damage from dripping oil and dirt from overhead shafting, etc., during transportation and storage between machines.

3 *Saving in power and maintenance expense* often results through a carefully engineered straight-run layout, such as the range drive, as compared with the old system consisting of a multiplicity of shafts, belts, pot eyes, quarter turns, etc.

4 *Saving in executive and office work* due to greater simplicity and ease in scheduling and following up progress of goods through the plant.

5 *Increased production* due to the fact that machines may be designed and operated at maximum speeds. This, however, is likely of attainment only if run upon a few staple and similar lines of goods. Otherwise, the reverse is likely to be the case.

There are also inherent disadvantages in range drives which must be overcome as far as possible in order to obtain maximum economy. These, too, vary in number and importance, and should be the subject of thorough investigation for each individual case. The history of range drives is not one of uninterrupted progress, some ranges having been erected and later dismantled on account of inflexible and costly operation. One instance has been brought to the author's attention where it was attempted to

sulphur dye, wash, after treat, dry, finish, dry, and frame in one range. This was overdoing it, and it was found impracticable under the existing conditions at the plant to obtain either uniform shade or finish without frequent stops of the entire range which usually damaged much of the cloth.

Disadvantages of Range Drives

1 *The present market tendency toward a multiplicity of small lots and varied styles, and the demand for samples.* This results in disproportionate expense from set-up costs involving losses in machine and man-time caused, for example, from changes in the "making" for mangles, changing widths and speeds for frames, changing designs, colors, etc., for print machines. One authority states that the average range for vat dyeing cotton piece goods, consisting of padder, four or five wash becks complete with immersion, squeeze, skying rolls, and slip-belt batcher, cannot be economically run on less than 3000-yd. lots. Usually a reduction in the size of range permits reduction in the minimum economical number of yards per run. The above-mentioned market tendency toward small lots may also result in inability to utilize all of the individual units, thus causing idle machine time and consequent increased operating costs. Calenders seem, more frequently, to be driven singly or out of range on account of the many and varied types of calender finishes used.

Arrangement of range drives for selectivity, while adding somewhat to the expense, tends to increase flexibility of operation, and thus may eliminate to a considerable degree the above-mentioned idle machine losses. For example, ranges are often planned with sufficient space between different machines for trucks and boxes and also to include auxiliary folders or winders at these locations. The winder is ordinarily by-passed, but may be used if it is desired to segregate the previous machine. This machine being cut out, the remainder of the range may be used by passing the cloth over and free of it on fixed rollers down to the remaining machinery. With a drive of this sort, variable market demands are not so damaging to production costs.

2 *Range speeds are limited to that of the slowest member* unless selectivity is arranged for. Where tenters or dry cans are concerned this may well be a serious handicap if the weight of goods being processed varies appreciably. That is, unless a standard product can be counted upon, the probabilities are that for a considerable portion of the time, machinery like mangles can be operated at much higher speed. With proper selectivity, however, such machines may be cut out and perhaps operated over one shift where the remainder of the range might be operated continuously night and day. This happens sometimes where tinting is done with the starching.

3 *Breakdowns tie up the production* of the whole equipment besides resulting in damage to the cloth. They are therefore intolerable, and require extra careful and periodic machine inspection and maintenance.

4 *Additional building construction* may be necessary on account of length required, sometimes 200 ft.

5 *Operating losses* due to cloth damage in earlier processes continuing unnecessarily through subsequent processes.

6 *Somewhat greater initial machine expense.* This is largely due to automatic control features, especially if selectivity is required.

Acknowledgment

Grateful acknowledgment is made to the kind interest of various individuals in supplying data based upon their own practical operating experience in charge of finishing plants. These include Harry M. Burke, J. A. Campbell, M. A. Golrick, Jr., G. D. Harrison, Paul A. Merriam, J. D. Robertson, and John G. Shirley.

Discussion

J. A. Campbell.[2] The author mentions that range or in-train drives eliminate the older methods involving intermediate handling, etc., and that they also reduce the personnel. The writer considers these among the great benefits derived from these installations. It is understood that only certain machines can be put in range, and machines when grouped eliminate failure of the human element and considerably reduce the cost of production.

Many plants in other manufacturing lines pay higher wages than textile mills, and where there is a scarcity of skilled labor this industry must use machines wherever possible.

In "Application I" selvage guiders also can be used to advantage, as one of these machines will eliminate one attendant and will pay for itself in from three to nine months, depending upon the type purchased.

In "Application K" this range is used to frame goods for printing, and a batcher with a cutting-off knife can be used. With the common type of batcher the machine will need to be slowed down to cut the goods, but with the cutting-off attachment the machines can be kept running at maximum speed.

Mark A. Golrick, Jr.[3] The author has covered his subject from many angles, and the writer only can emphasize some of the statements and elaborate on others. This subject is of vital importance to most finishing plants, as many are partially range driven, while others are ready to go to extreme limits and be almost entirely range driven.

The statement made by the author that "the question now is how much equipment to place in range, the number of machines being limited by economics rather than by mechanics," might well be a definition of the application of range drives and is of prime importance as the fundamental basis of all range drives, which can be made mechanically perfect enough to include almost the entire finishing process. The limiting factor is to determine exactly what constitutes an economical range, rather than how many machines can be arranged successfully in tandem from the mechanical standpoint of production. This point cannot be overemphasized, and I am glad that the author's closing thought has been on the other side, or the disadvantages, rather than the sometimes overstressed advantages of range drives.

A clear description has been presented on the types of drives and controls for the various systems of either alternating or direct current, mechanical-shaft drives, and steam. This section may well serve as a textbook for any one considering range drives, or even for those who are familiar with certain types which have met their own requirements, but very few have been privileged to experience the complete picture which has been presented here.

In designing a range a few features that may be noted are that special light goods often require a change in machine design, such as the introduction of ball bearnings. The thought must be constantly borne in mind that, with the changes in type of goods to be run, a range may soon be obsolete unless careful planning and forethought provide for its necessary alterations in design. As usual, additional cost is added to the equipment to be installed, but it is generally a paying investment.

Another feature is the growing tendency of cotton converters to handle lighter and high-priced fabrics, requiring the finisher to have better machines than the type that has been used previously on the general run of cotton goods. In this change of style the thought that must be in the mind of the designer of range drives is

---

[3] Production Manager, Dutchess Bleachery, Wappingers Falls, N. Y. Jun. A.S.M.E.

that in the case of the substitution of rayon for cotton, particularly on printing machines, there will be required a more powerful drive and, often, a strengthening of certain parts. On the other hand, the lighter goods will require a machine which will run with the minimum of friction, the goods to be kept in almost perfect alignment, and the parts must be rigid and yet offer little resistance to the cloth, which often, of necessity, must drive the roll.

While the author has spoken of the operating features, it is well to note that, in attempting to start operating range drives, another feature that must be carefully considered is the general opposition of foremen, as well as the individual employee, the view being that the new machine cannot do the work equivalent to the old. It is always pointed out by the employee that, with range drives, when one unit breaks down, it holds up the entire process; another point that is emphasized by the employee is the fact that damage or other similar operating fault on a range will be far in excess of that on the original individual machines.

Another feature of operation is that of better lubrication, which is important, as an oil spot may start on a set of cans in tandem with a frame and a batcher, and in range drive the delayed inspection means a greater tendency to extend the fault. Knowing this, the employees and foremen have an argument to support their contention that it is more difficult to inspect range goods, often at higher speeds, than with the former individual machine operation. Of course, this is true, and it must be remembered that range drives require a superior type of employee to operate, a better and more thorough maintenance, and, finally, the supervision and planning of the routing of the material to be run on the range must be done with great foresight.

Individual preference and local conditions vary the types of ranges which one plant or another may consider superior to a competitor's, but the author has carefully considered the factors which tend to make a range drive successful, and also those limiting factors which must, of necessity, control the limits to which any machine can be applied successfully.

In summarizing, it might be said that, with proper cooperation of the employees, the foremen, and the management, range drives are a great success today in finishing-plant work. The plants which are not equipped for range drives either must limit their activities to special work and refrain from general competition or ultimately be driven to range drives of various types or modifications. Often the advantages have been overemphasized in many ways, and only the bright side of the picture has been painted, but this paper has given a presentation by an impartial judge.

Paul A. Merriam.[4] The author has covered the question of range drives in finishing plants most thoroughly. There is one advantage that is gained by the application of the range drive principle that the writer does not recall having been mentioned in the paper. This is the ability to determine and control cloth tension entering between machines or even within a machine. An example of this last advantage is the case of an open soaper for handling rayons or silks, where each nip is driven by its own motor and the speed of each nip is determined by the compensating roll acting on a rheostat between each pair of nips. This of course allows for variation in shrink or stretch and variation in roll sizes, etc., and assures a predetermined tension on the cloth as it progresses through the machine or machines.

The amount of this tension can of course be controlled by the amount to which the compensating roll is weighted or counterweighted.

[4] Chief Engineer, Providence Finishing Company, Providence, R. I. Mem. A.S.M.E.

Jules de Konkoly Thege.[5] The use of adjustable-speed small steam engines for finishing plants does not seem advantageous. Regarding the problem of superheated steam, as used in textile mills, the writer would ask if there is any tendency toward the application of adjustable-speed small steam engines for finishing plants in the textile mills of the United States.

In the writer's experiments in the Hungarian Cotton Manufacturing Co., Ltd., Budapest, the use of this type of steam engine was not profitable. Calculations were made as to whether the operation of the steam engine or the adjustable-speed motor or the constant-speed motor with mechanical variator is cheapest. Finally it was found that to drive the cylinder driers with steam engines is more expensive than with the other machines. By replacing the old adjustable-speed engine by a constant-speed motor with mechanical variator, it would pay for itself in a year. However, when exhaust steam may be used, it makes operating expenses cheaper. The manipulation of a motor, either with adjustable speed or with mechanical variator, is easier. It does not need skilled labor. Other disadvantages in the use of steam engines are the troubles from oil, dirt, etc.

Edwin H. Marble.[6] Lost time seems to have been so closely connected with the human element in any industry that its association with the mechanical element is often lost sight of, yet any efficiency engineer will show you how strong an influence it has upon the two sides of the balance sheet of an organization. With his stop watch he will give you the difference between the operating time and the elapsed time of the mechanical equipment under investigation. How to reduce this mechanical lost time has been given careful study in many processes, and how to operate each machine at its normal rate of production has been the object of many a close investigation. It is one form of research that has paid dividends when properly conducted, and research is one of the best investments in the textile industry.

This research has demonstrated two clearly defined causes of losses in production—first, the loss caused by less than normal output of the machine and, second, and perhaps in many cases the more important from a financial point of view, the poorer quality of a portion of the output caused by the speed reduction.

Discussing the first, on machines giving a nominal output of 100 yards per minute, a stop of two seconds means a loss of $16^2/_3$ yards, with all the other expenses except power remaining the same. In the second case, the stopping of any machine when the fabric is being processed means a difference in quality of the output that is quite serious in most cases. To quote a remark made by an old manufacturer, "If there is any portion of the fabric that is below quality my customer will discover that portion first." With this preliminary, the writer will bring to your attention an example of how a common intermittent operation has been eliminated.

In the singeing of fabrics, any halt in the normal transit of the fabric through the machine causes an unequal quality which is very noticeable. The stopping of the normal rate of travel for any reason not only reduces the production directly in proportion to the length of time the stop occurs, but the regaining of normal speed adds its quota to the proportion of unequal-processed fabric. To make this particular process continuous there has been adopted a sequence of attachments or units.

The fabric has been previously assembled in several loom lengths or cuts, usually amounting to 300 to 500 yards. The normal speed of travel through the singeing machine may be 180 yards per minute. The assembled fabric is unrolled or taken from the truck by an unrolling frame and deposited in a scray or re-

[5] New York, N. Y.

[6] President, Curtis & Marble Machine Company, Worcester, Mass. Mem. A.S.M.E.

ceptacle capable of holding 2000 to 3000 yards, this unrolling being done at a speed considerably faster than the normal speed of the singeing machine. This increased speed allows time to sew the tail end of the entering piece to the head end of the following piece, with the best type of sewing machine for that purpose being determined by the style or character of the fabric being run.

The singeing machine is usually equipped with two small brushing attachments, one in front to remove any foreign matter and one at the back to clean the fabric of any chaff or burned particles, these three sections being operated as one unit. The fabric is drawn from the scray through the brushing attachment, is singed, again brushed, and is deposited in a second scray back of the second brushing attachment, the fabric being carried along at the normal singeing speed. Back of this second scray is an independently driven unit in the form of a rolling-up section with suitable guiding attachments, being driven by a two-speed motor with the slower of the two speeds arranged to synchronize the speed of rolling with the normal speed of the singeing machine. The second or faster speed is 20 to 25 per cent faster.

From the scray the goods are drawn along to the rolling section at the normal speed until the roll thus built up is as large in diameter or contains as great a yardage as is desired. When this has been accomplished, this unit is stopped, and the goods are allowed to accumulate in the scray. The roll of fabric having been removed, a new shell is inserted, the cloth is started along, but at the faster of the two speeds and drawing from the accumulation in the scray until that accumulation is reduced to a minimum. The speed is then changed to normal until it is necessary to again change the roll.

J. D. Robertson.[7] In the installation of direct-current adjustable-speed range drives one fairly obvious point that sometimes has been overlooked is that the pulley sizes must be so chosen that equal cloth speeds in all units of the range will result from equal motor speeds with the dancer-roll rheostats completely cut out.

For example, if the motors used are 500 to 1500 r.p.m. motors and the desired cloth speed is from 30 to 90 yards per minute, it is necessary in order to get the full range of speed that the pulleys be chosen so that when the cloth is running at, say, 30 yards per minute in all units, all the motors will be running at 500 r.p.m., with all dancer-roll rheostat resistances cut out.

The number of operations to be put in a range and the extent to which range drives can be used to increase profits are largely determined by the number of kinds of work a plant has to handle and the frequency with which the kinds change.

For example, if a concern in a cutting-up trade, such as a shirt maker or a curtain maker, finishes its own goods, it can profitably tie up more money in an elaborate range of operations than a commission finisher handling a large variety of work and subject to all the whims of fashion in a large number of lines, because the cutter-up will be able to use his equipment a much longer time before fashion shall require it to be changed than will the commission finisher.

However, when deciding on the installation of an increased number of operations in range, careful consideration should be given to the difficult-to-estimate, profit-increasing factors involved in any industrial layout tying a number of operations together such as the chain-assembly methods and materials-handling systems first developed so highly by Ford and now generally used throughout the automobile trade and many other metal-working lines. In such cases a considerable investment in material-handling equipment is made in order to eliminate the delays and increased inventory required by handling goods in boxes and trucks. Practically all the advantages of such an investment are available to the cloth finisher merely by carrying the goods from operation to operation in the rope or open width instead of in boxes and by using range drives where necessary.

Henry M. Burke.[8] It has occurred to the writer that one matter might be injected into the discussion, and that is the question of the development of the B.T.A. motor for variable-speed range drives. It is probably not a well-known fact in plants that have not the advantage of direct current that it is rather difficult to secure satisfactory variation in the drive with the alternating-current variable-speed motors that have been built in the past.

Take, for instance, a large vat dye range operated by alternating current: it is quite necessary to stop this range, which is made up of dye pad and a series of six-seven-eight boxes, to take off swatches. It is quite necessary to start in threading it at a very low rate of speed. There may be several hundred yards of cloth in the machine passing through the dye pad and a series of boxes which cause a great deal of trouble when trying to get an absolutely uniform shade where variation in speed occurs. When the machine is stopped, the cloth is permitted to remain in the dye and re-reducing tanks, absorbing more color, so that the cloth in the bath at the time the machine is stopped is to be sacrified on account of its being off shade. This is very important when vat dyes are used, as it becomes a difficult problem to knock down the shade or build up the shade, if that is necessary, when that yardage is subsequently rehandled.

If a machine is not properly designed and free from friction, sometimes the cloth breaks on account of lack of uniformity in the rolls and unequal tension in the various boxes. When the goods break, time is lost in trying to rethread the machine properly, and also unevenness of shade is caused. These losses, if not looked after, are the cause of serious disadvantage on a long range, especially if the lots put through are of the minimum quantity that could be economically dyed on such a long range.

Another disadvantage of range is that it is an expensive unit to build, and if the plant is small and the lots being processed in it are small, the cost of operation becomes less attractive than in a plant, even where these long ranges are being operated on very large lots and more continuously.

When various pieces of equipment are put in range, unless special precautions are taken to have sufficient space between the various units, the individual units become a part of that range and cannot be operated independently. The speed of a long range is determined by its slowest operating unit. This is a disadvantage, because quite frequently and in times of poor business this long range becomes practically inoperative on account of not getting sufficient business to run economically. The small plant with a limited amount of capital is sometimes forced to run units in accordance with the maximum speed, so that if they have several units it becomes more advantageous for them to keep them individually operated than to tie them up in a long range.

Much has been said about the advantages of range drive, but the writer thinks that a careful study of the excellent paper will bring those contemplating range drives to a consideration of the disadvantages and the methods to overcome these disadvantages. Take, for instance, range drives today that are built for certain widths of cloth; should the styles change so that wider fabrics are necessary, this range drive for the narrow fabric becomes obsolete. The obsolescence of such an expensive machine is a very serious matter with a small plant operating with small capital. On the other hand, if a range is built to take the wide cloth, the operating of a wide machine takes more dyestuff and liquor than necessary, and that is a serious handicap.

[7] Plant Engineer, Mount Hope Finishing Company, North Dighton, Mass. Assoc-Mem. A.S.M.E.

[8] General Manager, Dutchess Bleachery, Inc., Wappingers Falls, N. Y. Mem. A.S.M.E.

Therefore, the range drive may be the solution for low costs in one plant and may work out just the opposite in another.

Later on in the discussion, the question arose as to operation of textile machinery with the use of superheated steam. The writer feels that a paper could be presented before the Textile Division that would bring out the advantages and disadvantages of superheated steam in processes. Another subject that is brought up from time to time is the subject of the most advantageous steam pressures. A paper covering this subject would be of great value.

WARREN B. LEWIS.[9] The author has presented the pros and cons of range drives as they apply to the finishing of cotton piece goods in a very impartial and thorough manner and has brought out the basic reason for such drives, which is to reduce manual handling, and the damage resulting therefrom.

As to the method employed, the writer would like to add that about one-half of the power used in a cotton piece-goods finishing plant is essentially of a constant-speed characteristic and one-half is variable speed. If the generating plant is about 50 per cent direct current and 50 per cent alternating current, with a motor-generator set to transfer 20 per cent in either direction, relatively high efficiency of distribution is assured and excellent flexibility of control, from full production to a very low rate.

In such a plant the use of adjustable-speed direct-current motors represents approximately half the power and constant-speed alternating-current motors the other half, assuring relatively high efficiency, a minimum of equipment, and relatively low maintenance expense. Adjustable-speed motors can then be operated in range or the several units be operated independently, as suggested in the paper. Complete alternating-current generation involves either the use of alternating-current or direct-current conversion, with added investment and added losses. This would be justified where a small amount of direct-current power was required, but the case is rather unusual. In such cases constant-speed alternating-current motors with mechanical variators are satisfactory; but frequently the first cost is high, the control far less convenient, and the maintenance objectionable.

The author refers to certain objections in range drives, one being the operation of part of a range at speeds lower than might be possible if operating independently. In most cases this is not economically bad, as elimination of separate handling results in a labor saving in excess of the fixed charge on the machine.

The variable-voltage control has little or no advantage over the adjustable-speed constant-potential system, the former being particularly applicable where very great variations of speed are needed, which is not the case in finishing cotton piece goods. A variable-voltage system multiplies the number of machines in operation, and the total horsepower of electrical equipment is four times that actually applied to the machine.

[9] Consulting Engineer, Providence, R. I. Mem. A.S.M.E.

An interesting and wholly practical arrangement of range drives is in the bleach house, where cloth may be handled continuously from the kier to the white bins through ten machines in range, and yet each one may be used independently or any combination be used independently. Such a range can be made so nearly automatic that labor is reduced to little else than supervision or to straighten out an occasional tangle. Such a range reduces the time in process by days.

The writer believes that he was the first to introduce range drives in the textile industry more than thirty years ago, and utilized a variable-voltage system, today practically extinct, which consisted of six definite voltages produced through a master balancer set and a controller which applied these definite voltages to the motor armatures. For speed controls of as high as 7 to 1 ratio this system was very successful, but the complication of wiring and certain inherent faults in controllers presented disadvantages as compared with the adjustable-speed motor, which was at that time being rapidly improved.

AUTHOR'S CLOSURE

The discussion has certainly proved most interesting and useful in substance and volume, and, together with the unusually large attendance at this meeting, it seems to indicate growing realization that success in the textile industry lies increasingly along the lines of refinement through careful fact finding and analysis.

Mr. Campbell's pertinent remark regarding a further advantage incident to the reduction to personnel, that of eliminating sources of potential human-element failure, is noted. This aspect of the situation resolves itself into human failure versus machine failure, and in some cases it should constitute a partial answer to the difficulty of which Mr. Golrick speaks and which difficulty many have found to be a very real one—that of overcoming the prejudice of operators who are in the habit of pointing out the serious effect of mechanical breakdowns in tying up the productivity of a whole series of machines when in range.

The author also wishes to thank Mr. Merriam for calling attention to the advantage regarding regulating cloth tension. The determination of cloth tension by proper weighting of dancer rolls would, in certain instances, seem undoubtedly to be an additional advantage with range drives.

Answering Mr. Thege's question, and as stated in the paper, trouble from oil, dirt, etc., as well as considerations of fuel consumption, seem to militate against the extensive use in range of adjustable-speed steam engines.

Needless to say, examples of range drives given in the paper are intended only to illustrate certain existing applications and should not be taken as a blanket recommendation for their adoption anywhere without carefully weighing the various disadvantages and advantages applicable to the particular case in mind.

Advances in Control of Plain, Chase, and Schreiner Calenders

By JAMES A. CAMPBELL,[1] GARNERVILLE, N. Y.

A better product from the textile finishing plants has resulted in the past few years, together with greater economies in the processing of goods, as the result of scientific study to obtain the facts. To operate at a profit the modern plant must meet present economic conditions by taking advantage of every opportunity to improve on quality and process. Calendering has become a most important process, as a larger proportion of cotton materials are now so treated; and the paper compares the principles, the designs of machines used, the methods of operation, and amount of production at the present time compared with 1910.

RADICAL advances in the operation of textile finishing plants during the past few years have made it possible to turn out a better product and to realize economies in the processing of goods. The outstanding contributing factors in these advances, i.e., improvement of quality and more economical operation, undoubtedly have been almost entirely made by scientific studies to obtain facts, as very few real facts were generally known in the trade.

The so-called "good results" of the past are not sufficient for the operation of any modern textile plant which expects to operate at a profit. Economic conditions require that advantage be taken of every opportunity continually to improve on present methods, as well as those of the past. Successful plants of today are employing new management methods, which develop initiative in the individual departments. They also continually compare their operations with scientifically possible standards. Specifically, the improvements usually are best handled by separating any problem into its elements. These elements are analyzed for their limitations and interrelations when functioning as a working unit.

As a larger proportion of all kinds of cotton materials are calendered today than in the past, calendering, in its various forms, has become a more important process than ever before in the finishing of cotton goods, and has come in for considerable study, where before it was very much neglected and done in a more or less hit-or-miss fashion, depending upon the ideas of the man in charge of the plant.

This paper will, therefore, compare the principles as well as the design of the machines used, the methods of operation, and amount of production at the present time, with those in 1910, in order to show the tremendous advances that have been made.

The outstanding improvements in calendering have been mostly in actual machine operation, and in improving the design, strength, weight, and methods of driving the machines. There has been, however, no change in the underlying principles of the machines themselves.

From Table 1 a general comparison of the fundamental factors in typical calenders of 1910 and 1928 can be made. Referring to this table it can be seen that:

1 The fundamental principles of the machines are the same

2 Belt-and-clutch drive has been replaced by direct-connected motor drive

3 The average increase in the number of rolls used is two. Modern five-roll heavy calenders with roller bearings usually have a filled roll on the top and bottom. The latest development is to use six rolls having the top and bottom rolls of chilled iron. The latter rolls will last for years, and the same journals are always in the roller bearings. The reverse is the case when filled rolls are used, since they require frequent changing which necessitates equipping all filled rolls in use and spares with hardened-steel sleeves, so that they are interchangeable

4 The increase in diameter of the composition rolls is from 2 in. to 8 in.

5 The increase in diameter of the iron rolls is from 3 in. to 4 in.

TABLE 1 COMPARISON OF TYPICAL CALENDERS OF 1910 AND 1928

	Item	1910	1928
1	Principles of machine itself	Same	Same
2	Method of drive	Belt and clutch	Motor
3	Number of rolls	3 to 4	5 to 6
4	Diameter of composition rolls	18 in.	20 in. to 26 in.
5	Diameter of iron rolls	9 in. to 12 in.	12 in. to 16 in.
6	Width of face of rolls	40 in.	50 in. to 120 in.
7	Bearings	Plain	Roller
8	Pinions	Cast iron	Composition
9	Dampening	Sprinkler (separate operation)	Atomizer attached to calender
10	Expanders	Barrel	3 roll Mycock
11	Roll raising	Hand wheels	Motors
12	Hydraulic pumps	Belted	Direct connected

6 The width of the face of the rolls employed has increased from about 40 in. to 120 in., a majority being about 50 in.

7 Roller bearings are tending to replace plain bearings

8 Composition pinions are generally used in place of cast-iron pinions

9 In the most progressive plants, direct-connected atomizers have replaced the sprinklers, eliminating a separate operation

[1] Production Superintendent and Mechanical Engineer, Rockland Finishing Co. Mr. Campbell was born in Wellington, New Zealand, and after graduating from technical school served an apprenticeship with Robertson & Co., engineers and shipbuilders. He then went to Scotland and was for four years engineer on mail steamers running from Glasgow to the United States. After securing all marine certificates, he took the special course of naval architecture and mechanical engineering in Watt Memorial Engineering and Navigation College and Alan Kerr Laboratory. He then taught for one year in McGibbons Engineering Academy. In 1912 Mr. Campbell came to reside permanently in the United States and has occupied the position of mechanical engineer in several large textile plants. In 1923 he was elected chairman of the Providence Section, A.S.M.E., and was elected chairman of the Textile Division in 1926 and reelected in 1927. Mem. A.S.M.E.

Presented at the National Meeting of the Textile Division, Greenville, S. C., Oct. 17, 1928, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

10 Three rolls Mycock expanders are being more and more favored over the barrel type

11 The tendency is to raise the rolls by motors instead of of the old hand-wheel mechanism. Hydraulic pumps operated by hand are also used

12 Plants operating under the most advanced methods are driving the hydraulic pumps by direct connection to the driving shaft.

As the basis of the best operation of any calender is derived from careful time studies, the progressive finishing plant, therefore, has to make numerous checks of all the elements in calendering, so that all unnecessary operations are eliminated, and the machine will be handled in the best possible manner to secure the maximum production with the lowest cost.

Accurate time studies have brought out, of late, the following facts which were only more or less recognized a number of years ago:

1 Calenders which are operated on one side only, require only one operator. On machines where the feed is on one side and the batcher on the other, part time of a helper is required. Large calenders should be installed adjacent to each other, so that one helper can take care of the extra work on two machines. This gives a personnel of $1^1/_2$ men per machine. When only one calender is operating, the helper should receive the same rate as the operator, but when two machines are running, the helper should receive half the earnings of each calender operator. Should a heavy calender be located at a distance, the spare time of the operator can be used to run another machine, such as a sprinkler, paster, or button breaker.

2 The efficiency of the calender operators can be increased greatly if adequate service is provided by the truckers in the department. The truckers should receive a bonus based on the average hourly earnings of the calender operators.

3 The supply of the rolls of cloth should be taken care of so that the operator does not need to leave his machine. Many yards are lost per day through the operator having to move from his machine to get new rolls or wheel away the completed roll.

4 The size of the rolls of cloth must be standardized for different fabric weights.

5 It is important to have shell centers of suitable size and weight, and these must pass freely into the shells so that no time is lost in changing rolls of cloth.

6 Accurate measuring drums should be installed on the machines with clear-figured counters connected to the drums. The counters should be in the line of vision of the operator, and this can easily be arranged by the use of sprockets and chain drives. The gears should be such that the counters directly indicate yardage.

7 Forms for recording the yardage, lot, style, etc., must be designed so that the clerical duties of the operator are reduced to a minimum. The information must be complete. Then accurate records can be made for payment and for cost accumulation. The importance of correctly designed records will be clearly shown by the following. In one instance, it required 1.04 min. for the operator to record the information required on the job card; by rearrangement of this card or form, the time of recording was reduced to 0.30 min. per roll. This change alone added 36 min. per day to the running time.

8 Holders are necessary for the operator's card. These can be installed on the frame of the machine.

9 Calendering operations are satisfactorily compensated by piece-rate payment, the operatives being paid a predetermined rate per 1000 yd. of goods calendered.

10 The installation of piece rates either on straight production or on differential rate, based on increased production, has proved effective for increasing the output. It should be emphasized, however, that the standard upon which such piece-rate payments are based must not be determined in the old-fashioned hit-and-miss manner, but developed scientifically.

11 With judicious rates of payment, the quality of the product is assured.

12 The service time varies slightly. The rates of payment for this time should be computed from the basic hourly rate. As this rate is lower than the piece rate of an efficient worker, there is an incentive to reduce the service time. After the service time is reduced to an apparent minimum, time studies should be made on the complete operation, and standards set for the production of the machine. Table 2 shows typical service, as well as running time per roll.

Table 3 gives a few typical cases which show how scientific study, development of the machine itself, and definite constant control of operating calenders (1) reduces the service time, (2) increases the running time, and (3) increases the yards produced per unit of running time, with consequent reduction in the number of machines necessary to turn out a definite amount of work.

TABLE 2 CALENDER OPERATIONS

Calenders	Yards per minute per machine of	Minutes per roll 800 yd.	Minutes per roll of 1000 yd.	Standard service time in min.	Total standard time per roll of 800 yd.
Plain	100	8	10.00	3.04	11.04
Hydraulic	107	7.47	9.34	2.73	10.20
Chase	127	6.30	7.87	3.91	10.21
Schreiner	25	32.00	40.00	2.36	34.36

A summary of all the facts outlined shows that:

1 Calendering is a scientific process, not an "art."

2 There has been no change in the fundamental principles of the machines.

3 There has been a definite advance in the actual design of the machines.

4 Most machinery was run on beliefs and not facts.

5 Considerable machinery is now being run on facts and not beliefs.

6 The tendency is to substitute continuous for intermittent processing.

7 It is better to replace human guesses or judgment by chemical, physical, and mechanical control.

8 With scientific control, definite schedules can be maintained more closely.

9 With scientific control, the earnings of the operatives have been increased.

10 With scientific control, the cost per yard has been reduced.

It is the opinion of the author, therefore, that:

TABLE 3 COMPARATIVE DATA 1910–1928

Types of calender used	Types of materials calendered	Speeds in yards per minute Actual 1910 Average	1910 High	1928 Low	1928 Average	Difference between 1910 and 1928 average Actual	Per cent	Division of operating time in per cent 1910 Running	1910 Service	1928 Running	1928 Service	Production in yd. per hr. 1910 Actual	1928 Actual	Per cent increase
Plain	Shirtings and dress goods	60	110	110	110	50	83.3	50	50	85	15	1800	5280	193
Plain	Heavy linings	70	180	160	170	100	142.8	50	50	70	30	2100	7140	240
Chase	Shirtings and dress goods	70	135	120	127	57	81.4	50	50	80	20	2100	6096	190
Hydraulic	Dress goods	70	112	100	106	36	51.4	50	50	80	20	2100	5385	156
Hydraulic	Sateens	70	112	100	106	36	51.4	50	50	80	20	2100	5385	156
Schreiner	Dress goods	18	46	23	25	7	38.8	78	22	90	10	540	1350	150

A There will probably be no radical changes in the underlying principles on which the machines operate.

B There will be a more general knowledge of the facts of calendering.

C Operation will be based more and more upon scientific facts and definite control of operation.

D Quantity and quality will increase through better control of (*a*) temperature, (*b*) pressure, (*c*) conditions in which the goods arrive at the calender, (*d*) better methods of handling, (*e*) further experiments should be carried on to run two rolls of cloth at one time on chase calenders, and (*f*) more consideration should be given to mechanical handling of cloth rolls.

TEX-52-4

Theory and Practice in Textile Drying

By B. R. ANDREWS,[1] CAMBRIDGE, MASS.

THE process of coloring and finishing textile fibers is almost without exception carried on while those textiles are wet or become wet by means of the process. This wetting and drying out may occur from two or three times to seven or eight times in the preparation of a single fabric. Therefore, drying is one of the large costs in the manufacture of any textile, and the drier an important manufacturing unit.

The relative values of different driers to any manufacturing plant depend solely upon the relative earning capacities of those driers, and this earning capacity must take into consideration the overall earning capacity of any range of machines of which the drier is a part and in which it is the limiting factor of the capacity of that range.

The cost of operation of a drier alone can be divided into a charge for interest and depreciation of the investment, which must include the proportional floor area occupied by the drier and its appurtenances, as well as the cost of installation, maintenance, labor, power, and steam. Where the drier is one machine in a range of machines, similar charges must be applied to all of the equipment in the range and consideration given to the cost of performing the operation or operations accomplished by the range.

The following tables give the cost of operation in unit production of two very common ranges:

COST IN DOLLARS PER 1000 POUNDS OF DRY STOCK OF BACK WASHING, 52-HOUR WEEK

Pounds of dry stock per hour	Steam and power	Labor	Overhead	Total
100	2.80	3.28	7.85	13.93
200	1.50	1.64	3.97	7.11
300	0.90	1.09	2.62	4.61

COST IN DOLLARS PER MILLION YARDS OF STARCHING AND TENTERING, 52-HOUR WEEK

Yards per week	Av. yd. per min.	Steam and power	Labor	Overhead	Total
62,500	20	265	416	1494	2075
125,000	40	260	208	781	1250
187,000	60	255	139	549	945
250,000	80	250	104	423	779
312,000	100	245	83	354	681

These values are based on 6 per cent interest, depreciation in ten years, labor at $1500 a year for the starching range and $1250 for the back-wash range, steam at 30 cents per 1000 lb., and power at 2 cents per kilowatt-hour.

The speed-of-production limits given in these tables are well within the actual operating conditions in the average plant today, and it is quite evident that those having equipment capable of the higher capacities enjoy a great advantage in the cost of operation over those whose production per unit is still low. The tables are also based upon the assumption that the thermal efficiency of the driers is good; yet this is not a fair assumption, for driers with a high thermal efficiency are almost always those of high capacity, so that the spread between different plants is actually more than the tables indicate. Inasmuch as the figures given show that the importance of production capacity overshadows thermal efficiency to such an extent, an analysis of those points which contribute to maximum capacity should receive first consideration.

A large part of the drying in a textile plant is done on contact driers, such as the well-known dry can. Here the rate of evaporation is directly proportional to the surface of goods in contact and to the temperature of the surface of the can, provided the drying is completed. Therefore, once proper provision has been made to remove water and air from the cylinders, the only engineering in addition necessary to secure maximum practical speeds is to provide a sufficient number of cans.

Other textile-drying operations carried on in heated compartments are subject simultaneously to all the complicated variables of transmission of heat from air to water in the material and those things which contribute to create a difference between the partial pressure of the liquid being evaporated and that of the atmosphere in which it is being dried, all with proper allowance for the interference which substances with a high molecular weight, such as glue, will place in the path of the transference surface.

The capacity of any drier varies directly with the surface of material exposed to the drier atmosphere, so that it is important to see that the holding capacity is the maximum possible without interference with efficiency of heat transfer from drying atmosphere to water in the material being dried. For example, a loop drier should have the longest possible loops with the minimum distance between them.

Many drying operations must be carried on while the goods are being held in machines of a size necessarily limited and the expense of which, both as to first cost and maintenance, is high, such as a cotton or worsted tenter. Here the maximum capacity per unit of goods in the drier is needed, and consideration must be given to those things which give maximum evaporation per unit area and time.

It has been established definitely enough for practical purposes that the rate of drying varies directly with the velocity of the drying atmosphere at the surface of material being dried, where the rate of diffusion from the center to the surface is as rapid as the rate of evaporation. This is the case on such materials as cotton cloth. It is therefore good economy to deliver the drying atmosphere to the cloth in volumes up to the point where the cost of horsepower is greater than the gain from increased production, and so long as the delivery is so uniform that uniform drying is still obtained from edge to edge of the goods.

The variation of drying capacity with temperature is much more complicated. There are two temperatures which must be considered—one at which the drying atmosphere is delivered to the goods, the other that at which it leaves. Up to the point where the drying atmosphere leaves the goods at a temperature only enough above the boiling point of the liquid being evaporated to indicate that the liquid in the material is below the boiling point one rate of evaporation exists, and above this temperature quite a different rate obtains. The whole subject of variation of rate with variation of temperature under either constant or variable conditions of moisture is too large for even a brief discussion in this paper, but it will suffice to say that the rate continues to rise somewhere in the proportion of the wet-bulb depression in the first period, and as the mean temperature difference between drying atmosphere and the goods in the second. Therefore, for maximum capacity it is necessary to have maximum velocity and maximum obtainable and usable temperature,

---

[1] Treasurer, Andrews and Goodrich, Inc. Mem. A.S.M.E.

Presented at the Northern Textile Meeting, Boston, Mass., May 2, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

and from a further analysis of the tables of cost of operation of the starching range it will be noted that the reduction in cost of the operation exceeds the cost of steam within very small limits.

The large amount of steam used for drying makes a careful study of the thermal efficiency of a drier of great importance. The heat supplied may be distributed to evaporation of water, loss by radiation through drier walls, and loss by heating of air entering the drier. The different destinations need to be analyzed separately.

The latent heat of the water evaporated in the drier at atmospheric pressure is greater than the latent heat of the steam condensed at any pressure above zero pounds gage, so that a perfect drier would not be able to show a pound of water evaporated for a pound of steam condensed.

The loss by radiation can be reduced to a very small quantity by well-insulated housings, and while heavy insulation does not show a large return on the investment, in most cases it does produce sufficiently improved working conditions to warrant its installation.

The loss from heating new air is reduced by the use of higher temperatures until it reaches zero at a theoretical exit temperature of 212 deg. This is illustrated by the following table which gives the cost in steam for new air when the exit air from the drier is 25 per cent saturated and outside air is zero:

Temperature exit air	Expended for heating new air in pounds of steam per pound of water evaporated
100	3.38
140	2.00
180	1.26
200	0.93
220	0.84

From this table it is obvious that high thermal efficiency requires high temperature. When this drier temperature is carried still higher, it is quite evident that air is not necessary to the drying operation, for the application of heat is the only thing required for the conversion of a liquid into a vapor. That is, a drier can be built into which the material containing water or other liquid is placed, and into which heat is supplied, and from which only water vapor and dry material are removed.

Inasmuch as such a drier can most conveniently be maintained at atmospheric pressure, the theoretical temperature above which this form of drying takes place is 212 deg. fahr. The actual temperature is, however, somewhat above this. Therefore if a drying atmosphere which is superheated vapor diluted with leakage air is delivered to the material at a temperature of 300 deg. and is taken away at 260 deg., no other new air will be required, and the only expenditure of heat will be for evaporation, radiation, and the small loss caused by leakage.

It is possible to improve the thermal efficiency of can drying by enclosing the stacks in insulated houses so that the exit air may be maintained above the temperature of water vapor at atmospheric pressure, but the gain is apparently less than the cost of obtaining it, so that very little is being done along this line.

While temperatures as high as 300 deg. fahr. are not practicable on worsted cloths, the limits which have gained credence in that industry are much below perfectly practicable drier temperatures, and much higher economies may be had than are general practice in the woolen and worsted finishing.

For those classes of materials where diffusion of moisture to the surface becomes a determining factor it is of no avail to continue to carry surface evaporation to a point of dryness when the center is yet wet. Furthermore, the dry surface in itself becomes an insulator between the heat supply, which is the drying atmosphere, and the wet center. However, heat is the only means by which diffusion can be accelerated without vacuum, so that such materials require driers that are a combination of contact and air drying.

The determination of the relative capacities of different driers is a problem of some difficulty due to varying conditions of wetness both entering and leaving, and an expression of the capacity of a drier must take into account the ratio of water to dry stock, both at entrance and exit from the drier, for it is obvious that a given drier will evaporate a smaller number of pounds of water an hour from a material which is partially dry when it enters the drier than it will from a material which is very wet. Consequently, there is a curve of drying capacity in pounds of water per hour plotted against the ratio of water content to dry goods which is an expression of capacity of any drier, and its capacity can only be expressed by a simultaneous establishment of this ratio.

While the mechanical excellence of the drier is not a theoretical consideration, either of its operation or design, it is a feature which may outweigh the lack of proper recognition and proper application of theory.

A drier is a manufacturing unit. It must handle the goods efficiently without interruption or damage and with the minimum labor both for operation and maintenance. The materials which go into its construction must not deteriorate from vibration or heat. The housing must maintain its insulating value and its ability to prevent air leakage. It should be easily demountable for access to its mechanism or for re-erection in a different location. All bearings and drives must be designed to avoid bearing trouble or oil spots on goods, and all parts should be easily accessible from the inside.

When these considerations of mechanical excellence are combined with the theoretical dictates of efficient and rapid drying, the textile manufacturers and finishers will be operating with equipment that will keep the cost of the operation down to a minimum, and only then.

TEX-52-5

Present Status of Measuring Physical Properties of Textiles

By W. F. EDWARDS,[1] NEW YORK, N. Y.

PROCESSES of manufacturing yarns and fabrics from textile fibers in every part of the earth where silk, cotton, or wool was found were probably known before written recorded history, but there appears to be no record to indicate that the physical properties of these yarns and fabrics were defined up to very recent times. Quality was judged as a result of long experience which was passed along from father to son or from mother to daughter, and became more or less cumulative, and ripened and developed an experienced artisan who was jealous of his art and wished it retained within his family and its descendants as a more or less specialized and secret thing.

There was no motive for a knowledge of physical properties that could not be obtained by organoleptic tests such, for example, as getting a rough idea of strength by tactile and muscular senses, a method of guessing that has come down to the present time. This guessing of strength is of value in the hands of persons experienced in handling light yarns and fabrics for the purpose of roughly indicating relative strengths, but cannot result in safe numerical values. This condition of measuring physical properties of yarns and fabrics may be said without serious error to have continued without much improvement until the beginning of the present century notwithstanding that the processes of manufacturing textile yarns and fabrics had undergone profound changes, especially in regard to machinery and speed.

The two most common motives for measuring quantities or properties are those of detecting fraudulent practices and of determining factors of safety. The latter has been a prominent incentive to measuring physical properties of textile yarns and fabrics so as to give numerical values to the properties in terms of defined units in order that reliable comparisons can be made.

The factor-of-safety motive in the development of standardized tests on textile yarns and fabrics has been the means of developing tensile tests and other strength tests to a point where they may be considered reliable and sufficient for most practical purposes as a measure of the factor of safety of such mechanical fabrics, mostly made from cotton, as are used in the construction of automobile tires; rubber and fabric belting; rubber water, steam, and air hose; and a great variety of rubber goods whose strength is mainly dependent on cotton fabrics; bags for sugar, cement, fertilizers, and various other commercial products requiring bag-like containers; airplane cloth, bolting cloth, balloon cloth, etc.

Interest in this factor of safety became widespread and intense enough so that the American Society for Testing Materials in the year 1915 authorized a standing committee, D-13, on textile materials, notwithstanding that there were probably a majority of the members of the society who were not convinced that textile materials belonged in the scope of the activities of the society, i.e., it was not altogether clear to them that textile materials could be classed as engineering materials. The name of the society does not contain the word "engineering," but its charter states that: "The corporation is formed for the promotion of knowledge of engineering materials and the standardization of specifications and methods of testing."

Committee D-13 was organized at once and devoted its early efforts to the standardization of methods of testing which resulted, in the year 1915, in the publication of tentative general methods for testing cotton fabrics, which included thread count, weight, thickness, strength by both the strip and grab methods, (with illustrations showing how to cut the samples from the fabric), and gave a definition of moisture.

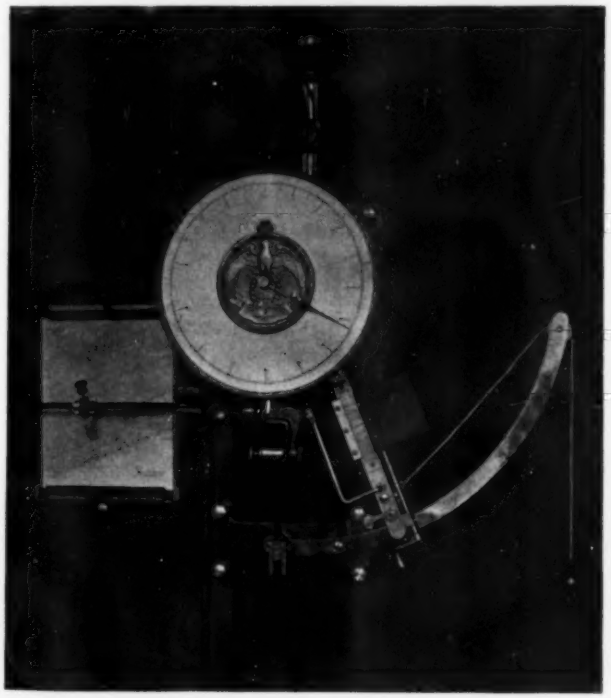

FIG. 1 HEAD, DIAL, RECORDER, AND SLIDING WEIGHT FOR WEIGHING DEVICE

This tentative standard was revised in 1916 and three tentative tests on cotton fabrics used for different purposes were published. The three new tentative tests were: (1) Tentative tests for automobile-tire fabrics, (2) tentative tests for cotton fabrics for use in hose, belting, and similar articles, and (3) tentative tests for cotton fabrics for use in bags and bagging material. These four tentative methods formed a very good starting point for comparisons. Tensile strength comparisons soon discovered many discrepancies that could not be accounted for by any probable variations in the samples used. It was found that samples from the same roll of very excellent fabrics would often give quite different tensile strengths in different laboratories or even in the same laboratory on the same machine.

These discrepancies led to investigations at the Bureau of

[1] Director of the Laboratories, United States Testing Company, Inc.

Presented at the Northern Textile Meeting, Boston, Mass., May 2, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Standards at Washington, D. C., the Massachusetts Institute of Technology, and various other places, and resulted in a number of published reports which in turn led to further investigation and other published reports. It was shown that machines of the same type and different capacities might give discordant results if tests resulted in values coming outside of certain limited ranges of values for two different machines; that speed of separation of jaws on the same machine resulted in different values for the test; that the length of specimen between jaws at starting made a difference in the results obtained; that the moisture content of the specimen affected the results obtained to a very considerable extent; that tests made by the strip method could not be compared with results of the grab method; that tests made by a grab method with one-inch jaws could not be compared with tests

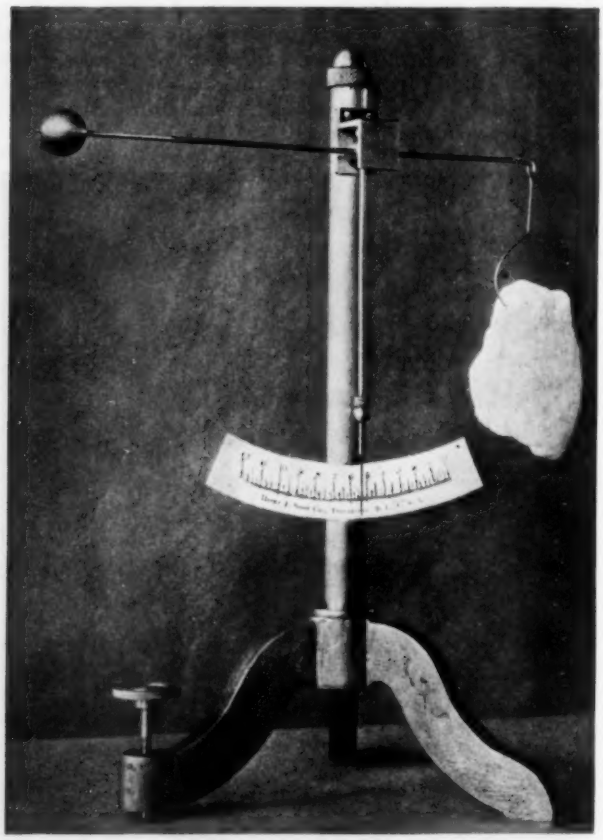

FIG. 2 SAMPLE ON WEIGHING DEVICE

made by the grab method with one- by two-inch jaws, and other less harmful discrepancies were found.

A study of these discrepancies in the tensile-strength tests resulted in the adoption of standard general methods of testing cotton fabrics in 1920, and in a proposed tentative standard specification for textile testing machines also in 1920. The first was adopted after two revisions in 1927 with its name changed to "Standard General Methods of Testing Woven Textile Fabrics." It had been found that the methods used for cotton woven fabrics were quite generally satisfactory for practical purposes when applied to other woven textile fabrics. The second was also adopted in 1927 in a somewhat revised form. Meanwhile, the three tentative tests for cotton fabrics used in automobile tires, in hose and belting, and in bags and bagging material were apparently forgotten, but some twenty or more other standards either as proposed tentative standards or adopted standards had been published embracing a variety of textile materials as indicated by the titles, a few of which follow as illustrative, including two or three published later than 1927: "Standard Specifications for Tolerances and Test Methods," (*a*) for cotton yarns, single and plied, (*b*) for electrical cotton yarns, (*c*) for cotton sewing threads, (*d*) for 23/5/3 carded American tire cord, (*e*) for electrical silk and cotton tapes, (*f*) for asbestos yarns. "Tentative Standard Specifications for Tolerances and Test Methods," (*a*) for rayon, (*b*) for knit goods, (*c*) for Cuban (jute) sugar bags, and (*d*) for asbestos tape for electrical purposes.

These standards and tentative standards indicate that much had been done to give confidence in standardized tests on textile materials, but the practice of using them as a part of the specification in buying and selling contracts was not so general as one could wish. There are several possible partial explanations for the lack of use of these standards, a few of which may be worth brief discussion as throwing light on the present status of measuring physical properties of textiles.

The usual inertia in taking on new ways is doubtless one partial explanation which in this case is emphasized by the fact that many laboratories in the larger units of the industries had been using methods of their own for several years, and had accumulated data that were working out well enough so that naturally there was hesitation to go over to a standardized method the relation of the numerical results of which, to those with which they were familiar, were unknown. How far-reaching this could be is well illustrated by a manufacturer who makes large quantities of a mechanical cotton fabric. He complained that he was selling and manufacturing this fabric to 14 specifications more or less alike, but the relations of which were not well enough known, but that he felt that he must fortify himself by making a portion of the tests for each of the specifications in a somewhat modified way. That the specifications usually involve tensile-strength tests is another quite probable partial explanation of sufficient importance to require further elucidation.

The most troublesome condition of the tensile-strength test on textile yarns and fabrics is the standard moisture condition of the samples at the time of test. This moisture condition must be the same in the buyer and seller laboratories if concordant results are to be obtained. A sample of cotton fabric, for example, tested under ordinary atmospheric conditions on a humid day in a Southern mill in winter may show in the buyer's Chicago laboratory on a cold winter morning a variation of 10 to 40 or even more per cent. The Southern mill laboratory may show a result higher than would be found under the standard moisture condition and the Chicago laboratory might show a result much lower than would be found under standard moisture conditions.

The most common way to produce the standard moisture content is that of exposing the samples from one to four hours, depending on the character of the samples, in a standard atmosphere. The production and maintenance of this standard atmosphere at a reasonable cost in a room large enough to be used as a testing laboratory has been considered by many as prohibitive. Four substitutes have been proposed for the testing room with constant standard atmosphere, but so far no one of them has attained a confidence that has led to its substitution for the test in a room with standard atmosphere for practical purposes.

One substitute method is that of making the tensile-strength test in a comparatively small cabinet in which both the test samples and the testing machine are placed. The operator manipulates the samples and machine by suitable devices from the outside. This method has been perfected to a point such that it is very competent for experimental purposes, but is not practical for mills or laboratories making a large number of routine tests daily.

A second substitute method is that of making the tensile-

strength test on the sample "as is," drying the sample immediately to determine its actual moisture content at the time of the test, and computing by correction formulas the strength of the sample for its condition in equilibrium with the standard atmosphere. Correction formulas have been worked out for a variety of cotton fabrics, but so far do not seem to have gained sufficient following to be brought into general use.

A third substitute method is that of making the tensile tests on all yarns and fabrics in a completely dry state. This seems very simple, but when put into operation it is discovered that it is very difficult to take the dried sample from the drying oven, place it in the jaws of the machine, and make the break without a considerable regain of moisture during the test. It also leads to undue haste in placing the samples in the jaws of the machine which may lead to improper results. A fourth substitute method is that of making the tensile tests on all yarns and fabrics in a completely wet state. This is easy to carry out, but so far there is not enough data to show that it is practical.

Still another partial explanation is the quest for better methods, i.e., more fool-proof or more scientific and accurate methods than those of the proposed standard methods; for example, the variability and magnitude of the stretchiness of textile yarns and fabrics have caused some investigators to go in quest of some better method than the constant speed of separation of jaws because they find that constant speed of separation of jaws is not fool-proof and subject, therefore, to considerable variation. They believe, apparently, that a constant rate of loading is more fool-proof and more scientific in that two fabrics having quite different stretchiness but the same ultimate strength could be brought to the break in the same time by means of a constant-loading device. Some very ingenious devices have been brought out (some with autographic charts) in which a constant flow of water or fine shot constitutes the constant rate of loading. These machines have been used successfully for experimental purposes, but so far the author is not aware of adequate data to show that they are more fool-proof or more scientific than the dead-weight pendulum type of machine with constant rate of separation of jaws as described in the Standards.

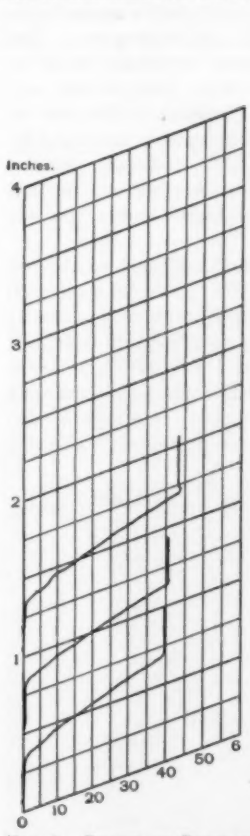

FIG. 3 CHART OF STRETCH IN BREAKING THREE SAMPLES—STRETCH RATIO 4 TO 1

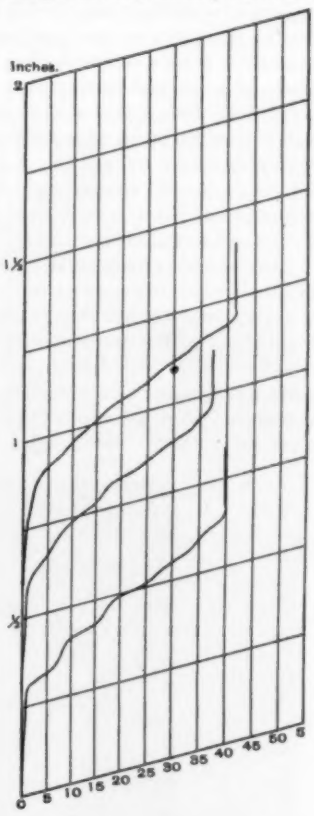

FIG. 4 CHART OF STRETCH WITH RATIO OF 2 TO 1

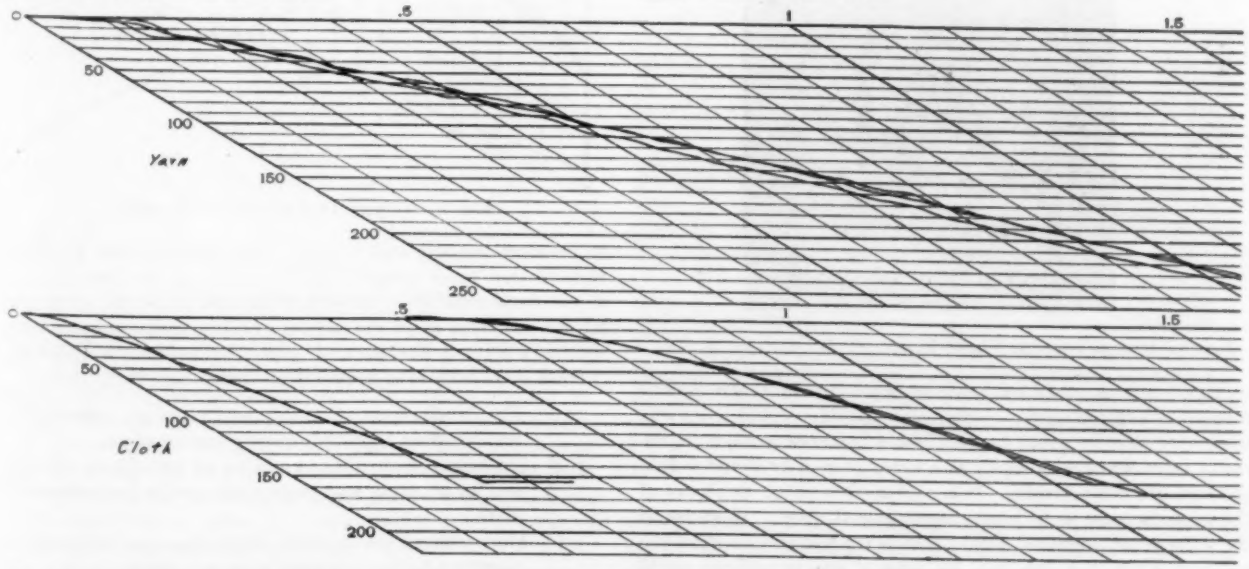

FIG. 5 ABOVE, TEST OF 28 COTTON YARN WITH STRETCH RATIO 10 TO 1—BELOW, TEST OF CLOSE-WOVEN COTTON FABRIC WITH VERY LITTLE STRETCH

Ballistic types of machines have also been proposed, designed, and tried out in a hope of more scientific and more accurate results. The data are not sufficient to warrant an opinion of their value in practical testing. It is desirable always to be looking for more fool-proof and more scientific methods, but such a quest should not stand in the way of using what has already been developed to a worth-while use. The author believes that the deadweight pendulum type of machine has now reached a state of perfection that warrants its very wide use in the textile indus-

tries. The errors due to operator and machine should not be greater than the variations in the materials to be tested or to errors due to the determination of the standard atmosphere.

Lack of confidence may be due also to impossible requirements due to ignorance of the complexity of the requirement. The busy-body groups, of which there is a large oversupply, think in terms of price and performance too much. Performance is a word that often covers a wide range of related factors each of which must be taken separately in the laboratory, and the relation established by continued and wide experience. All are interested in performance tests that are adequate and not too complicated, but the experienced laboratorian knows the difficulty of finding them.

Overconfidence may be as great a stumbling block to the use of standardized tests as lack of confidence. There are some with the very best of intention toward bringing about systematic buying and selling under specification and laboratory tests, but who have more zeal than knowledge, and who have had disappointing experiences due to ignorance and become active retarding influences. A single case will illustrate this. A certain woolen cloth for uniforms was bought on a specification in which too much stress was placed on tensile strength leading to disappointment in the price quoted. Any manufacturer could have told the buyer that he could furnish him a better wearing and generally more serviceable cloth at a lower price if he would reduce the strength requirement. It is perhaps too much to expect of the manufacturer as he might lose a sale thereby. However, if the seller (manufacturer) would always try honestly to show the buyer in a nice but firm way his error, a step in advance could easily be made.

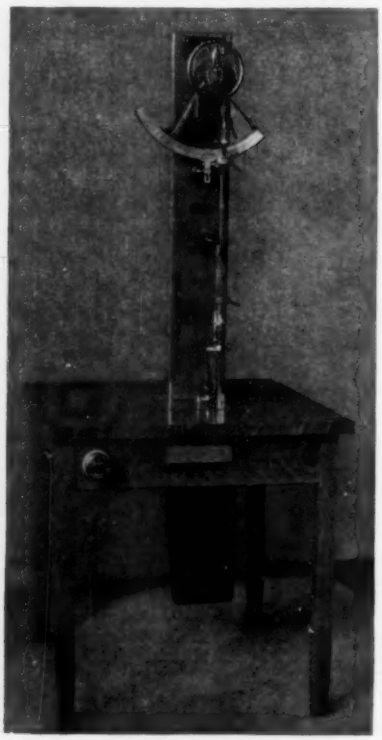

FIG. 6 MOTOR-DRIVEN, TABLE-MODEL SINGLE-STRAND TESTER

The art of the application and interpretation of the results of the measurement of the physical properties of textile yarns, threads, and fabrics with reference to their various uses, is to a great extent in its infancy. There seems to be a rapidly growing understanding that an intelligent try-out in practice is an essential safeguard to every interpretation. It may appear to some that undue emphasis has been placed on tensile-strength tests and standard atmosphere, and determinations of weight, width, thread count, twist in yarns, etc., have been forgotten. This has been done purposely as these latter tests seem to be in a fairly satisfactory state, their moot points in general having been due

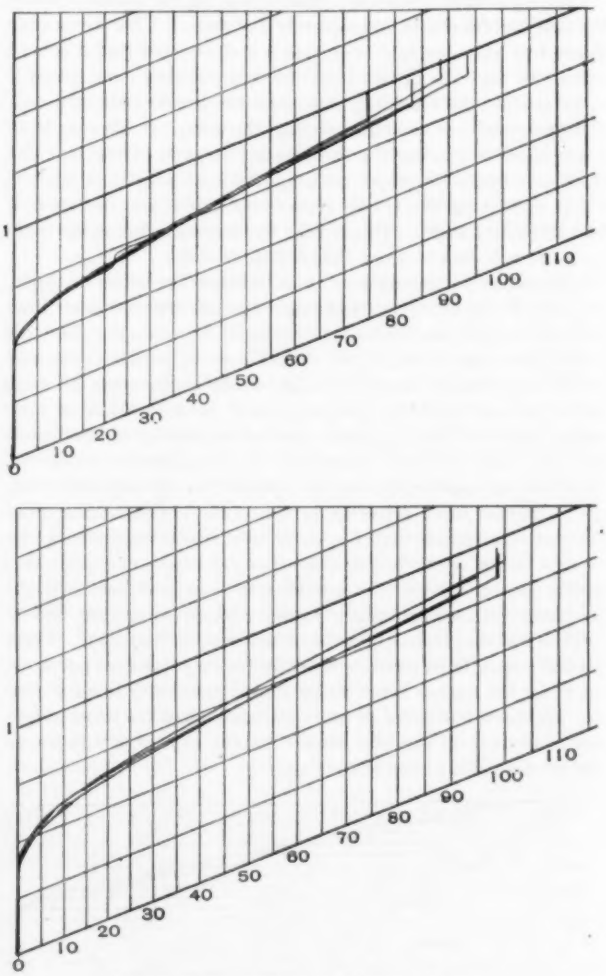

FIG. 7 REPEAT TEST OF MEDIUM FABRIC

to moisture content and stretch. The main purpose has been to show that much progress has been made in the last 15 years in the measurement of physical properties of textile yarns and fabrics, and that all of the ordinary routine measurements have reached a state to warrant their every-day use with confidence.

Some good fields of endeavor in the immediate future are:

- *A* The development of a standard constant temperature and constant relative humidity testing room
- *B* Investigations looking to making all tests in any room in an "as is" state and computing results for a standard state
- *C* More general use of stress-strain diagrams with special reference to their interpretation and use
- *D* Studies to determine the relative merits of the single strand, lea-and-strip tests for the determination of the average strength of yarns
- *E* Further study of the "ballburst" test and the interpretation and application of the results

F Further study of wear tests with reference to standardization of a machine and method of test

G Further study of the folding test, essentially as applied to paper, to determine whether it has a real utility value when applied to fabrics for certain purposes

H Investigations as to the possibility of grading textile fibers by physical measurements independently of organoleptic methods.

The dehumidifying at a reasonable cost has been the most problematical part of the constant-temperature and constant-relative-humidity room up to very recent times. Dehumidifying

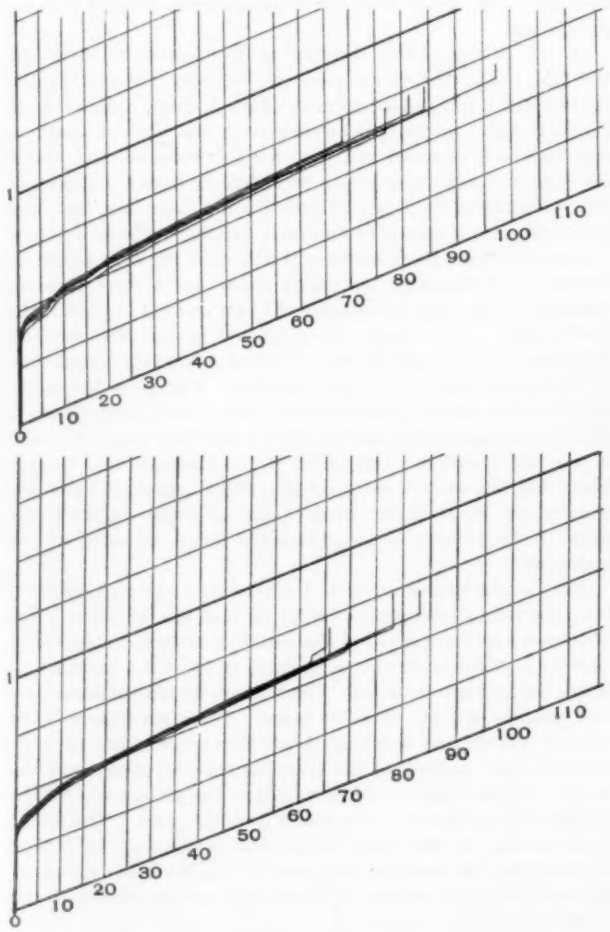

Fig. 8 Repeat Test of Light Fabric

can now be done by use of some of the cooling systems such as are used in meat shops in connection with the humidifying and temperature equipments usually found in laboratories for increasing the humidity and temperature in the winter season, at a reasonable cost for laboratories making large numbers of tests. It is desirable to have a standardized equipment worked out for rooms of various sizes to accommodate a fairly uniform number of workmen. The main requirement for the room is cork-lined walls and properly protected doorways.

The A.S.T.M. standard specification for tolerances and test methods for cotton yarns, single and plied, adopted in 1927, gives a method of determining the tensile strength of the yarn in the "as is" condition and a correction formula for computing the strength under standard conditions. It is based on the experience that regain on these yarns is under ordinary conditions of the atmosphere somewhere between $3^1/_2$ per cent and 7 per cent, the latter being that found for standard atmosphere, and the experience that the tensile strength at any regain up to, say, 10 to 12 per cent is the tensile strength in the dry state increased 6 per cent for each per cent regain found at the time of test.

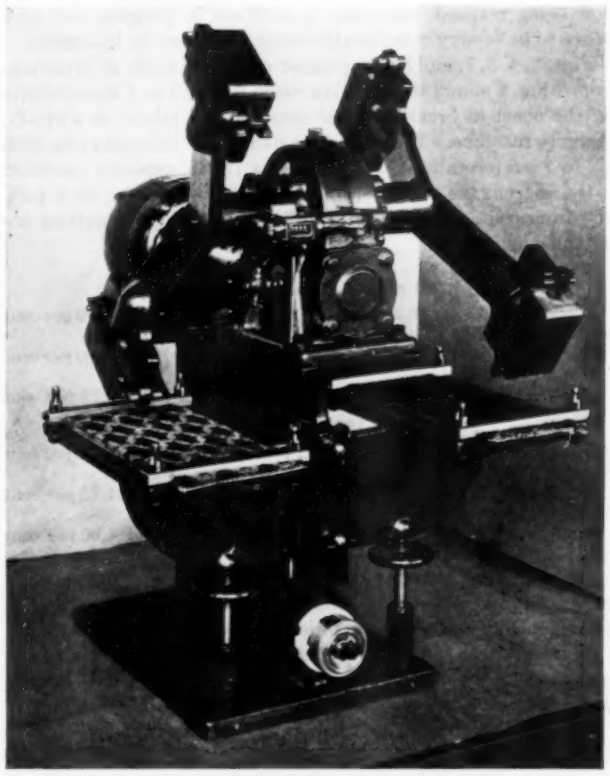

Fig. 9 High-Pile Machine With Samples of a Pile Fabric in Place

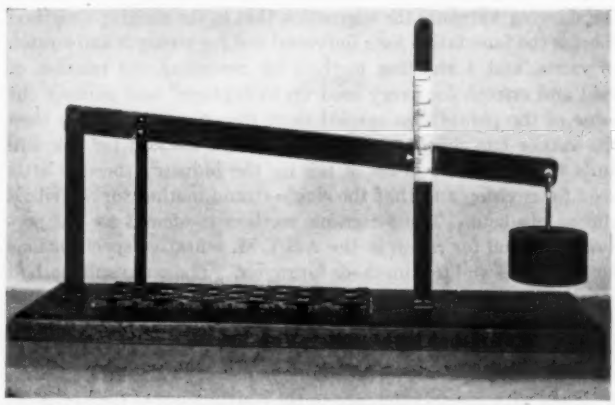

Fig. 10 Device for Setting High-Pile Machine

A machine and regain weighing device are now being placed on the market that do away with the drying operation and furnish the corrected reading directly from the dial of the machine. Fig. 1 shows the head, dial, recorder, and the sliding weight which is set according to the regain of the standard sample shown on the weighing device in Fig. 2. The stress-strain relation in the tensile-strength test on textiles warrants further investigation. From time to time the author has published items accompanied

by stress-strain curves to show that in yarns there is a considerable variation in this relation for different kinds of yarns as well as for different moisture content, twist, etc., in yarns from the same kind of textile fibers. These items and curves have been only suggestive of future work and are in no instance conclusive. The possible value of this relation in both yarns and fabrics is now being realized, and some studies are in progress that may prove to be of very considerable value to the textile industries.

Figs. 3, 4, 5, 7, and 8 may suggest some new fields of investigation. Fig. 3 shows three curves made with a 4 to 1 stretch ratio on the chart in breaking three samples of a fabric on a 110-lb. capacity machine. Fig. 4 shows a like test of three samples with a 2 to 1 stretch ratio on the chart on a 150-lb. capacity machine.

Going from the zero position and from the start to show pull, and from 5 lb. pull to 30 lb. pull in each curve, elongations are obtained as follows:

4 to 1 ratio, 110-lb. machine—Fig. 3

0 to 30-lb. pull....	17.25 per cent, 19.00 per cent, and 17.00 per cent
Start of pull to 30-lb. pull.....	14.00 per cent, 16.50 per cent, and 15.00 per cent
5-lb. pull to 30-lb. pull.....	7.25 per cent, 7.50 per cent, and 6.75 per cent

2 to 1 ratio, 150-lb. machine—Fig. 4

0 to 30-lb. pull....	18.00 per cent, 17.50 per cent, and 17.00 per cent
Start of pull to 30-lb. pull.....	12.00 per cent, 12.00 per cent, and 11.75 per cent
5-lb. pull to 30-lb. pull.....	7.00 per cent, 6.50 per cent, and 7.00 per cent

An analysis of such percentage in enough samples might suggest some changes in weaving, etc., for certain purposes requiring prominence of certain characteristics.

Fig. 5 is a test with a 10-to-1 stretch ratio on a 28 cotton yarn, and on a close-woven cotton fabric with very little stretch. The yarn curves are now shown complete.

At the March meeting of Committee D-13 of the A.S.T.M. in 1926, the author read a paper on a "Universal Tensile Test for Yarns" (published in the April 3, 1926, number of the *Textile World*) in which comparisons were given of a number of tests on silk, wool, cotton, and linen yarns by the single-strand, lea-and strip (serigraph) methods and stated in conclusion, "On the whole, the showing warrants the suggestion that in the serigraph method there is the foundation for a universal test for strength and stretch of yarns, and a charting method for recording the relation of load and stretch for every load up to rupture" and pointed out some of the points that needed more investigation. Since then the author has checked over the serigraph method for silk and finds that after five years of use by the industry there is little need for revision and that the single-strand method for raw silk is almost obsolete. The serigraph method is offered as the preferred method for rayon in the A.S.T.M. tentative specifications for tolerances and test methods for rayon. The serigraph method can be used to advantage for the finer sizes of spun yarns but there are insufficient data to warrant its adoption as a standard for all spun yarns.

An interesting motor-driven table model of single-strand tester, designed with special reference to the convenience of the operator, has recently come on the market. It is a double-capacity machine, 0–2 and 0–10 lb. capacity, and has as novel features, (1) an arrangement of the pointer so that the scale for the capacity used is the only one that can be read; (2) stretch indicator is carried only to point of break; (3) resets for next test by pushing reverse button. It is shown in Fig. 6.

W. H. Whitcomb, chairman of Committee D-13, A.S.T.M., at the March, 1928, meeting of the committee, read a paper on a ball-burst test apparatus which was described as an attachment for the vertical type of inclination-balance strength-testing machine. Data were given to show the probable value of the test in routine and research testing. Since that time further investigations have been carried on which show that a curve showing stress-strain relations may be of value. Figs. 7 and 8 show repeat curves on different samples of the same goods which are remarkably the same though the bursting strength is somewhat different for the different samples. The author understands that the ball-burst test apparatus is soon to be placed on the market as a full-fledged machine to do away with the inconvenience of using it as an attachment.

At the Spring, 1926, meeting of Committee D-13 of the A.S.T.M. the author read a paper on "Wearing Tests on Textile Fabrics which was published in the June 5, 1926, number of the *Textile World*. In this paper were given a few types of machines that had been designed and used for this purpose, and also a description of a machine which had been developed and used in the laboratory of the United States Testing Company, Inc., and gave some data to indicate its value in making comparative tests.

Since that time, Professor Geo. B. Haven of the Massachusetts Institute of Technology has read a paper on "A New Abrasion Machine" at the 1929 fall meeting of Committee D-13, A.S.T.M., at Providence and which was published in the November 2, 1929, issue of the *Textile World*. The paper was very complete as to description and use of the machine. The most important feature in the author's judgment is a device for making the speed of the abrading element uniform over a sufficient length to make it possible to examine the effect of the abrasion over enough fabric that has had the same rubbing effect (speed) to make the examination satisfactory, whereas in the usual reciprocating-stroke method there is no measurable length abraded at the same speed.

Recently the laboratory of the United States Testing Company, Inc., has been developing a carpet or high-pile abrasion tester which has a uniform speed of the abrading surface. A universal machine is planned on the same lines, but so far a satisfactory design has not been obtained. Fig. 9 shows the high-pile machine with samples of a pile fabric in place. The main feature is the circular motion and a spring device for keeping the pressure approximately uniform as the abrading element passes over the fabric. It was found advisable to adjust the platens so that the rubbers worked firmly on the fabric from the start. The device shown in Fig. 10 was finally adopted as satisfactory for setting the machine, the machine being set for the thickness shown on the scale when the pressure of about 30 lb. per sq. in. due to the weight is applied.

There have been a number of devices for determining the power to withstand flexure, such as that of a fabric belt running over pulleys which, like the folding test, are essentially fatigue tests, but so far there is no standardized test for textiles. It seems that there is here a hopeful field for future studies leading to standardized tests. The paper industry has standardized a folding test for certain types of papers. Perhaps the textile industries can profit from its experience.

On the whole, as such undertakings usually go, the textile industries have made a very creditable showing in the last 15 years in the measurement of the physical properties of textiles, and the standardized application of these measures for practical purposes in the industries.

Progress in the Wood Industries

Contributed by the Wood Industries Division

Executive Committee: Wm. Braid White, *Chairman*, Chester L. Babcock, *Secretary*, James S. Mathewson, Thos. D. Perry, and A. S. Kurkjian

SUBSTANTIAL progress throughout American woodworking and wood-using industries may be reported for 1929 in all technical and commercial aspects. Thus, in the field of woodworking machinery we find a still stronger tendency toward the use of individually motorized machines. Moreover electric current as the power source has now become so common a feature of woodworking factories as no longer to call for special comment. This again is leading to the general adoption of a standard of current, in this case alternating, at 60 cycles.

Power

There is also arising a tendency to employ Diesel engines for driving electric generators. Steam plants for generating current are adopting automatic shavings-feeding apparatus for the boilers. Better methods of burning waste wood are coming steadily into use, while at the same time there is a definite tendency to explore the use of what is known as "wood flour" (pulverized wood refuse) for fuel.

In certain plants the idea of sequential operation has been carried out to considerable lengths, especially in the upper Mississippi River district. In cutting departments of sash-and-door and similar plants, conveyor machinery is being installed for handling materials and advancing assemblies.

Short-length lumber is becoming sufficiently important to justify the construction and use of special machinery for using it in manufacture. A foreign-made gang saw has been introduced with some success for cutting small logs which hitherto have been left in the woods owing to the lack of any practical method of dealing with them.

Another interesting new machine is the electric-driven 4-in. molder, which is lighter and more convenient than other machines hitherto commonly used, and which is especially appropriate because of the fact that the greater quantity of all wood molding used is less than 4 in. wide.

Automatic ejectors for use with wood-turning lathes, to eject the finished stock, are being used. High-speed motorized machines are being fitted with automatic electric stopping brakes for cutterheads.

Other electric machinery recently coming into use includes the 2–4-pole motor, or two motors in one, which can be run at extremely high speeds, as high in fact as 9000 r.p.m. with 150-cycle current, and with a minimum speed of 4500 r.p.m.

An automatic clip saw for cross-cutting, which insures greater safety and higher speed, is also coming into use. So is an automatic shaping machine of the rotary-table type. So also is a "wood stamping" machine which simultaneously bores and embosses carved work through a hot-press process. This is being used on plywood work.

Lumber

The grade marking of lumber is becoming a regular practice, and by degrees the consuming trades are coming to demand this additional security, although so far only on softwoods. Hardwood grade marking is being heard of, but is as yet a matter of discussion rather than of practice.

There has been a great increase in the use of "wood flour" for the manufacture of bakelite and similar composite materials. The use of end-matched lumber is undoubtedly increasing. Plywood shows constantly widening uses, in the sash-and-door and the radio-cabinet fields. Radio cabinets have afforded the largest single outlet for plywood construction during the year, and some factories are demanding stock for outputs at the rate of thousands of sets daily.

Research

The search for a perfectly water-resistant glue still goes on. The Forest Products Laboratory of the U. S. Forestry Service continues to do work of the highest grade in this investigation. It has been shown that under certain conditions and within certain limits, animal glue may be made water-resistant to an extent that is useful if not complete.

Researches in the following fields are being actively carried on at the Forest Products Laboratory:

1. Determination and classification of characteristic defects of different wood species from different regions
2. Determination of differences of density in woods of different species
3. Survey of moisture content in softwoods
4. Study of standard measurements of the inflammability of wood to determine the fire-resisting properties of different species
5. Study of better methods of finishing wood
6. Study of the effect of grain direction upon the quality of glued plywood panels
7. Study of the strength of various wood sections, mainly for aeronautical purposes
8. Study of the holding power of various types of nails and screws.

A.S.M.E. Committees

The research committees appointed by the Society at the request of the Wood Industries Division have been carrying on their investigations with fruitful results. The Spark Arrester Research Committee has already made certain practical recommendations as to the design and construction of spark-arresting apparatus for use with steam and internal-combustion engines working in woods and forests. Tests in accordance with these recommendations are to be made on spark-arresting apparatus in the near future, by the Oregon State Agricultural College.

The Research Committee on Saws and Knives has pursued its course. The interest, and to some extent the collaboration, of the manufacturers of saws and machine knives is being secured, and the Committee expects to carry on its work to a fruitful end.

Meanwhile the New York State School of Forestry is giving courses in the utilization of wood. Work is being done on better methods for applying preservatives to wood, and a process of pretreating and finishing wood has been announced which, among other things, will permit the laying of floors ready finished.

Merchandising Study

In general, the whole question of more scientific methods of merchandising lumber, and wood products generally, is being studied. Wood is today compelled to withstand the competition of many materials offered as substitutes for it. The problem of

selling wood products therefore becomes more and more obviously one of scientific preparation and planning. The lumber associations, the societies of manufacturers, and other bodies are giving an attention to these matters which is not the less welcome for having been so long delayed.

Miscellaneous

Among the various interesting activities in the woodworking field may be noted the practice of shipping furniture in plywood boxes instead of in crates; the enormous increase in the use of plywood for the construction of radio cabinets; the gradual but steady transformation of the so-called "sash-and-door" factory into a plant manufacturing all kinds of builders' woodwork; and the general, though gradual, alignment of the wood industries with their younger rivals in their attitude toward the public and toward each other.

The excellent book "Wood Construction," by the Assistant Director of the National Committee on Wood Utilization, Department of Commerce, should be signalized as one of the important features of the year in our field. This is by all odds the best work of its kind which has yet appeared, and should be in the hands of every practical woodworking engineer.

Those, and they are not a few, who still think of the woodworking industries in terms of carpentry and the portable lumber mill, are invited to read the report of fifty years' progress in these industries which forms part of the Society's proceedings for the jubilee year. Today, one may fairly affirm, in machinery, in methods, in accuracy, and in speed, the wood industries can compare favorably with any of the mechanical-engineering branches. It is extremely unfortunate that technical schools and colleges have not long since recognized the evolution of woodworking methods; but for this neglect on their part, which has led to a dearth of trained wood engineers, the industries are themselves mostly to blame. Engineers will tend of course always to go into those fields which show themselves attractive. Only within the last few years has the great importance of wood engineering come to be recognized in any part. For speeding this recognition the Division feels that it may justly claim some credit.

Work of the Division

During the year now past, the Wood Industries Division has been active. Its national meeting at Rockford, Illinois, in October, was the most successful it has yet held. The Division is not unmindful of the fact that, small in numbers as it was and remains, it was the first of the Professional Divisions to hold a national meeting after the decision to allow such meetings had been announced. It has since that time held them regularly each year.

Wood engineering now takes its place as one of the definitely recognized branches of the mechanical-engineering profession. The Wood Industries Division of the Society is pledged to deepen and intensify this recognition. The present writer has been honored by his colleagues with the chairmanship of the Division for four successive years. In retiring from it, at the expiration of his term as a member of the Executive Committee, he believes he can claim to have seen each year a general improvement of woodworking engineering along lines both technical and commercial.

William Braid White, *Chairman.*

Modern Method of Manufacturing Classical Furniture

By HARRY KIMP,[1] LONG ISLAND, NEW YORK

Modern methods of manufacturing classical furniture eliminate nearly all hand operations. They are simplified by the use of the "rod" drawn on basswood to full size, from which measurements are taken by workmen for the construction of each piece of a suit. In this paper the author describes a process for preparing and drying lumber through various machine operations from the start to the completed furniture, preparatory to shipment.

CLASSICAL furniture is a high-grade type decorated to conform with the various style names such as Chippendale, Queen Anne, William and Mary, etc. It is, therefore,

Fig. 1 Cabinet of Ornamented Design

usually special in design and must harmonize with surrounding decorations. In spite of these limitations in some cases it can be made in fairly large quantities. Manufacturing plants for furniture are usually located in congested districts or in large cities since the demand for the product is greatest there. In New York City, there are more plants of this kind than in any other section. In the old days beautiful furniture was hand made, but now mass production has changed matters, and use of modern mechanical equipment eliminates hand work, excepting some hand carving, sanding, and assembly operations.

The personnel of a modern classical-furniture manufacturing plant now includes artisans in design, chemists for wood preparation and finishing, machine mechanics, cabinet makers, hand carvers, veneer laminators, competent production engineers for systemizing the highly developed productive machinery, and others.

As many of the designs (Fig. 1) include ornamentation that cannot be dimensioned on drawings conveniently, it is the practice to draw the designs to full scale on thin basswood. These sheets are called rods and usually include three compact diagrams to show the piece in plan, side elevation, and end views. The rod is thus a long narrow board with the design drawn in pencil, after which it is shellacked.

Fig. 2 shows such a rod. The designs are sketched to full scale by designers and draftsmen to determine the relative proportions and intricate details of the design. They include turnings, carved ornamentation, profiles of moldings, etc. Drawings of this type also include the complete interior assembly or construction of the entire individual design.

Basswood is used instead of paper for the material on which designs are made. Paper expands and contracts with varying weather conditions, and since dimensions are scaled directly from the rod accurate measurements are essential. Paper also has the disadvantages of tearing, the lines disappear with use, and handling operations are more difficult. Information is given to

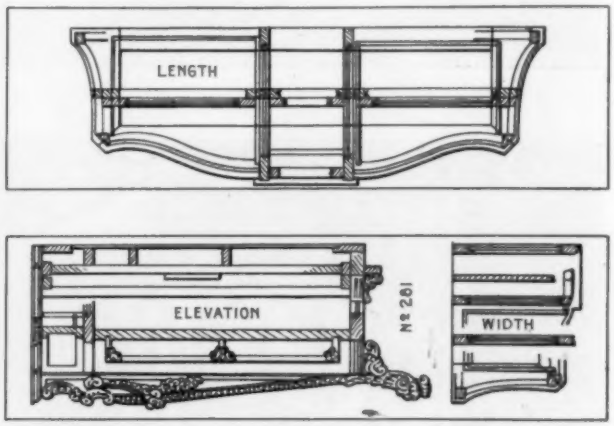

Fig. 2 The "Rod" Is a Board With Design Drawn in Pencil

the cutting department by means of stock sheets. These have a complete listing of material and sizes as obtained from the rod. The stock sheet accompanies cut stock through the machine departments; in some instances the information is transferred to stock tags, blue prints, or similar forms.

Lumber is unloaded from freight cars on to dry-kiln trucks, which pass through a steam-heated kiln, to reduce the moisture content to approximately 5 per cent. This is an important factor for producing workable material. Dried lumber is taken from the kiln into temper rooms where it gradually reaches normal temperatures. In the larger plants lumber lifts are used to facilitate handling. The stock is first cut on a cut-off saw to approximate lengths as listed on the stock sheets. It is then ripped on a chain-feed straight-line rip saw (Fig. 3) which cuts out defects and in the same operation makes the joint for gluing as used for cores, for veneered panels, and in some cases for solid tops. In some cases where the stock is long, it becomes twisted in drying. Then if used for library-table tops, etc., a tongue-and-groove joint is made to insure proper alignment, and to obtain the maximum finished thickness. As very few long tops are made the in-

---

[1] Designer, Chesterfield Furniture Company.

Contributed by the Wood Industries Division and presented at the Annual Meeting, New York, N. Y., Dec. 2 to 6, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

stallation of a continuous-feed glue jointer is not warranted so the jointing operation is usually performed on a hand jointer.

In a modern plant with good dry kilns stock is dried straight, and when cut in lengths of 5 ft. and less, it is not necessary to face it on a jointer feeder. After the cores have been glued in a clamp carrier (Fig. 4) they are run through a jointer feeder (Fig. 5) to remove the glue, and take out wind preparatory to the finished surface-planing operation which reduces them to the required thickness.

The beautifully figured veneer used in classical furniture is very expensive. It is cut from flitch stock by veneer cutters to about 0.28 in. in thickness, and when received by the furniture manufacturer contains from 10 to 12 per cent moisture which must be reduced slowly by a veneer re-dryer (Fig. 6) to about 5 per cent to prevent cracking or splitting. This veneer is matched and cut on a veneer cutter which is the same type of machine used for paper cutting. The matched pieces are then drawn very closely together, and are taped by a veneer taping machine which makes perfect joints.

Animal or hot glue is mixed in a container. This drains into a glue spreader which consists of two rollers rotating in a reservoir of glue. The face veneer is not run through these rollers, but the under-veneer or cross-banding which is usually of rotary-cut poplar is glued on both sides by the rollers, and this eliminates the necessity of gluing either the face veneer or the core. One or several cores, with cross-banding and veneer applied are placed in a heavy hydraulic press which eliminates all surplus glue and air pockets, and causes the glue to adhere perfectly. The panels remain in the press long enough for the glue to set, and then they are removed and placed in a dry room where the moisture absorbed by gluing is removed. They are then taken out and trimmed to finished size.

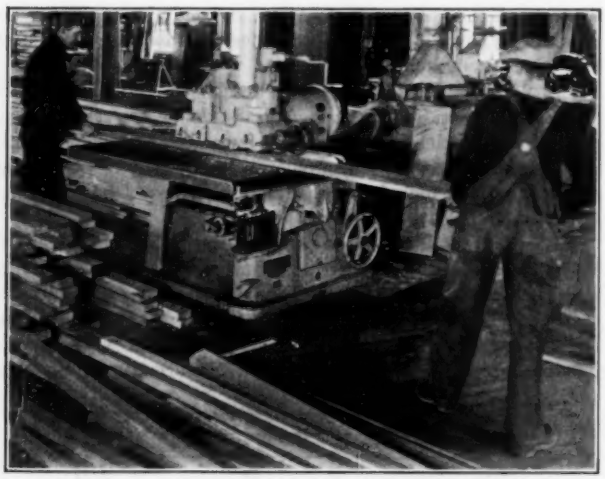

FIG. 3 MOTOR-DRIVEN CHAIN-FEED RIP SAW

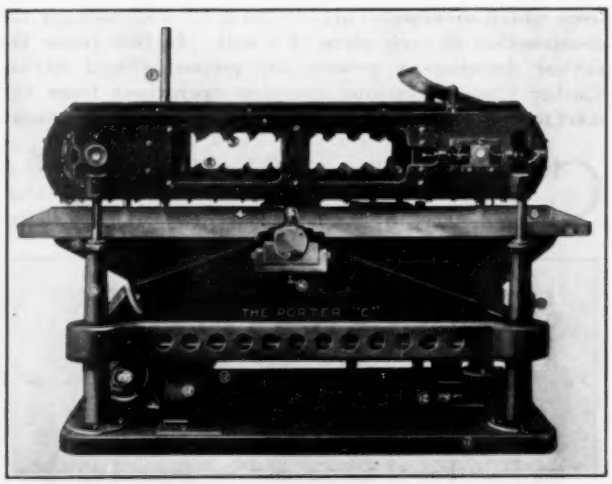

FIG. 5 PORTER TYPE CM FACING PLANER

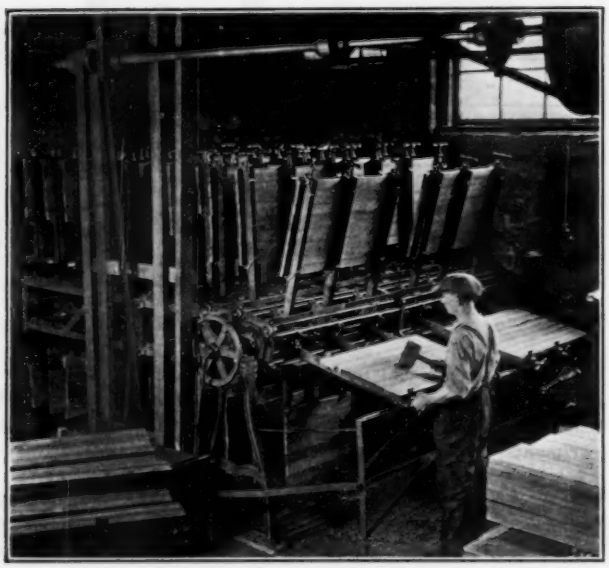

FIG. 4 GLUE-CLAMP CARRIER WITH TWENTY-NINE SECTIONS

FIG. 6 CONTINUOUS-ROLLER VENEER RE-DRYER

Band saws (Fig. 7) are used for sawing the irregular shapes of which there are many, and double-spindle shapers (Fig. 9) are used for molding these irregular shapes. On this type of furniture with its irregular shapes, there are no mortise-and-tenon joints as dowels are used to better advantage. Therefore, both horizontal and vertical single- and multiple-boring machines are used.

Most of the legs for this furniture are polygonal in shape and the automatic shaping lathe (Fig. 8) is used. This machine has cutters revolving at 3000 r.p.m. in approximately a 14-in. circle while the stock to be shaped or turned revolves very slowly. This

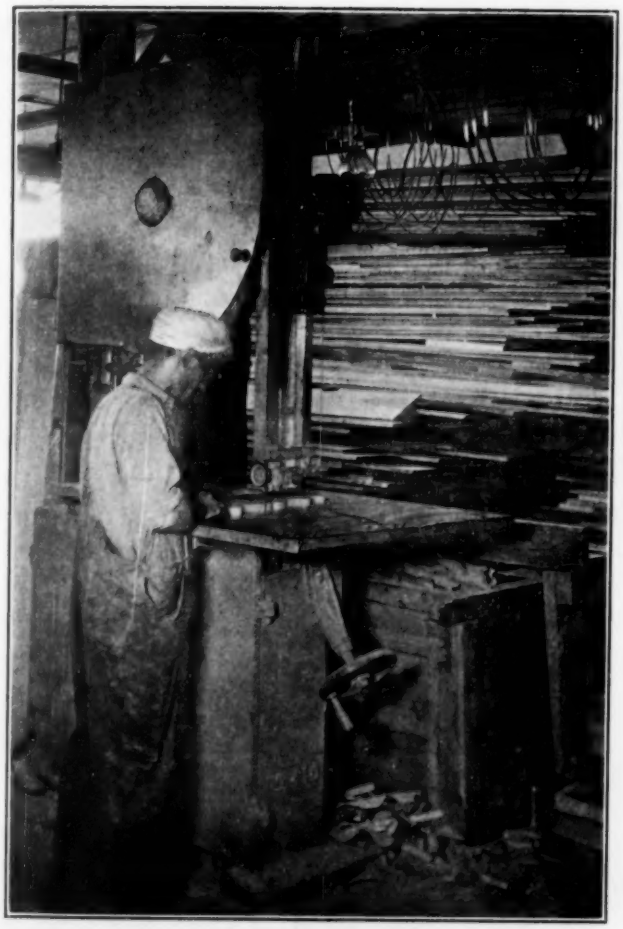

FIG. 7 BAND SAWS ARE USED FOR CUTTING IRREGULAR SHAPES

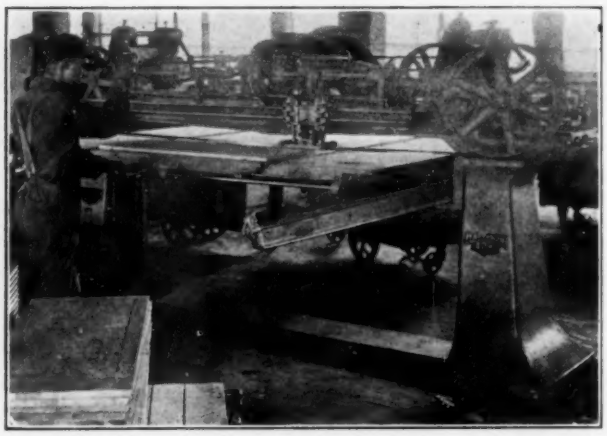

FIG. 13 AUTOMATIC POWER AND HAND-STROKE BELT SANDER

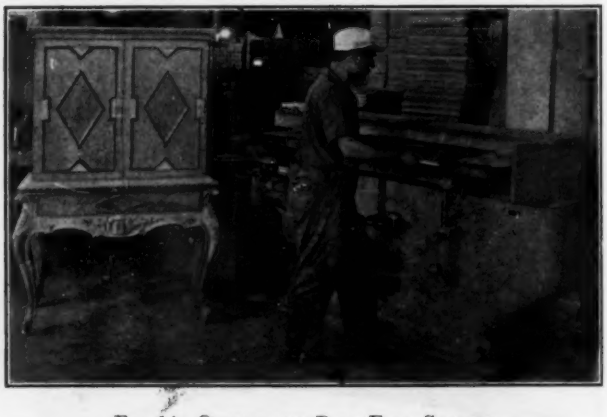

FIG. 14 OSCILLATING-BELT EDGE SANDER

operation produces a very smooth turning which requires very little sanding. Practically all drawers are dovetailed together as no other lock joint is as satisfactory or as simple to manufacture on this class of furniture.

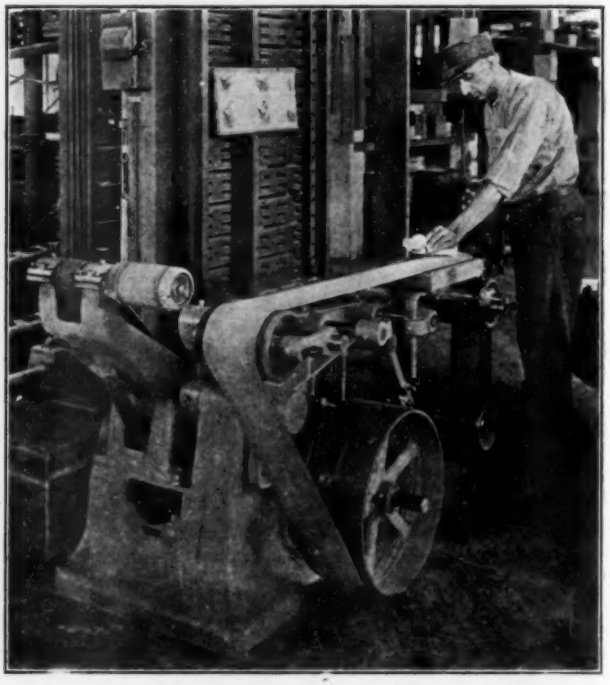

FIG. 15 VARIETY BELT SANDER

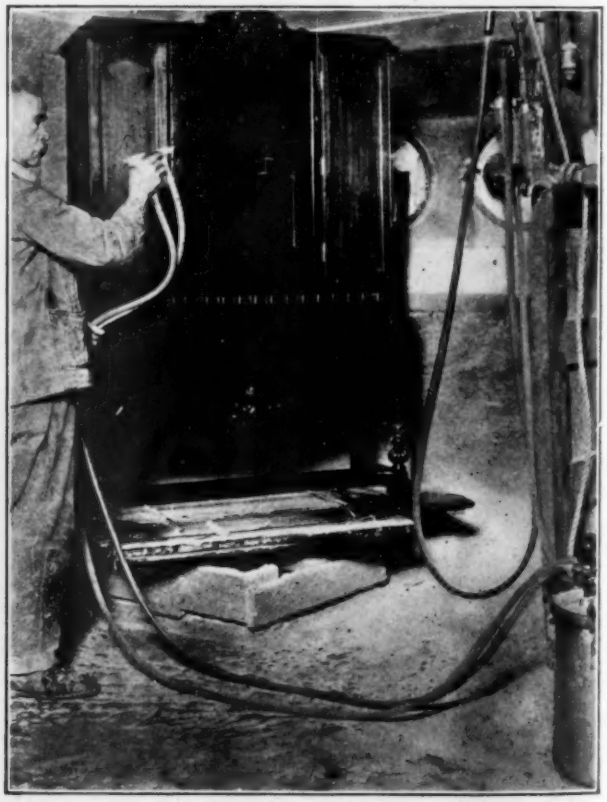

FIG. 16 SHELLAC, LACQUER, AND VARNISH ARE APPLIED WITH SPRAYING EQUIPMENT

Nearly all of the large amount of carving required is done on carving machines (Figs. 10 and 11). The first piece which serves as a model must be hand carved. Several blanks are clamped in a carving machine at the same time, sometimes as many as twenty-four. There is a tool over each piece being carved, and all are directed from a central point where the operator moves a small guiding pin over the hand-carved model. This machine makes complicated carvings in quantities a very simple operation. Some of the intricate carved parts are sanded by hand, but aside from these, practically everything is machine sanded. Small flat parts and flat panels are run through the triple-drum endless-bed sander (Fig. 12), the tape is removed, and a good smooth surface is obtained.

To insure a perfectly smooth panel, however, with no waves, it is necessary to finish sanding them on an automatic stroke sander (Fig. 13). The oscillating-belt edge sander (Fig. 14) is used for sanding straight as well as curved edges. The variety belt sander (Fig. 15) consists of two small pneumatic sanding drums and an endless sand belt which can be operated vertically and horizontally. It typifies its name as it will sand nearly every small piece or furniture part, whether shaped or straight.

The assembling of pieces of classical furniture is practically all done by hand, for owing to the small quantities and irregular shapes, suitable furniture clamps with sufficient range cannot be obtained. In the finishing, much care and attention must be devoted to obtaining the proper color, and therefore each piece is first stained and then all pores are filled. A fine hand sanding then eliminates all raised grain. This is followed by shellacking with a spraying machine (Fig. 16).

Another light sanding is succeeded by one or more coats of either lacquer or varnish, depending on the finish required. This application being dried, the flat surfaces are rubbed with rubbing machines, and irregular surfaces are rubbed by hand with either oil or water and pumice to provide a glossy finish, after which they are allowed to dry thoroughly. The addition of doors, handles, glass, and other fittings completes the work. Although classical furniture is distinctive and individual in design, very little hand work is required in producing it, and modern mechanical equipment is extensively and profitably used, even in the smallest plants.

From the Master Cabinetmakers to Woodworking Machinery

The Medieval Carpenter-Furniture Maker—The English Master Cabinetmakers—The French Influence—Materials and Processes—Early Hand Tools—The New Era—Bentham's Planer and His Comprehensive Patent—The Newberry Bandsaw

By J. D. WALLACE[1] and MARGARET S. WALLACE,[2] CHICAGO, ILL.

THE history of woodworking machinery from earliest times until today may be likened to a great and complex drama of interwoven comedy and tragedy. The action opens when the first man uses a block of wood for a seat; the plot and subplots develop steadily through the Middle Ages, reaching a climax in the great industrial revolution of the eighteenth century; the conclusion is modern industrialism with its power machinery and mass production. The tragic moment—if one wishes to call it that—is the passing of the great English cabinetmakers.

Until about 1716 in England most work was purely manual. Machines were not used because they had not been invented. Mass production, industrialism, and capitalistic organization were unknown. The prevalent form of industrial organization was the guild, wherein master worked with his men; and men, in due course of time, all became masters.

The Carpenter-Furniture Maker

Throughout medieval times the carpenter exercised all the functions of joiner and cabinetmaker as well as those of his own trade, for there were no specialists in those days. The carpenter who built a house made all the furniture as well; there was no one else to do it. This method was much more practicable in medieval times than it would be now, because the furniture of that time was very rude and very scant. Plain benches or stools without backs, tables, chests, and beds were practically the only articles of furniture available, even in the homes of the nobles. Those were the days when bathtubs were unknown; when floors were covered with rushes; when all the scraps from dinner were thrown under the table to the dogs. In the houses of peasants, manners were cruder and pieces of furniture fewer than in the homes of the aristocracy.

As time went on, carpenters became interested in making their work ornamental as well as useful. In the thirteenth century the introduction of Gothic architecture into England stimulated the carving of furniture. The relation between styles of architecture and of furniture has always been close. Finally civilization reached the point when men no longer wore their heavy armor while spending an evening at home. Furniture at once could be made lighter. A bench with dainty legs would be comparatively safe for an unarmed man to sit on, whereas it would undoubtedly have collapsed in splintered destruction under a full suit of mail. In the time of James I, the early fourteen hundreds, when the exquisite gentleman arrayed himself in a stuffed and padded jerkin, trunk-hosen, and doublet, furniture was stuffed and padded to match, and made increasingly elaborate.

During the first part of the seventeenth century, oak could be obtained very cheaply, for forests of oak planted by the preceding generations were coming to maturity. This gave an additional impetus to furniture making, and new pieces of furniture were added. Politics and religion had a share in furniture styles also. After the restoration of gay Charles II at the end of the seventeenth century, great popularity was given to the day bed, or sofa, a piece of furniture which the Puritans had eschewed with horror, considering it nothing short of indecent to recline in public.

Fig. 1 Chair by Chippendale, Mahogany, in the Gothic Manner
(Courtesy of Furniture Publishing Corporation Jamestown, N. Y.)

With the increasing complexity of furniture, the trade passed from the hands of carpenters to a group of more specialized workmen. Thus in the eighteenth century came the zenith of individuality in the art of furniture making. Never before or since has the world produced at one time the like of the great English cabinetmakers.

The Master Cabinetmakers

Until the time of Chippendale, furniture took its style name from its period—such as Tudor, or Jacobean, and not from its maker. Thomas Chippendale, who was born in the early seventeen hundreds and died in 1779, was the first cabinetmaker to stamp his own personality upon his products. The man had a good eye for advertising and salesmanship as well as talent in furniture making. His book "The Gentleman & Cabinet Makers Directory," was the earliest of its kind. Chippendale's special skill was in the making of chairs, though he possessed astonishing versatility. Carving was his favorite form of decoration, and he indulged this taste lavishly on his furniture—much of it mahogany, an admirable medium for this style of ornamentation. (See Fig. 1.)

The four brothers Adam (the Adelphi), outstanding figures from 1762 to 1792, were architects as well as designers of furniture, and both houses and furniture designed by them showed the same simple, classic influence. Two of the four brothers, Robert and James, really made the family name famous in the furniture trade. They were designers, not craftsmen, and their commissions were executed by Chippendale, Heppelwhite, and Sheraton,

(By courtesy of Westing, Evans and Egmore, Philadelphia, Pa.)

as well as by workmen of their own employment. The Adam style was a strictly classical one, employing straight lines, restrained ornament, and beautiful painting and inlaying of rare woods. This was in distinct contrast to the florid, curvilinear styles of previous years. Being architects, the brothers did their finest work on cabinets, and it is for these that they are best noted. (See Fig. 2.)

A sort of halfway mark between the brothers Adam and Sheraton is found in Heppelwhite, whose designs, outlasting his life, were most popular from 1765 to 1769. Heppelwhite used curved lines more than the brothers Adam, being much influenced by the French Louis Seize style. He employed light woods, and was partial to painting and inlaying. His articles, particularly the chairs, showed, in spite of their lightness, the sturdier build typical of English furniture. (See Fig. 3.) Heppelwhite's styles were given much notice by the posthumous publication of his two books of design: "The Cabinet Maker and Upholsterer's Guide" and "The Cabinet Makers' London Book of Prices and Designs of Cabinet Work."

Furniture designers of the last decade of the eighteenth century were dominated and guided by Thomas Sheraton. He was more a designer than a craftsman, though he was skilled in all the details of furniture making. Many of his designs reflect the style of French furniture, particularly that of Louis Seize type. Sheraton employed straight lines, graceful contours, and much inlaying and marqueterie. (See Fig. 4.) He was a classicist, but also foreshadowed the modern employment of geometrical designs for ornament. His ingenuity in the invention of double-purpose furniture is very interesting. Commodes and wash-hand stands, in a period when modern conveniences were lacking, were developed into pieces of furniture—"used in genteel bedrooms, and were sometimes finished in a style a little elevated above their use," as Sheraton puts it. A desk is cleverly contrived so that a drawing board on it may be raised and lowered, and tilted to any angle; a Pembroke table (see Fig. 5) is fitted with a shelf ladder folding into its drawer. These and other pieces of furniture make interesting his remarkable book of designs, "The Cabinet Maker and Upholsterer's Drawing Book—the Whole Embellished with 122 Elegant Copper Plates." It may be said that furniture-design books of that century were all, excepting that of the brothers Adam, the work of practical cabinetmakers.

(Courtesy of Furniture Publishing Corporation, Jamestown, N. Y.)

The French Influence

Throughout the eighteenth century English cabinetmakers derived inspiration from the French, the three noteworthy styles of French furniture at that time being the Louis Quatorze, from 1643 to 1715; the Louis Quinze, from 1715 to 1774; and the Louis Seize, from 1774 to 1793. The Louis Quatorze style (see Fig. 6) was rectilinear, but gorgeously ornamented to fit the character of the "Roi Soleil," as he was called. The Louis Quinze style (see Fig. 7) was more graceful and much less formal, employing a florid, curvilinear structure. A reversion to classicism, extreme lightness and elegance, and the continued use of gorgeous upholstering fabrics characterized the elegant Louis Seize furniture. (See Fig. 8.) Under Louis XIV a very popular form of decoration was Boulle work, an inlay of tortoise shell and metal over a ground of painted wood. Chippendale and Sheraton in particular were influenced by the French, but these English designers Anglicized, as well as copied, the French ideas, so that the product was truly English.

Fig. 4 Sheraton Card Table, Mahogany Inlaid With Satinwood
(By courtesy of Furniture Publishing Corporation.)

Practically all the work of these great cabinetmakers was executed by hand tools, the total output of each designer being comparatively small. It was not until the very end of the eighteenth century, when the time of the great masters was almost ended, that power woodworking machines were invented, and it was still later before they were commonly used.

Materials and Processes

In spite of the handicaps imposed on them by the lack of machinery, the master cabinetmakers were eminently skilled in many processes. Carving, turning, gilding, lacquering, veneering, painting, japanning, inlaying, marqueterie, and fretting were used during the eighteenth century. Veneering, practiced in early times by the Greeks, had been rediscovered in the Middle Ages by Filippo Brunelleschi, an Italian. In 1565 the first veneer mill was set up at Augsburg in Germany by a man named Renner.

Varnish mixed with oil had begun to be used in the sixteenth century, while a manufactory of varnishes—in imitation of the Oriental products—was set up in Brunswick, England, in 1765. Canework was known and used in late Stuart times, and during the William and Mary period (1688–1702) until the Dutch influence overwhelmed it, that is, throughout the seventeenth century. Under Sheraton, canework returned to vogue, frequently being used in company with satinwood and japanned surfaces. A number of polishing methods were used. A list of prices published in 1788 shows that the cost of polishing the outside of an article with hard wax was twice that of oil polishing; while polishing with turpentine and wax cost half again as much as the oil polishing. Decorative processes were naturally dependent on the woods then obtainable for furniture making. Discovery and exploration of the New World during the fifteenth and sixteenth centuries opened new fields to trade and commerce, and brought many new and valuable woods to England. From 1500 to 1660 oak was the predominant wood, while deal and chestnut were rare and valuable at that time. Walnut was not grown in England until the beginning of the sixteenth century, and was then much esteemed because of its rarity. Mahogany, first noticed for its hardness and durability by a carpenter on Sir Walter Raleigh's ship in 1595, was brought to England and used extensively during the eighteenth century. Much of it came from the West Indies, Jamaica alone exporting 521,300 ft. in 1753. During the eighteenth century many other light and rare woods were used in smaller quantities, among which may be mentioned satinwood, rosewood, amboyna wood, tulipwood, holly, thuja, kingwood, and ebony.

EARLY HAND TOOLS

Tools employed in furniture making were hand tools. Under Chippendale the beautiful decoration of chair backs and legs was done with the carver's chisel. During the Heppelwhite period, grooving and reeding planes came into use. The legs of chairs, if not left quite plain and square, or simply turned, were ornamented by the use of these planes. Sheraton, in his drawing book, mentions the center bit, the sash saw, and the plane. He was an experienced craftsman, and here and there in his book inserts bits of helpful information about tools to be improvised. Thus he gives instructions, in making a door, ". . . . .for working the astragals (molding or beading) on the edge; which may easily be done, by forming a neat astragal in a piece of soft steel, and fixing it in a notched piece of wood and then work it as a gauge..." Typical hand tools available during that period are illustrated in Figs. 9–13, reproduced by courtesy of the Victoria and Albert Museum of London. Tools in this collection, while dated as far back as 1694, are not the earliest examples known, but are representative of those in general use during the eighteenth century.

FIG. 9 JOINTER'S PLANE, 2 FT., 7 IN. LONG; 3 IN. WIDE, BEECHWOOD, WITH CARVED HANDLES; ENGLISH, DATED 1771

FIG. 10 MOLDING PLANE OF WOOD WITH IRON BLOCK STAMPED ON ONE END, "MICHAEL SAXBY AND F. C. 1756;" LENGTH, 1 FT.; HEIGHT, 6 1/4 IN.

THE NEW ERA

All this time, until the end of the eighteenth century, the action of the drama had been rising to a climax which came with the industrial revolution, when inventions of modern machinery were made in rapid succession.

The tool, removed from the hand of the craftsman and guided instead by some mechanism having a prearranged motion, ceased to be a tool and became a machine. The modern machine is threefold; it consists of the motor mechanism, the transmitting mechanism, and the tool or working element. Such machinery makes possible the use of greater motive force, and greater exactitude in its application.

These developments would seem to offer great advantages, and although one would not expect an ignorant people fully to appreciate them it is rather surprising to known that in 1663, when a Dutchman erected the first sawmill near London, it was attacked by a mob and had to be abandoned because of public disapproval. Even as late as 1768, another sawmill started by James Stansfield was attacked and caused to be abandoned; though in other parts of England mills were started and run successfully by Stansfield with the aid of the government. These were all wind-power mills with jigsaws, until in the year 1777 one Samuel Miller patented a sawmill using a circular blade.

Up to that time inventive progress in woodworking machinery was comparatively slow, but at the end of the eighteenth century there arose a remarkable man, Sir Samuel Bentham, who within a few years invented and patented almost every known variety of woodworking machine.

His father was wealthy and sent him to Westminster School in London, where he completed his studies in 1770. Thereafter he was apprenticed for seven years to the master shipwright of Woolwich dockyard. His apprenticeship served, he spent eighteen months visiting other dockyards, and in 1779 was sent by his government to tour the northern part of Europe, examining the shipbuilding and other arts. In Russia he stayed for some time as a naval engineer, holding, in 1785, the rank of colonel

(Reproduced by permission of Albert and Victoria Museum, London.)

in the Russian army. Here he devised a plan for the central inspection of his Russian shipwrights, a method afterward suggested as a means of supervising convicts. Shortly after 1779, while still on his tour, Bentham invented the first planing machine for wood that really could be called an organized operating

machine. The one patented in England in 1776, by Hatton (see Fig. 14), is almost too crude to be considered.

In 1791 Bentham returned to England, where later he became brigadier-general and inspector-general of the naval works of England. Here he found his brother, Jeremy Bentham (the famous writer on political economy) in charge of a number of industrial prisons, containing ignorant convicts who must nevertheless be put to profitable work. Apparently they were incapable of doing handwork in wood, but perhaps they might be able to run a simple machine; thus reasoned Sir Samuel. He therefore devised a large number of woodworking machines for use in these prisons. The residence of Jeremy, at Queen's Square Place, Westminster (now a part of London), was in 1791 made into the first manufactory of woodcutting machines. In the Bentham factory were made machines for planing, molding, rebating, grooving, mortising, sawing—in coarse and fine woods, in curved, winding, and transverse directions—and shaping wood in all sorts of complicated forms. They even made a machine which could make a highly finished window sash, and another which could make an ornamental carriage wheel, both items finished except for assembling.

FIG. 12 EARLY ENGLISH HAND TOOLS

(Left: Mortise chisel, steel with boxwood handle cut with bands of ornament, dated 1761, length 10 in. Middle: Gouge, steel with boxwood handle, dated 1761, length 8 3/4 in. Right: Screwdriver, steel with boxwood handle, dated 1757, length 9 1/4 in.)

FIG. 13 EARLY ENGLISH HAND TOOLS

(Left: Hammer head and shaft, signed Leander Green, English, dated 1694. Right: Handbrace of turned and carved boxwood, English (?), dated 1642, length 9 3/4 in., diameter of head 1 5/8 in.)

(Reproduced by permission of Albert and Victoria Museum, London, England.)

THE BENTHAM PLANER

Sir Samuel's inventive genius was inexhaustible. In 1791 he issued his first recorded patent, for a planing machine, which was in principle an enormous handplane with elaborate mechanisms for passing it forward and back along the stock. Bentham described the essence of the invention as a "method of planing divesting the operation of skill previously necessary, and a reduction of brute force employed." No drawings are included with Bentham's inventions for his stated reason that "they tend to confine the attention to a particular mode, whereas words cover the construction in a general way." It is interesting to note that the British Patent Office of that day sanctioned the omission of drawings.

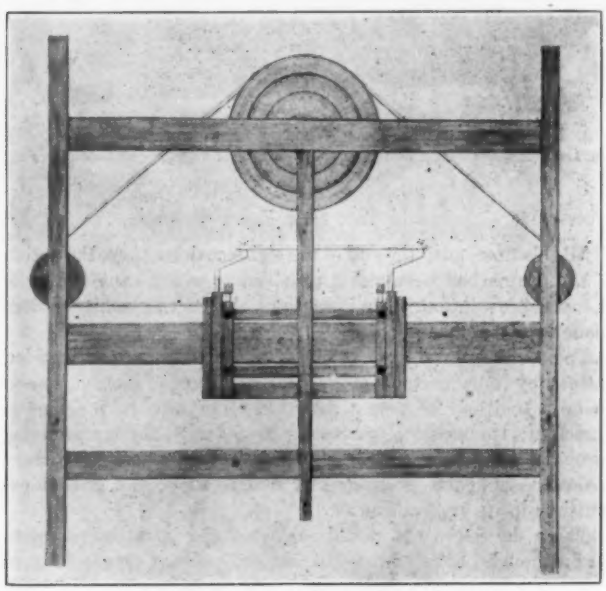

FIG. 14 HATTON'S PLANER

(The first step away from the hand plane. Drawing and description copied from original English Patent No. 1125, issued in 1776. Referring to letters on diagram of planer: *A*, the frame with pulleys and wheels; *B*, the bench on which wood to be planed or fluted is laid; *C*, the bar which keeps the sliding frame in a line; *D*, the sliding frame with closing screws and stock screws; *E*, the stock in which are fixed the several tools for planing and fluting; *F*, the pendulum or handle for moving the sliding stock and tools. By moving *F* backward and forward to the outlines *A*, the work is performed by the tools lodged in *E*, the wood to be planed or fluted lieing on *B*.)

In the Bentham planer the bit or knife is as wide as the stock to be planed; the board is laid on a bench longer than itself; "cheeks" extend down over the sides of the knives; and the ends of the plane are rounded to rise up on the board. As the cut is started, a movable weight is pressed down on the front end of the plane, being shifted to the rear as the stroke is finished, while means are provided to raise the knife on the return stroke. A compound bench to support warped boards at the middle and two sides, and multiple bits to take successive cuts with one pass, are proposed. The suggested motive power is "wind, water, steam, or animal strength."

This planer, merely a development of Hatton's idea, was hardly prophetic of Bentham's following inventions, comprising British Patent No. 1951, issued in the year 1793. Few men have had the honor to cover their chosen industry so thoroughly with patents as did Bentham with this single application. In one all-inclusive document he originated, with broad claims, practically every woodworking machine and process that is in use today. The eleven sections of the patent, each describing a machine or process in general terms and without drawings, are worthy of detailed mention.

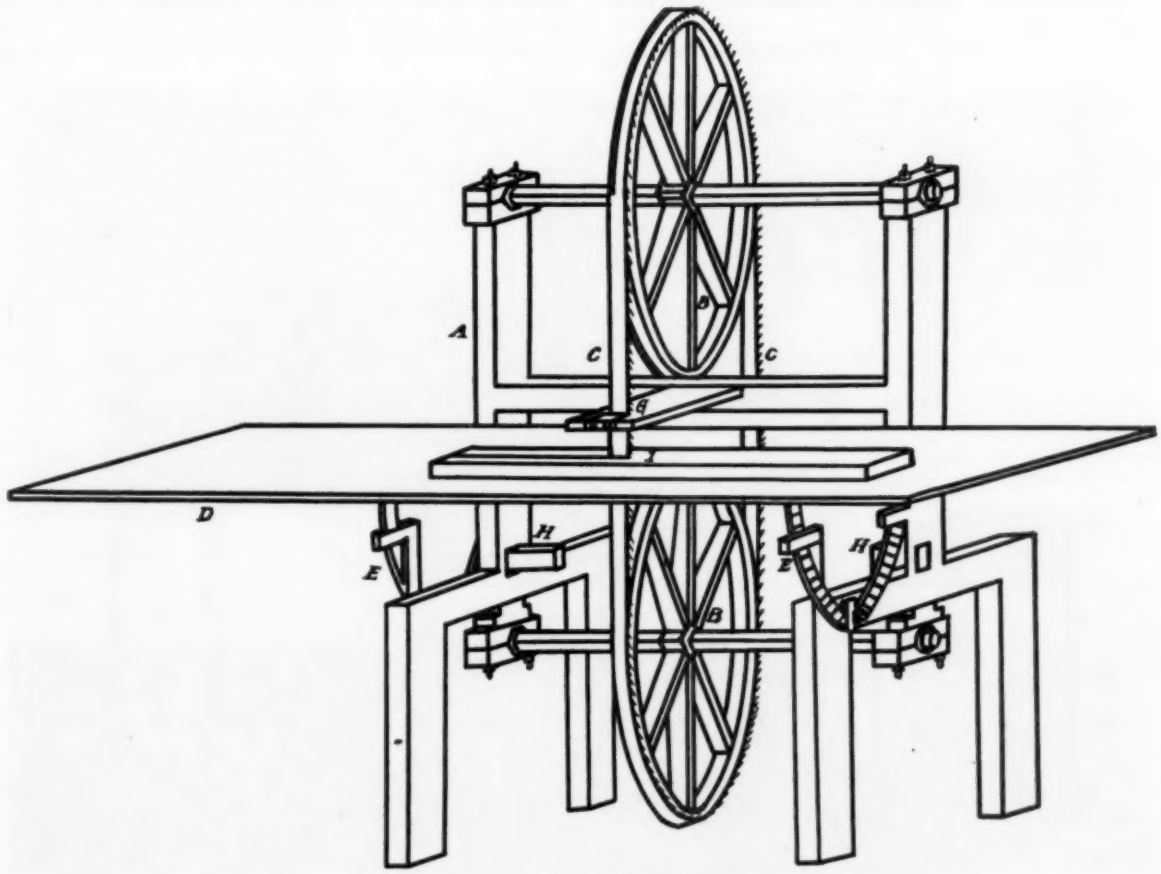

FIG. 15 NEWBERRY'S BANDSAW

(The first bandsaw, patented in year 1808. Drawing and description copied from original English Patent No. 3105. Referring to letters on drawing: *A*, cast-iron frame to carry on wheels; *BB*, wheels with iron plate screwed behind to prevent saw running off backward; *CC*, blade of saw; *D*, bench for piece being cut; *EE*, two semicircles of iron, fixed to *D* whose centers are parallel to part of saw blade which is even with top of bench, one marked with divisions of circle by which, turning on slides, bench may be placed at any angle; *G*, guide to keep saw line; *HH*, wedges to force down lower wheel to give saw tension; *I*, piece to be cut.)

THE COMPREHENSIVE BENTHAM PATENT

SECTION I. "Formations of Laminated Wood from Shavings." The shavings referred to are veneers, cut by the Bentham planer of 1791. This claim describes the first plywood panels, with additional specifications for winding veneers spirally on mandrels to make hollow tubes.

SECTION II. "Sawing by Reciprocate Motion." This section describes a vertically reciprocating saw, with means to handle stock for curves as well as straight cuts—the first jigsaw.

SECTION III. "Working by a Reciprocate Lathe." In this device the work, instead of the "jigsaw blade," is put in the reciprocating frame, and any shape produced by holding a tool against the work. As Bentham frequently refers to the use of this machine for working metals as well as wood, this claim easily covers the present-day metal-working planer.

SECTION IV. "Giving Curvature by Bending." Bentham here states that bending wood by wetting has been practiced from time immemorial, but claims originality for his specified process of building up a thick section in thin plies, making it easier to bend.

SECTION V. "Working by Rotative Motion of Tool." This is a notable section covering every circular-saw table, molder, or shaper in use today. Bentham describes saw tables with either blade or table tilting; describes the present-day cross-cut and rip fences; specifies driving the saw spindle by either belt or gear; gives methods of cutting wedges with a circular saw; describes the use of wide cutters instead of a saw blade; provides for adjustment of a spindle vertically with the table for shaper work; describes the production of moldings; describes both solid and inserted-knife cylinders; and suggests the use of wide rotating cutters in place of his 1791 planer.

SECTION VI. "Boring." This section includes details of core or plug boring, double-end drilling machines for boring long logs, and multiple-spindle drills.

SECTION VII. "Mortising." Machines described in this section mortise with a rotating and traversing bit with a flat end. The blind mortises are squared at the ends with a stamping chisel; and through, or "pervious," mortises are squared either with a square rasp or a "rasping punch," which is in reality a modern broach, the section progressing from round to square.

SECTION VIII. "Turning in a Lathe." Herein are described

methods of reproducing irregular shapes by means of a form for grinding the tool in a lathe.

SECTION IX. "Adjustment and Steadiment." This section gives practical methods of adjusting and holding work to saws and cutters of all machines.

SECTION X. "Advancement." This section broadly covers all methods of moving stock in contact with cutters, or vice versa. It describes the use of gearing connected with a rotative cutter for advancing the stock, long feed screws, gear and rack feeds, and the use of weights or springs.

SECTION XI. "Clearance." Here are methods of removing chips or abraded matter from saw teeth or cutters, such as using air to blow away chips, or having brushes to pass through the teeth of the saw.

Finally Bentham states that the above-described methods are "the fruit of my own invention matured more or less by my own practice." He suggests in addition to the well-known motive power, the installation of his machines in a carriage, if not too bulky, "deriving the power from the wheels on which the carriage runs, in this way, besides the advantage of portability, the power of horses or other beasts of draught may be applied at an expense less than that of erecting a horse mill."

FIG. 16 MODERN GRAND PIANO IN STYLE OF LOUIS XVI; WALNUT CARVINGS FROM SOLID, PRODUCED WITH MODERN MACHINERY AT A COST IMPOSSIBLE TO ATTAIN WITH HAND METHODS
(Courtesy of Chickering and Sons, Boston.)

THE NEWBERRY BANDSAW

Thus in one stroke did Bentham blanket the woodworking industries, leaving unmentioned only the scroll bandsaw, which was invented in 1808 by another Englishman, William Newberry. (See Fig. 15.) It is worthy of note, however, that the bandsaw did not come into general use for nearly fifty years, when in 1855 M. Perin, of Paris, France, exhibited at the French International Exhibition a bandsaw with greatly improved blades, capable of delivering a reasonable amount of service before breakage.

By this time none of the great cabinetmakers were living. They made their beautiful furniture during the eighteenth century, before power woodworking machinery was known or used. Even when Bentham made his machines it is probable that they were not much used by cabinetmakers, for they were rough, heavy machines, more suitable for cutting ship timbers than fine pieces of furniture. It must be remembered that Sir Samuel Bentham was a naval engineer, not a cabinetmaker. There is no record that any of the great cabinetmakers ever invented or made power woodworking machinery, though many of them as Chippendale and Heppelwhite, were practical craftsmen.

During the seventeenth century the use of hand woodworking tools had reached the zenith of development. A long background of experience enabled men to wield their hand tools with the skill of the artist, and to produce works of art in wood. The care expended on each piece was necessarily great, because it was done all by hand. Each article was executed as an individual work, not as one of a thousand similar pieces. If the cabinetmakers had employed the crude machines at their disposal toward the end of the century they probably would have produced crude, unbeautiful furniture, for men were not yet masters of the new machines.

As it was, the quiet atmosphere of preindustrialized cabinetmaking gave time and opportunity for the painstaking labor of a master designer and craftsman who took personal pride in his work; whereas now much of the furniture is made by hired laborers who are not intelligently interested in the artistry of their product. While in the old days beautiful furniture was hand-

made, rare, and available only for the few, today mass production has changed matters entirely. Beautiful furniture now is machine made—with greater precision, uniformity, and strength than the best of the old cabinetmakers could attain; it is abundant, and available to the great majority of people. Of the two eras, the old and the new, there are few of this generation who will hesitate, even though they may regret the passing of the old cabinetmakers, to choose modern industrial methods as best.

CHRONOLOGY

1565. First known veneer mill set up in Augsburg, Germany, by Renner.
1595. Mahogany first brought to England by Sir Walter Raleigh.
1663. First sawmill erected near London.
1765. Manufactory of varnishes set up in Brunswick, England.
1768. Sawmill erected in England by Stansfield.
1769. Steam engine invented by James Watt.
1603–1688. Jacobean Period.
1688–1702. William and Mary Period.
1643–1715. Louis XIV Period.
1702–1750. Queen Anne Period.
1715–1774. Louis XV Period.
1740–1780. Chippendale Style.
1762–1795. Adam Style.
1765–1795. Heppelwhite Style.
1774–1793. Louis XVI Period.
1780–1808. Sheraton Style.
1776. First planer patented by Hatton.
1777. Sawmill with circular blade patented by Miller.
1791. First manufactory of woodworking machinery set up in London by Bentham. Improved planer patented.
1793. Bentham's patent covering many woodworking machines.
1808. Bandsaw patented by Newberry.

Discussion

DR. HENRY C. MERCER.[3] As to the dead leveling by hand tools before machinery, among the chief agents of this were:

(*A*) The long jointer plane. We find on broadaxe-hewn ceiling beams or on dazed-surface furniture, also on the war clubs, oars, etc. of primitive peoples, dugout canoes, Anglo American bowls, spoons, paddles, etc. made with the draw knife (straight bladed or scooped), what might be called the "hills and valleys" of a waved surface, showing a gentle play of light and shadow, as observed by the sculptor on human flesh. Subsequent polishing or smoothing does not obliterate these wavings, but the long jointer plane, reducing the surface to a dead level, effaces them. Compare most interior walls of newly built houses today, spoiled by dead leveling with the plasterer's float, 5 to 6 ft. long, which no amount of subsequent "brooming" will cure.

(*B*) The broad-bladed hand saw, or pit saw. This will also super-level a wood surface, whereas the old thin-bladed saw, or still thinner-bladed bow saw, if not worked too accurately would not do this.

(*C*) The turning lathe. This would least of all take the life out of a piece of old woodwork, because the turner might neglect his calipers, and so vary the size and interspacing of his swells, or his lathe may be inaccurate and wabble. This latter alleged defect, in the writer's opinion, gives vitality to the Arab turnings of window lattices, etc. The writers of the seventeenth and eighteenth century, oblivious to this fact, strove for accuracy, and despised a wabbling lathe. A comparison between the retouched and not retouched earthenware of the past easily proves that the porcelain of Sevres and the wares of Japan, China, and ancient Greece have been blighted by what is known, but very rarely described, as dry-lathe turning.

Polishing or smoothing, as frequently practiced by primitive peoples and medieval woodworkers, still leaves the "hills and valleys" and has nothing to do with dead leveling.

As to the accuracy of the compass, the square, the gage, and the calipers, a very great charm at once appears when these tools are not used carefully and when, as often occurs in China, corners, distances, centers, and circles are guessed at by eye. Compare the colored plates made by accurate metal workers for Shaw's "Book of Tiles," where in the tile patterns (supposed to be represented, but falsified) the mechanics made the right side of a pattern duplicate the left. Then look at the original tiles in the British Museum which show that the monks made their designs by eye.

The art of the craftsman should be adapted to the raw material worked upon. The law of all wood is a more or less straight grain. Heppelwhite, Sheraton, Chippendale, etc. violated this law by dangerously cutting and deeply notching across the grain. Such carvers as Grinling Gibbons went beyond all reason by producing projections which look as if they would blow away if breathed upon. The medieval craftsmen carved close, and their work at once belittles the wood silhouettes of Chippendale and his school.

The foregoing defects appearing in the hand-made woodwork of the eighteenth century were all exaggerated by the machines of the industrial revolution now in use. One chair by Heppelwhite, too accurate individually, might vary somewhat in a second chair of the same type, whereas now a thousand chairs would be exactly alike. Nothing here said is meant to belittle machinery in its proper place. But the place of a machine is not in the field of art. If a piece of furniture is a work of art, we have not yet realized that no work of art can be made by a machine.

THOMAS D. PERRY.[4] In their researches did the authors come upon a number of illustrations of woodworking machinery, man-power, horsepower and water-power, published in the Theatrum Machinarium Novum in Nuremburg in 1662? These were evidently ideals of the author rather than actual examples of practice.

Firesafe Lumber

By RAYMOND W. STORM,[1] NEW YORK, N. Y.

Methods are given of rendering wood non-inflammable by impregnation with various chemicals in aqueous solutions, together with the subsequent drying of the treated lumber and the important characteristics of the products thus produced. The author has sought to emphasize mainly the commercial or practical side of manufacture and use rather than the purely technical or theoretical aspects of "Firesafe" wood.

AS EARLY as the first century A.D., the Romans, under Emperor Augustus, recognized the value of fire-resistant wood and employed a coating of alumina and acetic acid (clay and vinegar) which was plastered on over wooden building members, much as we might today enclose with Kalamein metal or encase our steel structures with concrete. This coating actually provided a fair amount of fire resistance, although of course impractical from the modern viewpoint. Thereafter, up through the Middle Ages, the absence of historical data indicates that "fireproof" wood seems to have been almost entirely neglected, although in 1841 Dr. Pyne, an Englishman, patented a sodium-tungstate treatment.

Attesting the more recent interest in "fireproof" wood, there are to be found in the United States Patent Office hundreds of patents, domestic and foreign, covering principally solutions of salts in myriads of combinations—ammonium chloride, phosphate, and sulphate predominating. A generation ago in New York City there existed a wood-treating plant which actually produced lumber which, from the standpoint of comparative fire resistance at least, was admirable. In the past decade, in fact, several plants have been established in the United States for the "fireproof" treatment of lumber, and apparently most of these plants have been moderately successful.

The impregnated lumber made by these pioneers was and is acceptable to the New York Bureau of Buildings, which first promulgated about 1900 the tests which are still in use, only minor changes having since been made, and which apply on all buildings over 150 feet in height. The Building Inspector in charge selects, preferably at the job, samples from each 2000 ft. of lumber and takes them to the official testing laboratory at Columbia University. If the samples fail in these tests, the builder is not permitted to use the lumber.

Due to excessively high costs, limited production, and especially the deliquescent nature of the chemicals used, the use of "fireproof" wood has been limited and it is not widely known. Some cases are reported where the treated lumber, being extremely hygroscopic, has attracted moisture to such an extent that globules of water (or solution) formed on the surface, causing leaching, and gradually by capillary attraction and evaporation removing some of the chemicals from the wood. In other instances, during periods of great humidity, varnished or painted woodwork has been known to have been damaged by the efflorescence of the salts. This affinity for moisture has, in fact, been the greatest stumbling block in the way of previous large development, and quite naturally it has in some quarters prejudiced people against "fireproof" wood.

When used in dry places, however, this material has generally been satisfactory. In fact, one great good has developed from these early treatments—it has been definitely shown that "fireproof" wood once dry and kept dry could be counted upon to retain its effectivity. Numerous examples of this are to be found. One of definite record is a test (see Appendix No. 3) made at Columbia University on August 1, 1929, of samples of "fireproof" trim

FIG. 1 CORNER OF LABORATORY WHERE FORMULAS ARE TRIED OUT

treated in 1912 and 1913, and removed from the Hotels McAlpin and Biltmore and 80 Maiden Lane in 1929. This and similar tests have proved invaluable as practical demonstrations of the stability of certain fireproofing chemicals in wood over long periods of actual use.

From the foregoing it is apparent that while considerable progress in the field of "fireproof" wood had been made by the pioneers, there remained, nevertheless, many problems in the creation of new formulas and processes and in the establishment of the product on a sound, scientific, and commercial basis.

RECENT DEVELOPMENT

With these definite purposes in mind, and with the further goal of recovering for their industry at large and their individual businesses in particular the prestige lost in some fields to competitive products, a group of lumbermen, including the Edward Hines Lumber Company, of Chicago, early in 1926 organized the International Fireproof Products Corporation, which company has carried on the program of intensive research and development presently to be described. Operating in three specially built

laboratories over a period of three years, the scientists of this company—chemists, engineers, and wood technicians, all specialists in their respective lines—first explored the field of "prior art" and then went on into new realms of research, eventually originating and perfecting the various formulas and processes as used today. Credit for these chemical inventions is due to Fernando Somoza Vivas, senior chemist.

Firesafe Trademark and Formulas

"Fireproof" wood is of course a misnomer, even an impossibility, nothing in nature being completely fireproof. Therefore, at the very outset, a more exact title was found necessary, and the word "Firesafe" coined. This name has become a trademark and must always be definitely associated with the numerous developments of the International Fireproof Products Corporation.

The chemicals used, while covered by a long chain of process patents, some of which have only recently been applied for, naturally cannot be divulged. It may be stated, however, that these chemicals are of several different groups—some that break up at low temperatures (200 to 1500 deg. fahr.), some at medium temperatures (1200 to 3000 deg. fahr.), and some at the highest temperatures found in burning buildings (2000 to 6000 deg. fahr.). These chemicals function in different ways: by giving off a non-inflammable, fire-extinguishing gas, by fusing over the surface of the wood in a protective coating, and by obstructing the pores of the wood and excluding the oxygen necessary to combustion.

All chemicals are dissolved in warm water in proportions established by exhaustive tests. To each gallon of solution is added a small amount of Firesafe "dope," a paste made in our laboratories having a strong catalytic and lubricating effect. It is largely this "dope" which makes Firesafe lumber so much more easy to mill than any other "fireproof" wood, although the careful filtration of the solutions also helps materially, as thereby much insoluble matter is removed which would later deposit on the surface of the lumber, causing abrasion. These are novel "Firesafe" features.

As previously remarked, the most important characteristic of a fireproofing formula is its comparative affinity for moisture, it being safe to assume that all chemicals used in fireproofing are in some degree deliquescent. Firesafe formulas are not offenders in this respect, and the treated wood may be relied upon not to exude chemicals in damp weather, it being practically non-hygroscopic. Lumber stored in open sheds by the East River has shown no dampness 99 per cent of the time, and only at the end of long periods of rain has it showed any surface moisture at all, and that very slight and unimportant.

Description of Firesafe Process

Generally known as the "full-cell" process, the routine of treatment is essentially as follows:

The lumber to be treated is locked in an air-tight retort or cylinder from which the air is evacuated, reaching gradually a vacuum corresponding to about 29 inches of mercury. This vacuum removes from the cells of the wood most of the air and some of the moisture, the latter depending upon the amount of initial heat present in the lumber. After a sufficient period of vacuum, varying with different species and thicknesses, the vacuum is broken by the inrush of chemical solution from the storage tanks, where it has been kept at a temperature of from 100 to 150 deg. fahr., depending upon the formula being used. In these storage tanks mechanical agitators are sometimes employed.

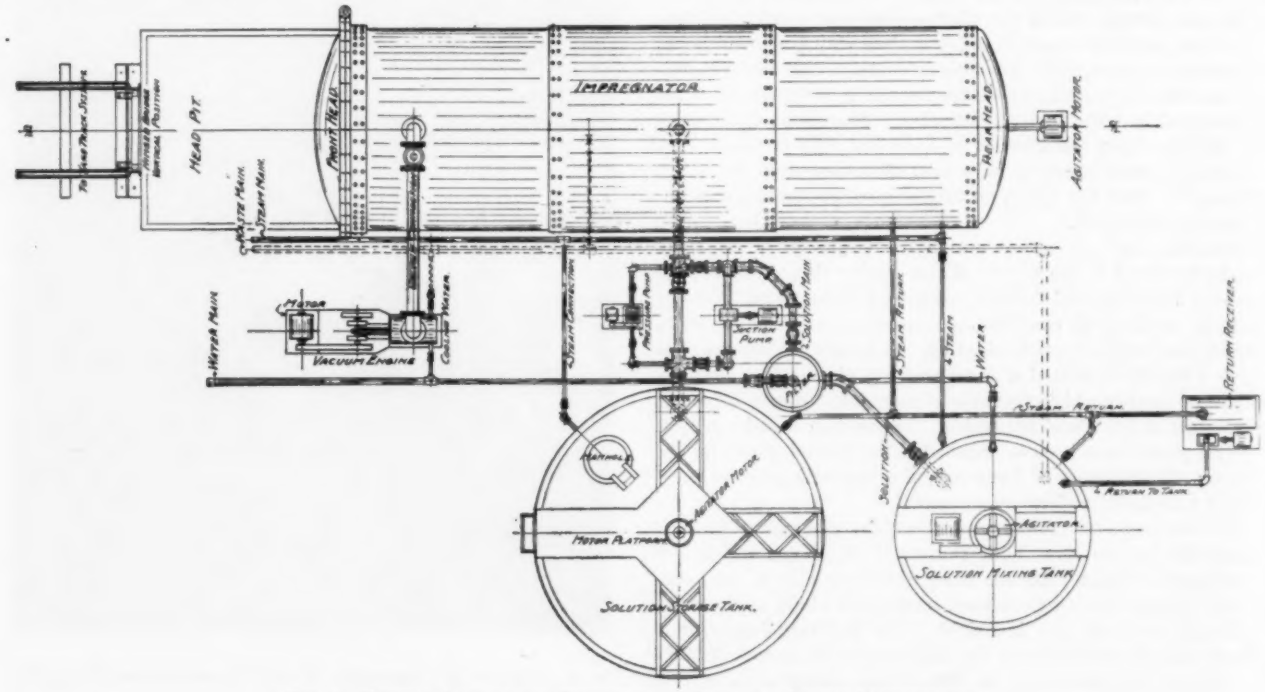

Fig. 2 Typical Layout for Fireproofing Unit for Single Impregnator

A large percentage of the necessary impregnation is obtained by prompt absorption, but when the flow into the cylinder becomes static, pumps are employed to force an additional amount of solution into the wood, pressures of from 100 to 250 lb. per sq. in. being employed. Each gallon is metered as it passes through the supply lines, and a further check is provided by gages on the storage tanks.

In the cylinder even temperatures are maintained by steam coils and recirculation by means of a propeller-type agitator. This cylinder agitator is a unique feature of the Firesafe process and makes for even saturation. Only a carefully controlled

number of gallons per hour per thousand feet board measure is forced into the wood, at a regular rate, until the desired total is reached, when the impregnation is stopped and the superfluous solution returned to the storage tanks by a separate centrifugal pump.

After a brief dripping period, during which the cylinder door is unbolted, the lumber is then removed from the retort.

If necessary, the wet lumber can be immediately placed in a dry kiln, but an oxidation period of one or more days is recommended before the actual mechanical drying starts.

The Dampsafe Treatment

Should the Firesafe lumber be intended for use out of doors or in damp places, a second treatment (before drying) is employed which accomplishes a rapid chemical reaction and renders the chemicals of both treatments insoluble. This reaction is very effective, and the resultant amorphous substance cannot be dissolved in water or even in a 20 per cent solution of hydrochloric acid.

If this reaction could be accomplished evenly throughout the cellular mass of the wood, a perfectly insoluble treatment would result, but due to the active affinity of the two solutions, the union is accomplished more effectively on or near the surface of the lumber. An average penetration of about 1/4 in. is to be expected, which is sufficient for most moisture or exposure conditions, but will not permit immersion in water for long periods without partial leaching of interior chemicals.

This Dampsafe treatment is not water-repellent or waterproof, and is rather to be likened to the condition of a brick which due to its porosity may absorb and exude moisture without deleterious effect. The result is decidedly non-hygroscopic lumber. There is noticeable, however, a slight surface deposit of a white, granular substance, easily brushed off, but which renders this doubly treated lumber hard to plane, although it may otherwise be cut easily.

While the Firesafe and Dampsafe treatments may be handled in one retort, provided careful washing is done between, a separate cylinder for the second treatment is recommended.

"Dampsafe" lumber is a novelty, and greatly enlarges the field of merely Firesafe stock.

It must also be added that Dampsafe lumber is largely non-corrosive, neutral, and non-poisonous. Ordinary wire nails have shown practically no corrosion after months of exposure in Dampsafe lumber.

An interesting phase of Dampsafe lumber is that under air conditions it dries more rapidly. In fact, for ordinary structural purposes, especially in partially impregnated stock (explained elsewhere), nothing more is recommended than air drying for a period of a few weeks.

Freedom from rot and greatly increased resistance to fungus and insect attacks of all kinds will place Dampsafe lumber in a class by itself. Due to the comparative newness of the product, it is impossible at this time to hazard a guess as to how much the Dampsafe treatment increases the useful life of lumber, but it should be considerable.

Finally it must be noted that Dampsafe lumber is not adapted for re-milling—the finished shapes only should be Dampsafed.

The chemicals used in both Firesafe and Dampsafe treatments are harmless and not poisonous; in fact, most of them can be taken internally without injury.

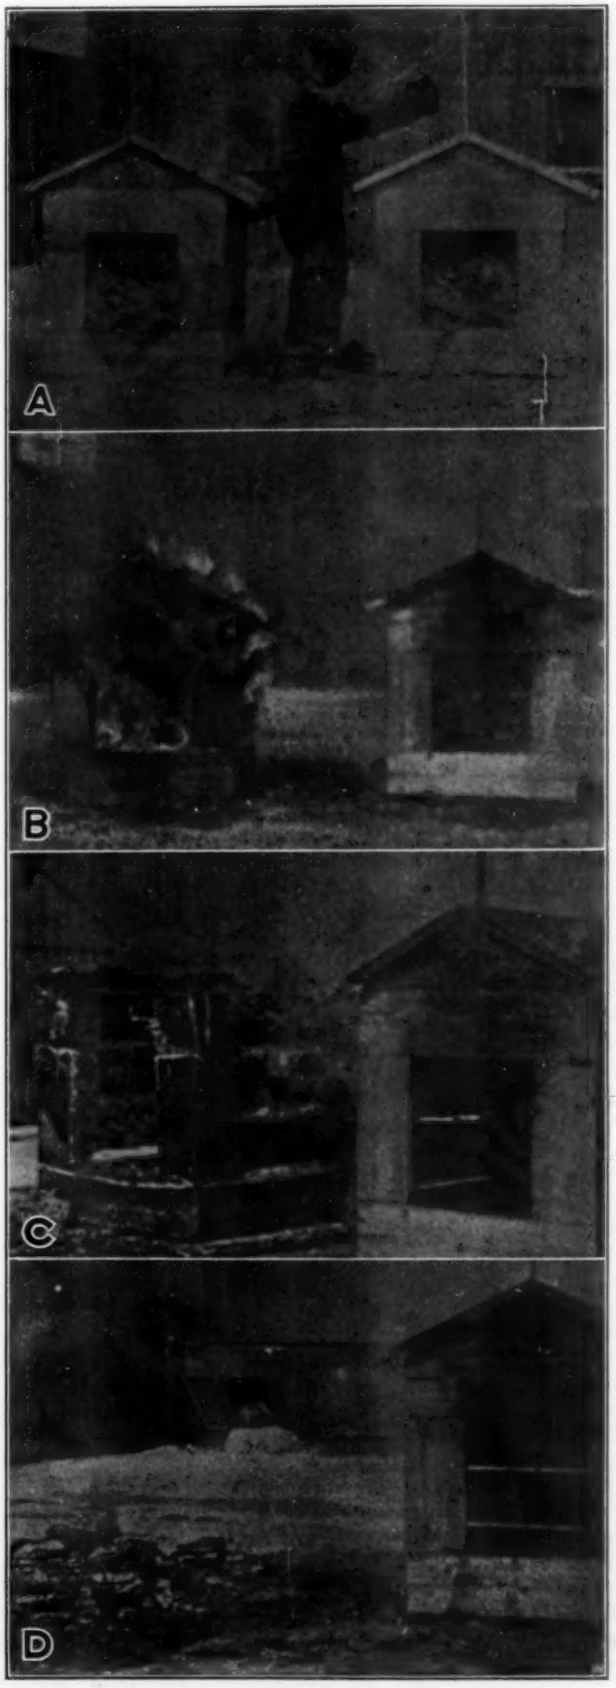

Fig. 3 (*Right*) Test of Comparative Fire Resistance

(*A*, small buildings of ordinary Eastern spruce, filled with excelsior and saturated with kerosene, the one at left not being treated and the one at right being treated by the Firesafe process; *B*, ten minutes after; *C*, twenty minutes after; *D*, thirty minutes after, the untreated wood being entirely consumed, while the Firesafe-treated building is in good condition.)

Partial Impregnation

Great fire resistance is obtained from surface impregnation; almost as much as from the full treatment. The thin coating of Firesafe wood acts like a covering of Kalamein and effectually retards the progress of fire. In a recent public test a flame of 6000 deg. fahr. under heavy pressure was directed at the surface of a piece of partially treated spruce lumber for a period of five minutes with only a shallow charred spot, the diameter of the flame, resulting.

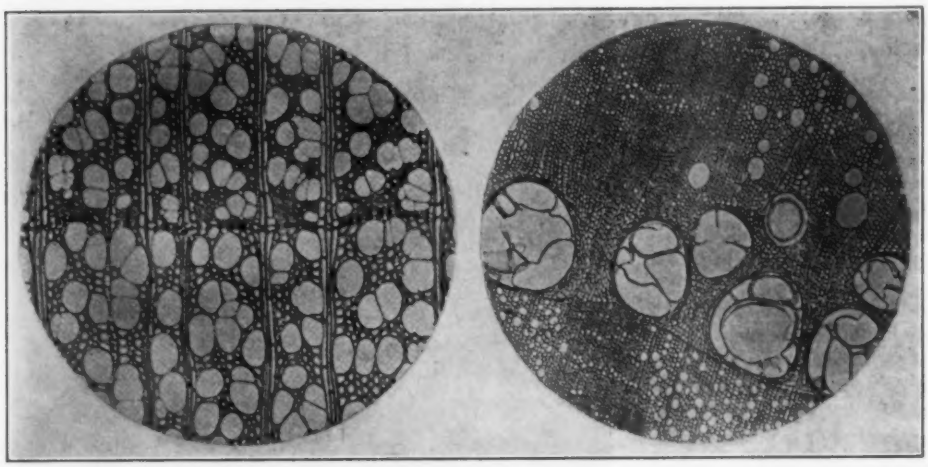

Fig. 4 Variations in Wood Structure; Poplar at Left and White Oak at Right

A severe practical test is shown in Fig. 3. Two small houses (4 by 4 by 5 ft.) were built from $1^1/_4$ by 9 Canadian spruce, all taken from the same pile. The one at the right was partially treated—that is, it was given the Firesafe and Dampsafe treatments, approximately $^1/_4$ in. deep—and then dried to 15 per cent moisture content. No boards were resawed or split but all were crosscut, exposing untreated ends. The one at the left was built of untreated (natural) stock. The houses were set 2 ft. 6 in. apart, filled with dry excelsior, and each one was saturated, inside and out, with five gallons of kerosene and ignited. The pictures tell the rest of the story.

Partially impregnated stock is ideal for many purposes; in fact, for practically all purposes where the lumber is not to be resawed or milled after treatment. The untreated ends present no danger, as fire will not work in against the end grain of the wood to any extent.

A great saving in cost on partially treated lumber is obvious; less chemicals are used, the drying is easier, and the stock is lighter in weight.

The Firesafe treatment leaves the lumber almost natural in color. It is therefore hard to distinguish, especially when mixed with other lumber on jobs. To prevent fraud and to protect the interests of all concerned, Firesafe lumber is in most cases colored a pale blue. This color may be easily covered by paint and is an important feature of this product. Careful tests show that the blue will not wash out of double-treated stock, although it may eventually fade. In the single-treated stock (Firesafe) it is less fast. Uncolored lumber may be had if desired.

Drying of Firesafe lumber in ordinary kilns is easily accomplished. The average drying time for $^4/_4$ fully treated stock is three to four weeks. In a patented type of vacuum kiln, known as the Triplex Dryer, which has been giving considerable satisfaction, this drying period has been reduced to approximately six days, and experiments are now under way which it is expected will reduce this still further.

Air drying on partially treated stock is recommended whenever the lumber can be piled up "single" for a period of a few weeks.

Species Treated

Wood structure is an important factor in impregnation. Some species are easily treated evenly to a depth of several inches; others are practically impenetrable. The pines, especially sugar pine, white pine, and short-leaf yellow pine, are particularly receptive to Firesafe treatment; also poplar, basswood, birch, and soft-textured red oak; while white oak and the fast-growing red oak of the South are practically impenetrable. The explanation of this is readily seen in the accompanying microphotographs (Fig. 4). Notice the regular spacing of the capillaries in the poplar and the absence of conspicuous bands of non-porous summer growth, and contrast these with the radically different structure of the white oak. Of course, in the white oak, there is a characteristic typical of this particular species (*quercus alba*) in the tyloses, or valves, which occur at frequent intervals in the arteries, closing them completely and setting up an invulnerable barrier to Firesafe solutions.

Then there is another group of difficult woods in the hemlocks and firs. In these occur dense, shell-like sections, non-porous and impenetrable, which effectually interrupt the flow of solution and partition off the softer parts of the lumber. In these woods a half-inch penetration is all that can be expected.

Generally speaking, the following commercial woods can be treated, and are arranged in the order of their receptivity:

First Group—Sugar pine, balsa, genuine white pine, pondosa, Idaho pine, California white pine, short- and long-leaf yellow pine, loblolly, North Carolina pine, chestnut, poplar, basswood, birch, maple, beech, ash, elm, soft-textured red oak

Second Group—Eastern spruce, Western red cedar, white cedar, Sitka spruce, mahogany, Southern red oak, balsam, cypress, walnut, redwood

Third Group—Fir, hemlock, pitchy pine, teak, aromatic red cedar

Fourth Group—White oak, rapid-growing Southern red oak, lignum-vitae, ebony, cocobola, hickory. (To date, these have not been successfully treated.)

General Characteristics

A knowledge of the characteristics of Firesafe wood is extremely necessary before a proper understanding of its qualities can be had. Considering first its negative features, although it will effectually resist combustion it cannot be expected to resist charring. Continued exposure to heat which would ordinarily cause wood to burn will eventually produce slow decomposition (charring). Further, as nature never repeats herself, no two pieces of wood are alike, and obviously some pieces are more receptive to the fireproofing chemicals than others. To impregnate a batch of lumber with enough chemicals so that every splinter in the load is fully treated is possible, but would mean heavy oversaturation in some parts. A commercial process is one in which the general mass of the lumber is rendered non-inflammable and an occasional spot or piece of poorly treated stock is tolerated, providing only that such spots or streaks do not occur in sufficient number to

materially impair the general efficiency of the product. All tests must be representative of the average condition of the lumber and must give an exact indication of what may be expected under actual fire conditions.

A positive fact not previously well understood is that while a piece of "fireproof" wood may be ignited by a match (low temperature), the same piece will show excellent results at very high temperatures due to the fact that only at relatively high temperatures do all the chemicals begin to function.

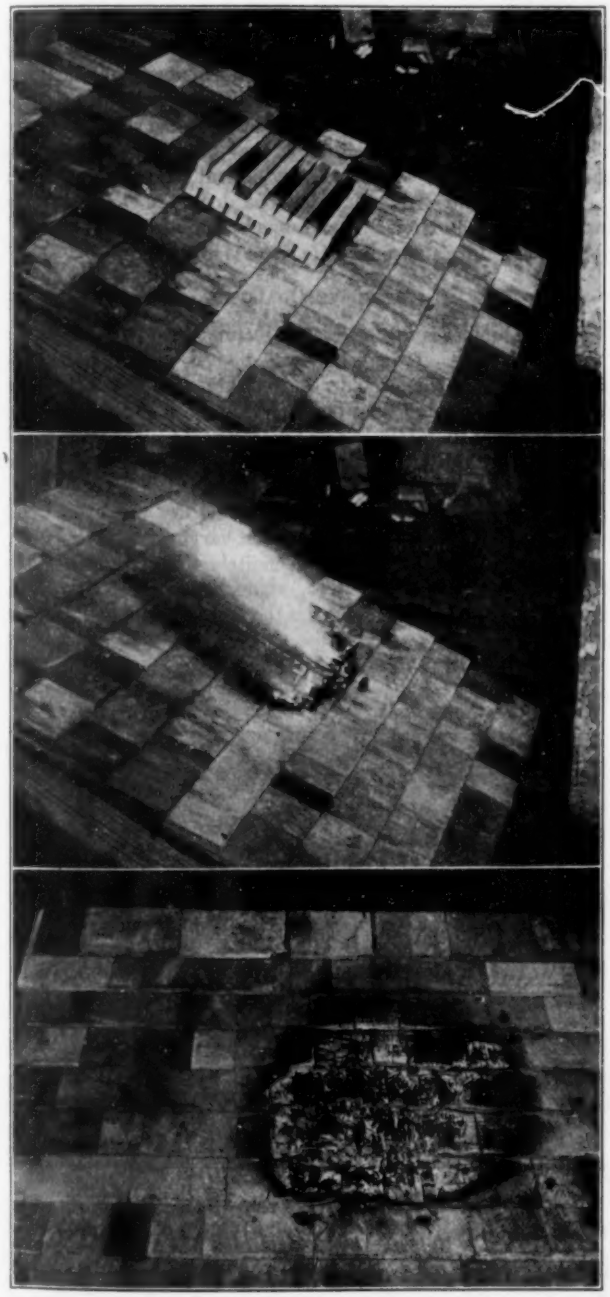

FIG. 5 BURNING BRAND TEST, SHOWING PROGRESS START TO FINISH
(Conditions of test are given in Appendix No. 2.)

EVERY CELL A FIRE EXTINGUISHER

Another fact of paramount importance is that every cell in a "fireproof" board is a diminutive fire extinguisher, for when heated it gives off fire-extinguishing gas. The larger the mass of

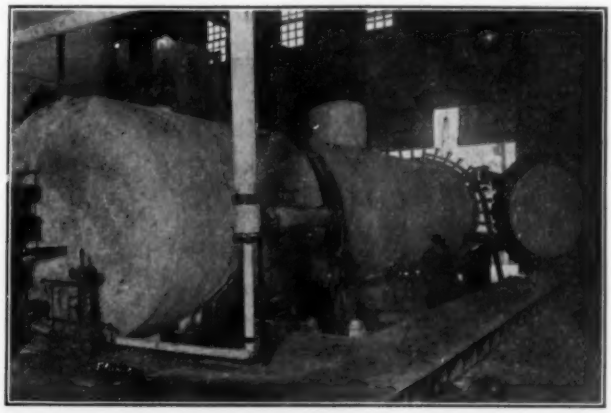

FIG. 6 IMPREGNATOR TANK OF GEO. H. STORM & CO., GENERAL BUILDING LUMBER

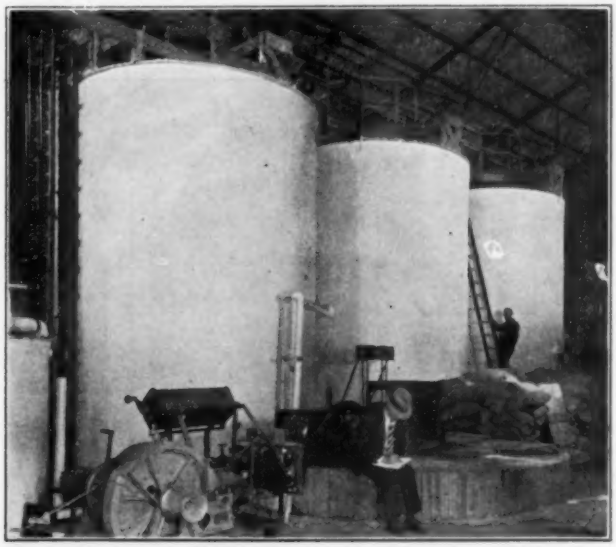

FIG. 7 STORM COMPANY'S STORAGE AND MIXING TANKS

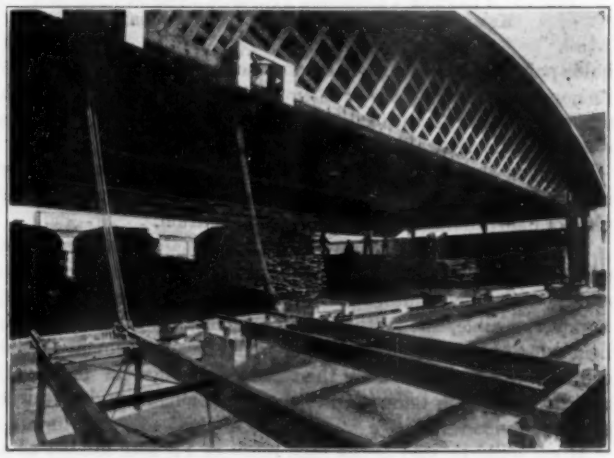

FIG. 8 STORM COMPANY'S LOADING SHED AND TRANSFER TABLE

"fireproof" wood heated, the more noticeable is the result. A "fireproof" wood floor gives off this gas at the base of a fire, the most effective point.

Firesafe wood may be finished like any lumber. It takes and

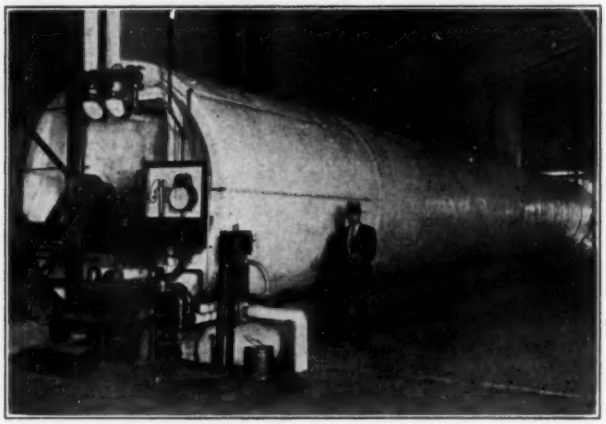

FIG. 9 STORM COMPANY'S TRIPLEX DRIER, TAKING FOUR CARS OF LUMBER

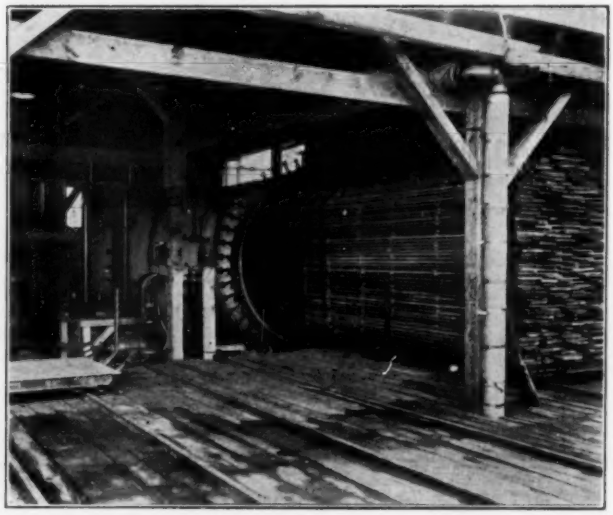

FIG. 10 PLANT OF TENNESSEE FIRESAFE LUMBER COMPANY, KNOXVILLE, MAKING SPECIALTY OF FLOORING

holds paints, varnishes, shellacs, and lacquers very well. Due to its non-hygroscopicity the problem of finishing, a difficulty which was encountered on earlier kinds of "fireproof" lumber, is in this case not difficult at all.

In gluing the same advantage applies. Glue joints made by numerous cabinet makers have been highly satisfactory, and after tests of many months still show no deterioration.

The strength of partially treated stock remains practically the same as before treatment, but a loss of 10 to 20 per cent must be expected on fully impregnated lumber. The treated lumber is, however, flexible, soft-textured, and resilient, any loss in strength being due only to a partial and sporadic disarrangement of the cell structure occasioned by the repeated changes in pressures, rapid variations in temperature, the transitions from dry to wet state, and vice versa.

Much could be said of the high merit of Firesafe lumber as a non-conductor of heat. Of course, wood generally is excellent in this regard, but not at high temperatures where combustion results. The Firesafe treatment makes available this natural excellence, as Firesafe wood even when heated above the flash point transmits the heat very slowly. So much so, in fact, that applying 1700 deg. fahr. to one side of a piece of $^1/_4$ in. thick Firesafe lumber for a period of five minutes raises the temperature of the opposite side very slightly. Thus a Firesafe wood door is vastly superior to a steel door as a fire stop. In actual tests Firesafe wood doors have withstood the direct attack of a severe fire five times as long as a standard Kalamein door and four times as long as a solid steel door. This means vastly greater protection. In addition to this, it must be remembered that a Firesafe wood door is easy to fit, meaning that less smoke will escape through the cracks, while it is very difficult to make Kalamein doors smoketight. Also Firesafe wood doors are comparatively inexpensive, and extremely handsome in appearance.

In electrical resistance Firesafe wood is low.

ABRASIVE QUALITIES

Firesafe lumber is much easier to manufacture than any other "fireproof" wood. It may be easily planed, sawed, and sandpapered. On machine molder knives, however, it means more frequent resharpening than on untreated stock, due principally to the fact that there is 20 per cent more mass to cut. High-speed machines and hard-steel knives which may be resharpened while in operation are the answers to this problem.

The average full treatment increases the dry weight of wood about 20 per cent; the partial treatment varying proportionately.

The question of cost cannot be definitely answered, as the cost varies with production, species, and sizes of lumber treated. In the average suburban residence the cost of making all lumber and shingles Firesafe would be not over 5 per cent of the total cost of the house. To use Firesafe trim, floors, doors, etc., in a "fireproof" city office building would increase the cost of the building

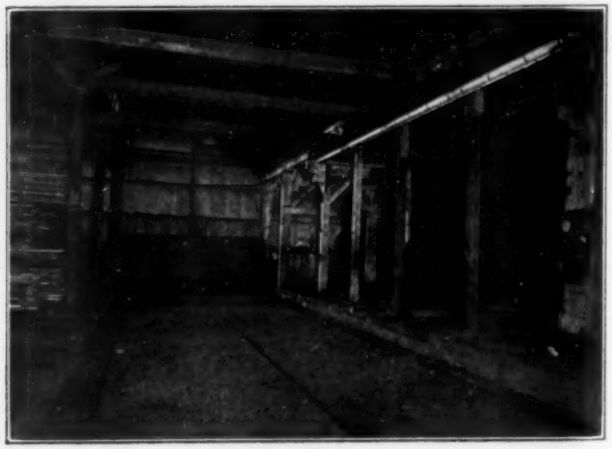

FIG. 11 PLANT OF SLOANE & MOLLER, NEW YORK, MAKING SPECIALTY OF TRIM

less than $1^1/_2$ per cent. To build a mill or factory building with Firesafe wood beams, floors, partitions, and roof would effect a saving over steel and concrete construction in these items of more than 25 per cent—and the building could be erected much more quickly regardless of weather conditions and would be superior in many ways. Firesafe wood partitions are cheaper, better looking, and far more fire-resistant than steel partitions. Firesafe wood-shingle roofs are most handsome, far warmer in winter and cooler in summer, and cost a minor fraction of the price of a good slate or tile roof.

Flooring

Many millions of feet of "fireproof" oak flooring have been used in New York in the last decade or so, and most of these millions have been "bad advertising" for "fireproofed" wood, for the very simple reason that the flooring was treated after manufacture instead of before as it is now being done. The warping, too tight matching, discoloration, and moisture-attracting features of these earlier treatments are a thing of the past. Already a large treating plant, together with a flooring factory, has started operations in the world-renowned, soft-textured oak belt of the Appalachian Mountains, and Firesafe oak flooring of all kinds, treated before manufacture, is now being produced. Builders, architects, and owners can now have all the beauty of oak parquet floors, thoroughly Firesafe, natural in color, perfectly milled, at lower cost than "fireproof" oak floors ever were procured for in the past.

Shingles

The most difficult of all fireproofing jobs is the treatment of wood shingles. Exposed to the elements for many years, "face up," these thin pieces of soft wood must be perfectly Dampsafe if the fireproofing chemicals are to retain their efficiency. Not only are the chemical problems large, but the question of coloring and the mechanics of impregnation and drying are individual problems of this one product.

Suffice it to say that although the many tests now in progress are still incomplete and conclusive data are not yet available, there is sufficient evidence to warrant the opinion that Firesafe

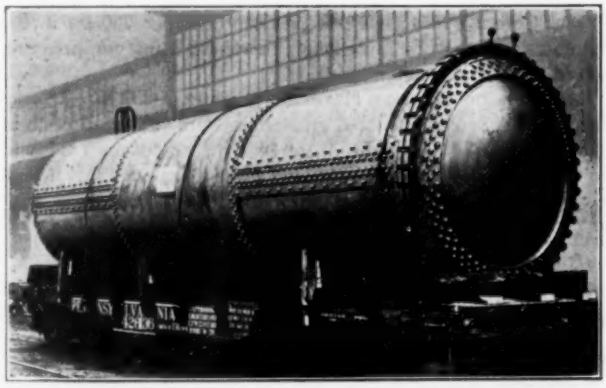

Fig. 12 A Treating Cylinder en Route to Plant of Chesebro-Whitman Company, Long Island City, N. Y., Who Make a Specialty of Scaffolding

shingles are an assured success. After six months of exposure on a roof during which period they were hosed for twenty minutes each day, the shingles show the original fire-resistance. Several laboratories are now running Weatherometer tests, and in a few months definite results will be known.

The Class "A" fire test of the Underwriters' Laboratories is shown in Fig. 3. Time and again Firesafe shingles have withstood the grueling punishment of this test, with no further damage than a charred area equal to the size of the burning brand.

Much success has been attained in the Firesafe treatment of both insulating and panel boards. This is a specialty process however, and must be done during regular manufacture of the boards—a mechanical problem upon which our engineers are now working. The chemical research is practically complete; Firesafe boards retaining full insulating values have been made; and this field, having large potentialities, is about to be opened.

It is not feasible to Firesafe standard panels in board form due to the fact that the interstices of the board are filled, causing a diminution of its insulating efficiency. Further, the problem of drying without warping presents an almost insurmountable obstacle.

Fig. 13 Scaffolding Job of Blue Firesafe Planks on Tubular Steel Uprights

In addition to those uses and applications mentioned, the following should be noted:

Scaffolding, sidewalk bridges, grandstands, stage scenery, motion-picture-studio equipment, airplanes, launches, ships, barracks, storehouses, residences, apartment houses, factories, garages, elevated stations, subway construction, temporary and permanent work in stores, hotels, expositions, furniture, showcases, vaults, storage bins, lockers, and—a most important use—seashore and mountain hotels and cottages.

Conclusion

The development of the Firesafe process has brought to lumber, that "most likable" building material, what has come to other products at earlier stages in their use.

Though tardy, this development is yet in time. It has been a serious work undertaken by responsible interests on a large scale. It has already reached commercial proportions and is growing rapidly. The laboratories are still being maintained, and, naturally, further and continued improvement is to be expected.

Appendix No. 1

REGULATIONS OF THE BUREAU OF BUILDINGS OF THE BOROUGH OF MANHATTAN FOR THE TESTING OF FIREPROOFED WOOD

Before any fireproofed wood may be used for flooring or interior trim where incombustible materials are required under the provisions of Section 356 of the Building Code, the material must be subjected to the following tests, which are to be conducted under the supervision of the superintendent of buildings or his representative, but at the expense of the owner or contractor or other interested party.

The superintendent of buildings must be notified promptly upon the arrival at the job of a consignment of the material. One test sample for each 2000 feet of material will then be selected by a representative of the bureau, marked for identification, and forwarded to the testing laboratory.

(1) For the *shavings test* a mass of shavings cut fairly thick from the outside and interior of sticks of the treated wood are tested separately. These shavings are placed at a depth of 2 inches in a metal vessel 12 inches square, the bottom of which consists of a wire screen of $^1/_2$-inch mesh. The shavings are packed down moderately to reduce the air spaces. A bunsen yellow flame is then placed beneath the receptacle so that the flame is in contact with the shavings. After 25 seconds the flame is removed. The flame at no time should show higher than 6 inches above the top of the bed of shavings and the shavings should not be consumed in less than five minutes.

(2) For the *timber test* two samples $^3/_4$-inch by $1^1/_2$ inches in cross-section and 12 inches long are laid side by side across the top of a gas crucible furnace with a pyrometer between them. The specimens are subjected to a flame at 1700 deg. fahr. for two minutes, the test pieces are then removed, and the time of duration of flame and glow are observed. The sticks are then cut through the middle at the most-burned section, and the area of the unburned wood is measured with a planimeter. The flame must not persist longer than 15 seconds nor the glow longer than 20 seconds; and in the case of hard woods, the unburned area should not be less than 55 per cent, nor in the case of soft woods less than 45 per cent.

(3) For the *crib test* twenty samples are prepared, each $^1/_2$-inch square and 6 inches long. These are built up on a ring support to form a cribwork five tiers high, four sticks to a tier, making the crib 6 inches by 6 inches and approximately $2^1/_2$ inches high. The crib is set 6 inches above a bunsen burner to which the crib is exposed for a period of one minute at a temperature approximating 1200 deg. fahr. The flame must not persist more than 20 seconds after the bunsen burner is removed, nor the glow last more than 30 seconds. The tendency of the flame to spread from stick to stick is also noted.

If the tests are satisfactory the entire shipment is permitted to be taken into the building and used. If not, the entire shipment is condemned and must be removed from the premises.

In general, acceptance is predicated upon the existence of a complete plant in full working order from which the material is shipped; also that each shipment, or where possible each piece, is trademarked in a conspicuous manner so that there may be no doubt as to its identity.

Appendix No. 2

"CLASS A" SHINGLE TEST OF THE FIRE UNDERWRITERS' LABORATORIES

Roof Panel. Make section of roof 4 ft. square with shingles set 4 inches to the weather. Raise "ridge" side so that panel slopes at an angle of 30 deg.

Brand. Cut 30 strips of kiln-dried spruce, extra-fine quality, dressed four sides, 1 inch square by 12 inches long. Have these dried to bone dryness, and the morning of the test nail together 10 strips to the layer, $^1/_4$ inch apart, making a cube with $^1/_4$-inch air spaces throughout.

Fire. Light the brand over a gas flame, and when burning freely, transfer to center of roof panel.

Fan. By means of an electric fan blowing directly against the burning brand, induce a 12-mile-per-hour draft. Continue until brand is burned out.

Shingles should not support combustion, and blaze should not spread.

Discussion

MR. RANDOLPH.[2] How does this affect the cost?

MR. STORM. At present the lumber is sold from $40 to $80 over the cost of the raw wood. We hope to reduce those prices largely with large production.

MR. COHEN.[3] You use one pressure of about 250 lb. in the cylinders. This wood is variable; therefore, using one pressure, would variable results be obtained?

MR. STORM. We use a maximum pressure of 250 lb. In case the wood is dense, we use a greater pressure. The criterion is the saturation of the wood. If the board when cut open is found to be fireproofed in the center, the pressure is enough; if it is not fireproofed in the center, the pressure is not enough.

TESTING LABORATORIES COLUMBIA UNIVERSITY NEW YORK CITY

NOTE: No responsibility is assumed by Columbia University for the results or conclusions of any tests made in these laboratories. Publication of results or tests in full may be made, but it is understood and agreed that no abstract of any report will be published as coming from these laboratories without the written consent of the Committee on Testing.

We have found that we can penetrate red oak and other commercial woods that we are using continually with 250 lb. pressure. From the consumer's standpoint that item is not particularly important. What he is concerned with is that he is getting a completely Firesafe board, Firesafe in the sense that it is saturated throughout. One may find in some places a splinter or an oil pocket which will give a little flame. We tolerate a percentage of that. It might be possible to make a board so fully saturated that it would not flame in any part, but that is not commercial. We want a load of lumber which will pass the usual tests. I do not mean that in a load of lumber every other piece will blaze, but I do mean that there are occasional pieces to be found in a charge of lumber which will give a little flame, but that is only because there are pockets and streaks and knots.

MR. POWER.[4] Is this lumber on sale anywhere or does it have to be obtained by having a car treated?

MR. STORM. We carry quantities of various kinds in stock. We aim to carry a stock of all kinds of Firesafe lumber for a diversified trade.

QUESTION. The extra cost of fireproofing is $40 to $80 per 1000 ft. Is it higher for the lighter or for the heavier sizes?

MR. STORM. It takes a longer time to penetrate the thicker lumber and also longer to dry it. The $40 price is for partially impregnated lumber. It varies with the quantity treated, the kind treated, the thickness, and the amount of impregnation, these four factors governing the price. Boards delivered from stock will have required more in handling, storage, and so forth. The lowest price would be obtained when a customer had carload lots brought in, treated, and promptly reshipped. All of these factors govern the price much as the price of lumber itself is governed. That is not peculiar to this industry.

MR. BLOOM.[5] If this chemical is soluble in water, how is the agitator on the impregnating cylinder necessary?

MR. STORM. There are certain parts of the chemical that are not completely soluble, the solubility varying with the temperature. As the lumber cools down, there is a lessened saturation. The agitator is underneath the cars at one end of the cylinder, and it circulates the solution up through the cars and back through the lumber. We take frequent hydrometer readings so as to maintain an even solution at all times.

MR. DONALD.[6] Have you had any measurements of the insulation value of the treatment, for instance for cold storage?

MR. STORM. We do not claim that the treatment increases the natural insulating qualities of wood. It makes available those natural qualities which cannot be used in ordinary lumber after it is heated up beyond the flash-point.

MR. O'CONNORS.[7] Have you carried on any tests in damp cellars?

MR. STORM. We have stored this material in open sheds by the river front for months at a time, and it has never shown any superficial accumulation of moisture except on very wet days, and then it is slight and unimportant.

RALPH H. MANN.[8] The paper refers to freedom from rot and greatly increased resistance to fungus and insect attacks of all kinds in Dampsafe lumber. The American Wood Preservers' Association deals with the preservative treatments of lumber. If we can combine a preserved stick with a Firesafe stick, the wood industry will receive material benefit. Have any tests been made on safeguarding the timber from fungus rot on top and decay in the stick?

MR. STORM. As to whether we have made tests to show the preserving qualities of our treatment, of course the preserving of the wood up to the present time has been secondary in our minds. It is important, we realize. The double-treated lumber, that is the Dampsafe lumber, placed in very wet locations, as on the ground under lumber sheds, for a period of over two years, shows no fungus attack and no rot. We have not carried the test out more scientifically than that, but we have great confidence in the treatment to resist fungus attack. As to what chemicals were used in the old-style wood-fireproofing methods, they were a combination of chemical salts. The weight put in was about 2¼ lb. per gal. of solution treated, with 280 gal. per 1000 board feet, measured with a lumberman's scale.

MR. DAVIDSON.[9] I might contribute one answer in connection with experience in the deterioration (or less deterioration) of Firesafe scaffold plank. I do not refer to the long-time decaying, but to the deterioration formerly on scaffolding lumber and other lumber that is used over again on structural operations when it is fireproof. We have discovered that we could not expect the scaffolding plank to be used many times because lime and plaster and cement would be ground into the plank, and the traffic across that plank makes it wear out very quickly. Since we have been using Firesafe plank we have discovered that though the lime, cement, and plaster fall on it as before, when it comes back from the job that material can be brushed off. In other words, it does not penetrate the fibers of the wood, and thus the lumber can be used over a good many times, far more than untreated lumber.

B. HUBER.[10] Would the so-called fireproof or treated lumber for fire-retarding purposes, made also dampsafe according to Mr. Storm's idea, have a logical application for roofing boards, lumber piles, and so forth? I understand the ordinary fire-retarded material would leach out unless some other preservative treatment were given to keep that fire-retarding material in. After a course of time the chemicals would leach out. The old cabinetmaker's bogy was the shrinkage and swelling of wood. Does a treatment of this kind promise any relief or aid in retarding the effect of shrinkage or swelling of wood?

MR. STORM. Firesafe and Dampsafe lumber swells and shrinks less than untreated lumber of a similar kind, I should say 50 per cent less. If it is desirable to have roofing boards Firesafe, we would recommend the treatment. If you want a weatherproofing board, something like Valspar varnish or some paint coating probably would give additional protection to the chemical treatment. We do not offer this as a weatherproof coating. We do not know whether a double-treated or Dampsafe board would outlast a board heavily painted with lead and oil paint, for example.

MR. HUBER. But the lead-and-oil painted board would be very highly inflammable as compared with the other. I am seeking to get the advantages of the fireproof or fire-retarded lumber for a covering board and have it last as long or longer.

MR. STORM. It is our feeling that the Firesafe and Dampsafe board will have very long life if exposed to the weather in the same manner as a shingle would have, but if one wanted to expose it for many years, perhaps the fireproof or Dampsafe board should be painted in addition to the fireproofing, and then one would have something more nearly permanent.

have fai'ed in the case of fireproof contents. Take, for example, a building of brick walls, steel frame, concrete floor of steel, supported by steel columns. In case of a hot fire inside, those beams have warped and failed. The floor above has caved in. That means, then, that the steel, although it will not burn, loses its strength. Is this Firesafe lumber so immune that though it will not burn it will still maintain its strength?

MR. STORM. There is a certain loss in strength due to charring. Do you want a comparison between a building constructed of steel and concrete and one constructed purely of wood?

MR. JONES. Suppose a steel beam will support 100 lb. per sq. ft. of floor surface; take the same floor construction of joist, maybe 12 in. apart, centered with a plank on top of the joist or board; will the flooring supported by the beams of steel stand up as long or longer than the wood?

MR. STORM. If the steel is unprotected by concrete, the wooden beam will stand up far longer than steel under the same load. We are now running tests on that.

MR. CARTWRIGHT. I would like to suggest that perhaps the point Mr. Jones seems to have in mind would be settled even more effectively by boxing in either the timber column or the beam or structural shape with an inch or two of fire-retarding treated material, which would not be counted upon for load-bearing capacity, but would be an insulation protection for the structural shape itself.

MR. STORM. We have that in mind. We feel that Firesafe wood as a protective coating for steel has a very large use. We have not carried our tests through on that yet, but we hope to soon. I think it is generally conceded that even a non-treated wooden post, while it may eventually burn up, will not give out as quickly as an unprotected steel post will under identical heat conditions.

(NOTE: Discussion of this paper jointly with that of T. R. Truax and C. A. Harrison by Frank P. Cartwright, Chief Engineer of the National Lumber Manufacturers Association, and by Ernest F. Hartman, President of Protexol Corporation, will be found in the discussion of the latter paper.)

WDI-52-4b

Measuring Fire Resistance of Wood

By T. R. TRUAX[1] and C. A. HARRISON,[1] MADISON, WIS.

The Forest Products Laboratory has devised the fire-tube test to accurately measure in definite terms the property of wood to resist the spread of flame. As an acceptance test, the fire-tube method promises to be useful in evaluating the factors and conditions which affect the fire resistance of wood, as well as a means of working out the problems of those in the business of treating wood with fire retardants.

WOOD, in common with other vegetable materials, decomposes when subjected to high temperatures and evolves inflammable gases. Wood also contains moisture which turns to vapor upon heating. When wood is heated, the moisture vapor is first driven off. If the temperature is increased and heating is continued, resinous and oily materials are volatilized and eventually the wood substance is broken down. During the decomposition both inflammable and non-inflammable gases are evolved, and a combustible residue, the charcoal, is left behind (4).[2] Continued heating of the charcoal at high temperatures in the presence of air causes combustion and a change into carbon dioxide, a non-combustible gas. This whole process of decomposition is accompanied by an evolution of heat. The temperature at which wood ignites and burns depends upon a number of factors, such as the time of heating, the moisture content of the wood, presence of extractives, size of pieces, amount of air available, and density and porosity of the wood. According to Lullin (7), when the temperature reaches 150 deg. cent. (302 deg. fahr.) inflammable gases (hydrocarbons, carbon monoxide) and carbon dioxide are evolved and the wood scorches until 230 deg. cent. (446 deg. fahr.) is reached. From 230 to 270 deg. cent. (446 to 518 deg. fahr.) "red charcoal" is formed, and at 300 deg. cent. (572 deg. fahr.) black charcoal is formed. Norton (10) reports that certain untreated species of wood ignite at 435 to 510 deg. cent. (815 to 950 deg. fahr.) and flash instantly into flame at 510 to 615 deg. cent. (950 to 1139 deg. fahr.). Prince (11) found that untreated woods (oven and air dry) ignited and burned within 15 to 40 minutes when heated at temperatures of 175 to 220 deg. cent. (347 to 428 deg. fahr.). When heated at temperatures of 350 deg. cent. (662 deg. fahr.) ignition occurred within one to three minutes. Likewise, Lullin found the temperature of glowing (incandescence) of different air-dried woods to be between 318 and 368 deg. cent. (604 and 694 deg. fahr.) and of the same woods, previously dried in a vacuum at 100 deg. cent., between 307 and 339 deg. cent. (585 and 642 deg. fahr.). He also found that the glowing temperature for wood charcoal was within the range of 400 to 500 deg. cent. (752 to 932 deg. fahr.), being appreciably higher than for wood. Lullin does not, however, give the time of exposure before glowing or flaming occurred. Hawley and Wise (4) report in connection with wood-distillation work that wood begins to decompose at about 275 deg. cent. and that up to this temperature the main changes that take place are the drying of the wood and the volatilization of various extraneous materials, water being the main product, although some acetic acid and a trace of methanol are formed.

The work of Norton (10), Prince (11), Banfield and Peck (2), and Lullin (7) shows that treating wood with fire-retardant chemicals increases the ignition temperature somewhat. The order of magnitude of this increase was found to be from 0 to about 200 deg. cent., depending upon the kind of chemical used. However, even with thorough impregnation of the wood with concentrated solutions of the most effective fire retardants the ignition temperature is well below the temperature of flames. Both treated and untreated wood char at temperatures which commonly prevail in fires (6). So far as is known no commercial treatment wholly prevents combustion and no treatment can prevent the charring of the wood.

The fire resistance of wood may be considered from a number of points of view. Chief of these are the extent to which it gives off inflammable gases when heated, its resistance to the spread of flame and to the building up of temperatures, its resistance to flame penetration, and its heat insulation. The effects of the treatment on other properties of wood, such as strength, finishing, gluing, hygroscopicity, and corrosion of metals in contact with it are all-important characteristics in the utilization of the wood, but are not a part of fire resistance. Still other properties may be important for certain special uses.

Various Methods of Test

Various attempts, resulting in many forms of tests, have been made to measure the inflammability or fire resistance of wood. In general these attempts may be classified under tests on samples of wood and tests on built-up assemblies under approximate fire conditions. Tests on built-up assemblies are expensive and are therefore limited in their application. This article deals only with the testing of samples or pieces of wood.

The flame-penetration test by which a gas burner or blow-torch flame is applied to a piece of wood has been used by many as a measure of fire resistance. Since it is quickly and easily made with simple apparatus, it has been more extensively employed than more accurate means of tests. In some forms of this test the time required for a flame to burn through a board or timber or for a loaded timber to fail when subjected to the flame is used as the measure of fire resistance (1). The depth of flame penetration in a board, the area of unburned wood in a timber,[3] and the time required for a loaded timber in contact with a flame to fail are essentially measures of the same property—namely, the resistance of wood to flame penetration. Undoubtedly, heat insulation is a most important factor affecting the rate of flame penetration and where possible may well be made a part of the test.[4] In tests of flame penetration, the density of the wood is a very important factor and may affect the results as much as the fire-retardant treatment.

A number of fire-resistant tests are based on measuring the time of flaming and glowing of wood which has been ignited and

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] The City of New York has for some time used tests to determine whether wood meets building code requirements (9). The timber test, one of three tests applied, is based primarily on the unburned cross-sectional area of pieces of wood exposed to a flame for a given time (13).

[4] In some flame-penetration tests made at the Forest Products Laboratory, a thermocouple, insulated from the air, was placed on the opposite side of the board from the flame and the increase in temperature during test was observed.

then removed from the source of ignition. Such tests as the "crib" (9), "splinter" (3) "shavings" (9), "timber" (13), and "muffle" (10) are wholly or in part based on this principle. This form of test has frequently been supplemented by measuring the time required to ignite wood as was done by Prince, or as in the "flue" and "kindling" tests (10) or by measuring the height of the flame as in the shavings, muffle, and "cob house" (10) tests. Most of these tests show differences in fire resistance between wood untreated and effectively treated with fire retardants, but the time required for ignition and of flaming and glowing after ignition depends upon so many conditions that such tests are of doubtful value as an accurate measure of fire resistance. Furthermore, the tendency to flame and glow after removal from

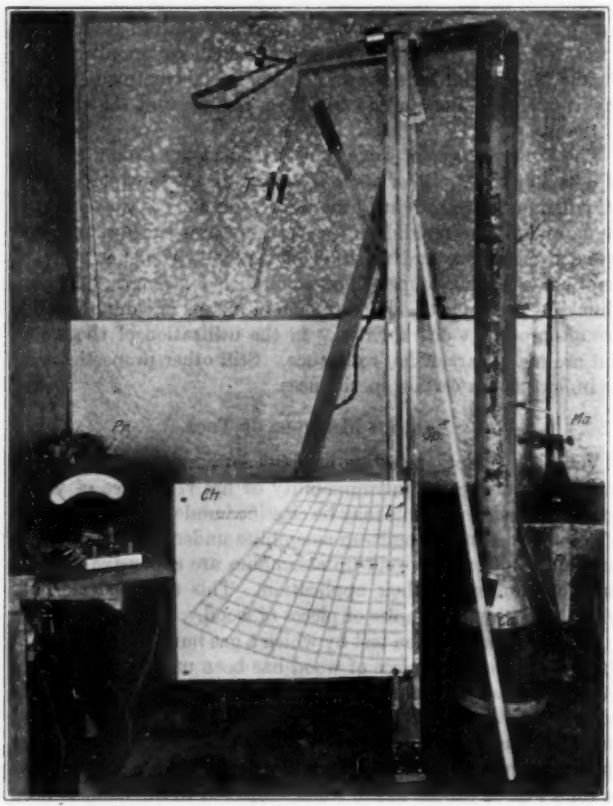

FIG. 1 THE FIRE-TUBE APPARATUS DEVELOPED AT THE FOREST PRODUCTS LABORATORY

a source of heat into ordinary room temperatures does not necessarily indicate the behavior of wood under fire conditions.

Closely related to the time required for ignition is the temperature of ignition. This was used in the "hot plate" test (10) and by Prince (11), Hicks (5), Banfield and Peck (2), and by Lullin (7). The test has been perfected until it is more precise and definite than the time of glowing and flaming, but here again the ignition temperature may or may not measure the essential property of fire resistance. It is possible, for example, for a piece of wood that ignites at a high temperature to continue to burn and give off more heat than a piece which ignites at a lower temperature. It is also true, of course, that wood either untreated or treated with fire retardants ignites at temperatures much below those produced in burning.

McKenna (8) measured the volume and character of gases evolved in heating wood in an electric retort at 680 deg. cent. (1256 deg. fahr.) and attempted to evaluate the fire resistance of wood in this way. Loss in weight during exposure of wood to ignition temperatures was recorded by Prince and Hicks, but neither used it as the principal measure of fire resistance. The spread of flame is also a factor in making certain tests such as the shavings, crib, and flue tests and Prince's inflammability test. No attempt appears to have been made, however, to measure it

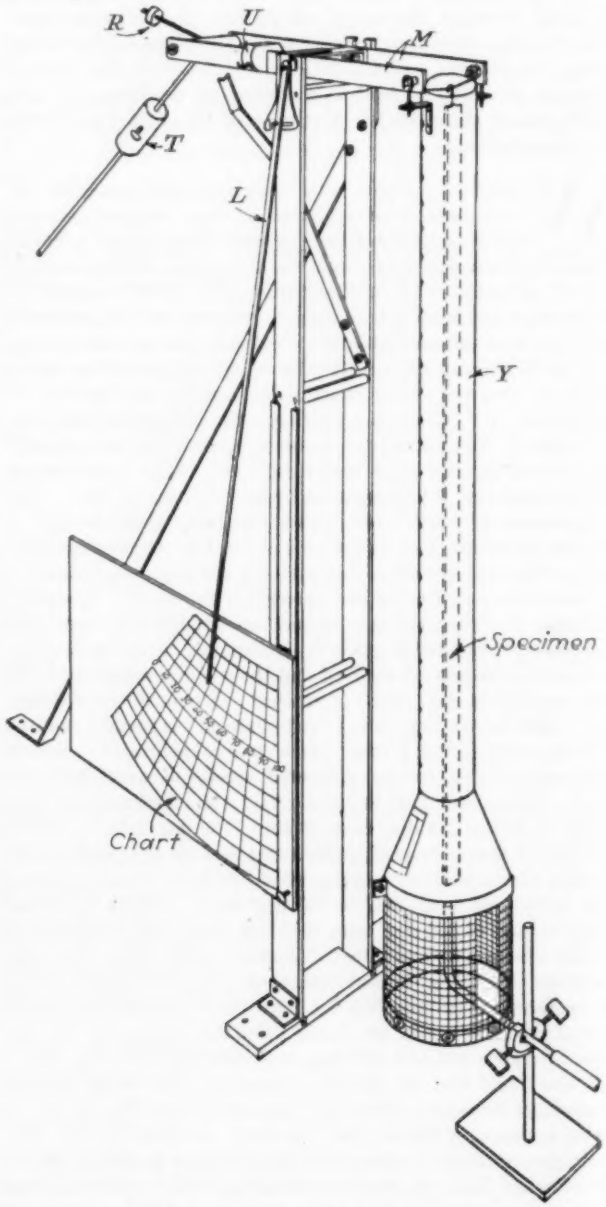

FIG. 2 DRAWING OF THE FIRE-TUBE APPARATUS

accurately or to report it concisely, although it has been recognized as an important factor in fire-resistance (13).

In nearly all the tests referred to comparatively small pieces of wood were used, and in most cases the entire pieces were subjected in test to uniform temperatures. As a result, the entire specimen starts burning at the same time in most tests and affords no direct measure of the tendency of wood to spread flame. It is also felt that greater attention should be given to the property of wood to increase temperatures under incipient fire conditions and thus to contribute to its own destruction. Ignition temperature,

flame penetration, and similar tests do not appear to measure this property adequately.

The Fire-Tube Apparatus

In trying to overcome the limitations of test methods used in the past, M. E. Dunlap, of the Forest Products Laboratory, devised what is now commonly called the "fire tube," shown in Figs. 1 and 2.[5] It is an apparatus which shows directly and progressively during test the loss in weight and the temperatures developed when a specimen of wood is exposed to conditions approximating those existing in fires. Observations are also made of the tendency of the charred wood to glow. It has been used extensively at the Forest Products Laboratory during the past two years and has been compared with certain other forms of test. The results of these investigations show that the fire-tube test has a number of advantages over other forms of test that are commonly used and is very satisfactory for research work. It is sensitive enough to show differences in the inflammability of different species of untreated wood or of the same species of wood at a different moisture content. It shows differences between the effectiveness of different chemicals, differences between various absorptions of the same chemical, and even differences between the outside and the inside of a board completely penetrated with chemical. Furthermore, the test results are expressed

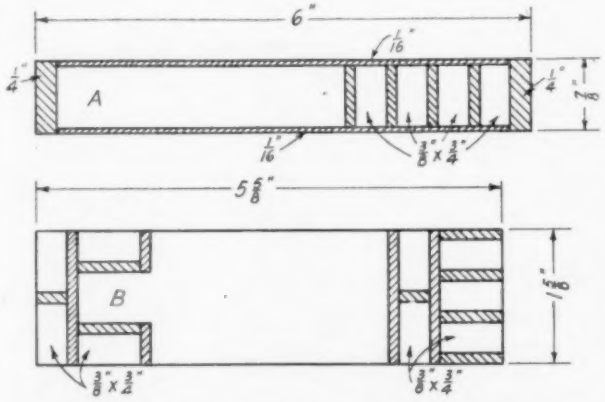

Fig. 3 Methods of Cutting Test Specimens

(*A*, Principal method used in tests described in this paper; surfaced after treatment. *B*, Possible methods of cutting specimens from unsurfaced dimension stock; unsurfaced after treatment.)

numerically and can be duplicated with a reasonable degree of accuracy.

On the other hand, the instrument is not proposed as a complete measure of fire resistance. It gives only part of the information needed in adapting fire-resistant wood to the requirements of the various purposes for which it may be used. Supplementary tests must obviously be employed, for example, to determine how long a load-carrying member will support its load while subjected to fire conditions, how rapidly heat will be transmitted through wood, and perhaps how rapidly flame will penetrate a board.

The Method of Test

In developing and perfecting the apparatus and the details of the testing procedure many tests were made on treated and untreated wood, some of the results of which have been reported (12). The following is a summary of the test procedure adopted as a result of that work:

Specimen. Use a single specimen 40 in. long and 3/8 by 3/4 in. in cross-section, conditioned to constant weight under a uniform relative humidity of 30 per cent and a temperature of 80 deg. fahr. Weigh the specimen immediately before test.

Heat Source. Use a horizontal, low-form bunsen burner, adjusted to give a blue flame 11 in. (±1/2 in.) in height with a tall indistinct inner cone; temperature 1000 deg. cent. (±25 deg.) at the hottest point of the flame and 180 deg. cent. (±5 deg.) at the top of the tube; the top of the burner to be placed 1 in. below the bottom of the specimen.

Duration of Test and Measurement of Results. Leave the ignition flame under the specimen exactly 4 min., and then remove it. Read the percentage loss of weight and the temperature at the top of the tube at 1/2-min. intervals from the beginning of the test until 2 min. after flaming stops. Note also the loss in weight at the exact time the flame goes out and the time at which the temperature reaches the maximum. Also record the tendency of the charcoal to glow after the flaming stops.

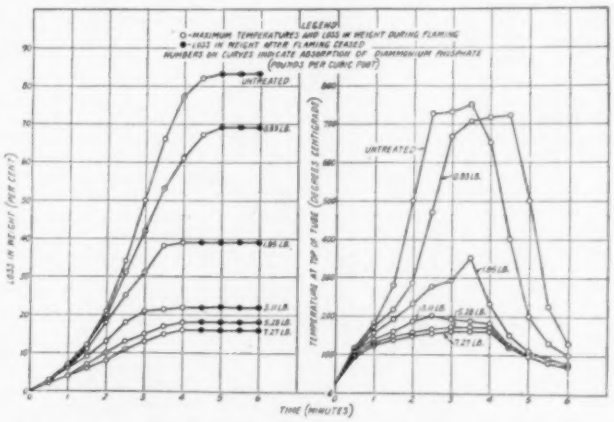

Fig. 4 Typical Loss in Weight and Temperature Curves From the Fire-Tube Test

(Each curve represents a single specimen of Southern yellow pine. Boards surfaced after treatment and drying.)

Preparation of Wood for Test

In preparing wood for test at the Forest Products Laboratory, the treated material is placed on stickers soon after treatment in a room maintained at a relative humidity of 60 per cent and a temperature of 80 deg. fahr. This brings untreated wood to an average moisture content of about 11 per cent. The moisture content of most treated wood will be about the same under these conditions, but some chemicals have considerable attraction for moisture, and wood treated with them may come to equilibrium at a somewhat higher moisture content than untreated wood.

After the boards have come to approximate equilibrium at 60 per cent relative humidity, specimens are cut about 2 in. longer than desired for test and placed in a room maintained at a relative humidity of 30 per cent and a temperature of 80 deg. fahr. This brings untreated wood to a moisture content of between 6 and 7 per cent. On account of the effect of moisture on the results of the test, it is important that the specimens be properly conditioned before testing. After the specimens are constant in weight, and immediately before test, they are trimmed to exactly 40 in., and then weighed and tested.

Boards may be surfaced after treatment or left unsurfaced, depending upon the class of material being tested. In sampling fire-resistant lumber which is to be surfaced before using, such as interior trim, the test boards should be surfaced after treatment and drying, just before the specimens are cut. Likewise, the specimens may be cut through the board from side to side or from one edge or one side depending upon the dimensions and

[5] A complete working drawing of the apparatus may be obtained upon application to the Forest Products Laboratory.

class of material being tested, as shown in Fig. 3, *A* and *B*. For example, lumber for interior trim should be surfaced to about $^{3}/_{4}$ in. in thickness after treatment and drying and the specimens cut from the surfaced boards as in Fig. 3*A*. In the case of dimension stock, such as scaffolding, or floor sleepers, which in practice are not surfaced before using, the specimens may be cut from the surface of the piece, as shown in Fig. 3*B*.

In making a test the empty apparatus is first balanced by means

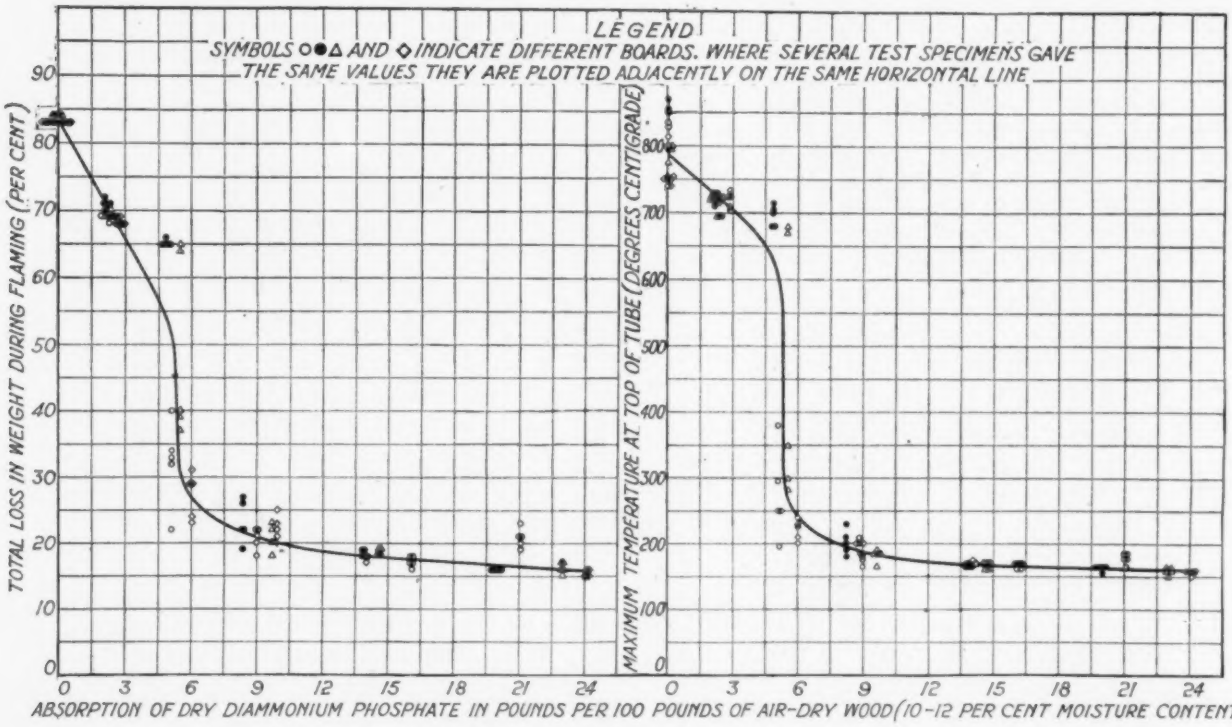

FIG. 5 EFFECT OF DIFFERENT ABSORPTIONS OF DIAMMONIUM PHOSPHATE (EXPRESSED AS PER CENT OF WEIGHT OF WOOD) ON FIRE RESISTANCE OF SOUTHERN YELLOW PINE
(Each point represents a single specimen. Boards surfaced after treatment and drying.)

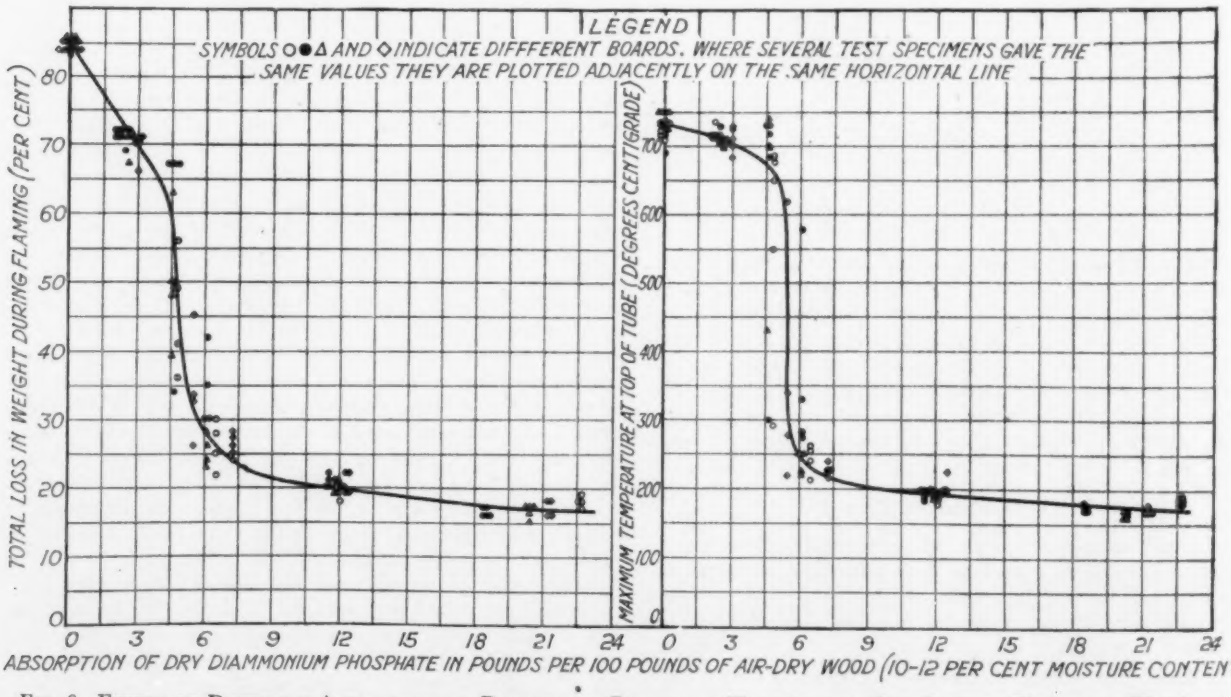

FIG. 6 EFFECT OF DIFFERENT ABSORPTIONS OF DIAMMONIUM PHOSPHATE (EXPRESSED AS PER CENT OF WEIGHT OF WOOD) ON FIRE RESISTANCE OF YELLOW BIRCH
(Each point represents a single specimen. Treated boards surfaced after treatment and drying.)

of counterweights *R*, *T*, and *U*, Fig. 1, so that the pointer *L* will read 100. A specimen *Sp* is then weighed and hung in the fire-tube *Y* by means of a small screw hook in the end of the specimen, which hooks into the top of the tube. The tube, in turn, is suspended from the balance arm *M*. The chart *Ch* is now moved up or down on its slide until the pointer *L* reads 0 when at rest. The gas burner is now inserted through the slot in the cage screen *Ca* at the bottom of the tube, and the flame *Fl* is made to play directly over the bottom end of the test specimen. To compensate for variations in pressure in the gas main, the gas pressure to the burner is kept constant, as shown on a manometer *Ma*, by regulating the valve on the gas line.

An untreated specimen ignites quickly, loses weight rapidly, and builds up relatively high temperatures at the top of the tube. An effectively treated specimen ignites with difficulty, if at all,

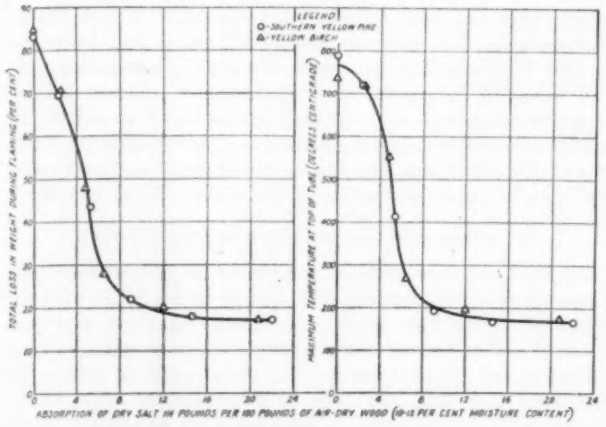

FIG. 7 AVERAGE RESULTS OBTAINED WITH DIFFERENT ABSORPTIONS OF DIAMMONIUM PHOSPHATE IN SOUTHERN YELLOW PINE AND YELLOW BIRCH

(Boards surfaced after treatment and drying. Each plotted point represents from 16 to 20 specimens cut from four boards.)

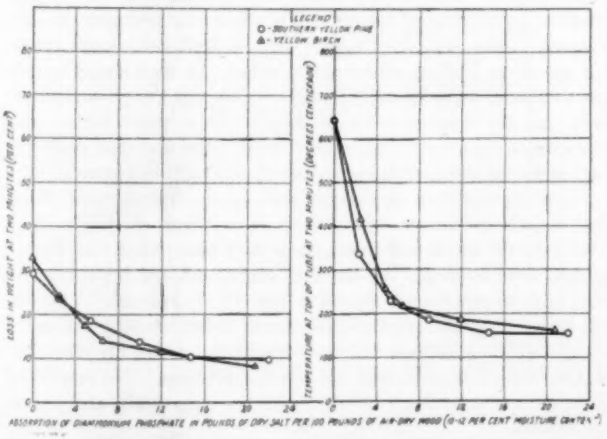

FIG. 8 LOSSES IN WEIGHT AND MAXIMUM TEMPERATURES AT END OF TWO MINUTES. DIAMMONIUM-PHOSPHATE TREATED MATERIAL

(Boards surfaced after treatment and drying. Each plotted point is an average of 16 to 20 specimens from four boards.)

is consumed slowly, and does not build up high temperatures at the top of the tube. When the flame is removed at the end of 4 min., an effectively treated specimen will cease burning very quickly, but an untreated specimen will continue to burn unless already consumed. At half-minute intervals during the test, readings are taken of the loss in weight as indicated by the pointer on the chart and of the temperature at the top of the tube as shown by the pyrometer *Pr*, which is attached to the thermocouple *Th*. If desired, the actual loss in weight of the specimen at each reading can be readily calculated from the weight of the specimen before test and the percentage-loss readings.

The loss in weight and the temperature data taken at half-minute intervals can be plotted as curves which afford excellent

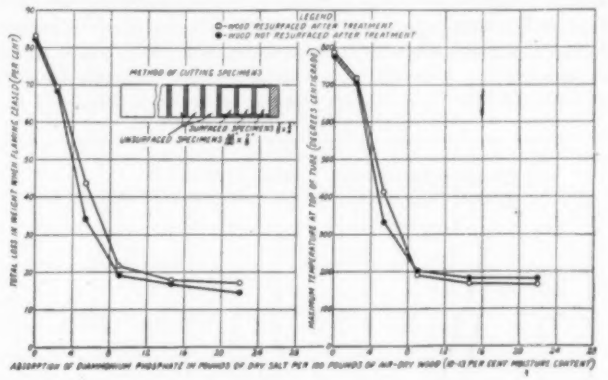

FIG. 9 COMPARISON OF RESULTS ON SURFACED AND UNSURFACED BOARDS OF SOUTHERN YELLOW PINE TREATED WITH DIAMMONIUM PHOSPHATE

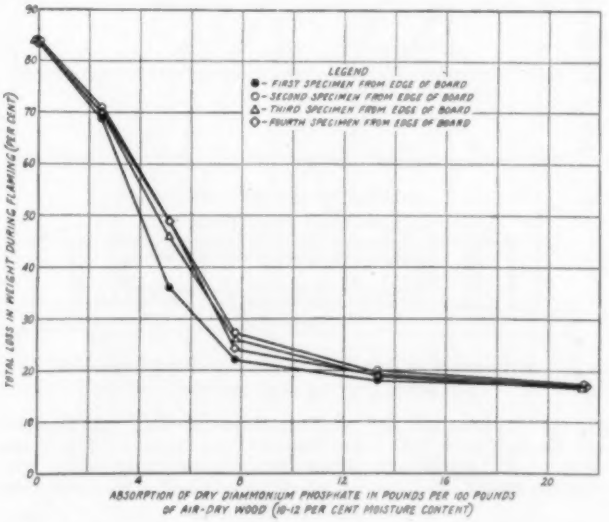

FIG. 10 EFFECT OF POSITION OF SPECIMEN IN TREATED BOARDS ON RESULTS OF TESTS. DIAMMONIUM-PHOSPHATE TREATED MATERIAL

(Each point represents eight specimens cut from eight different boards, four each of Southern yellow pine and yellow birch.)

means of comparing the results obtained from different specimens. The results of tests on individual specimens untreated and treated with different amounts of a fire-retardant salt are shown in Fig. 4 and illustrate typical curves obtained by the fire-tube test.

USE OF THE FIRE TUBE IN MEASURING FIRE RESISTANCE

With the fire-tube apparatus perfected to the point where it was considered a useful measure of fire resistance, tests have been undertaken to measure the fire resistance of wood treated with various fire-retardant chemicals. In Figs. 5 and 6 are shown the results of tests on Southern yellow pine and yellow birch boards treated with various amounts of diammonium phosphate. Nominal 1-in. boards 7 to 8 in. in width and 6 ft. long of each species were treated with the aim of obtaining absorptions of about 1, 2, 3, 5, and 7 to 8 lb. of chemical per cubic foot of wood.

The lumber was selected so as to obtain all sapwood in the pine and as much as possible in the birch. The material was further selected for density, and only the boards within an intermediate range of density for each species were used. The boards were pressure-treated under conditions that were intended to give complete impregnation of the chemical through the boards. Four boards were used for each treatment with each species and salt. Four or five specimens were tested from each board. The boards were $^7/_8$ in. thick when treated, and the parts from which specimens were cut were surfaced approximately the same amount on both sides to $^3/_4$ in. before testing, as shown in Fig. 3*A*.

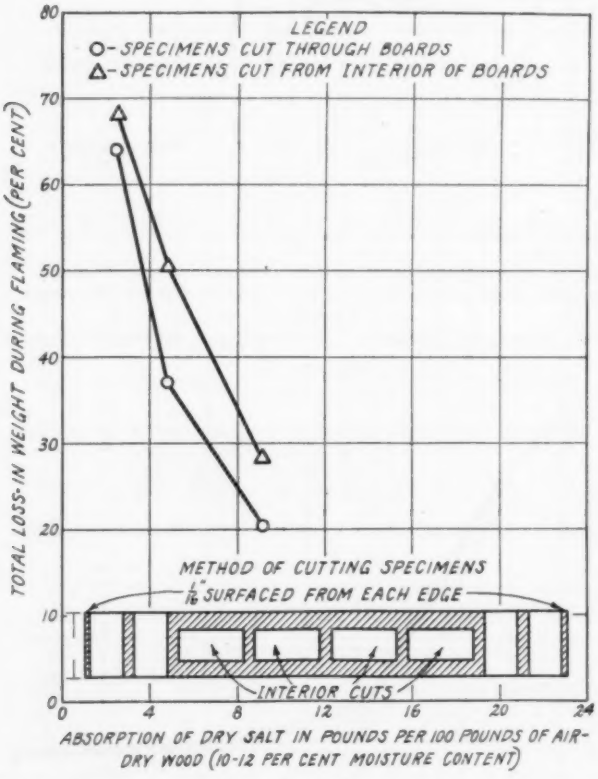

FIG. 11 COMPARISON OF THE FIRE RESISTANCE OF THE INTERIOR AND EXTERIOR OF SOUTHERN YELLOW PINE BOARDS THOROUGHLY IMPREGNATED WITH DIAMMONIUM PHOSPHATE

(The two plotted points for each absorption are based on the same number of specimens.)

The losses in weight at the time flaming ceased and the maximum temperatures developed at the top of the tube during test are plotted in Figs. 5 and 6 against absorption of salt in pounds per 100 lb. of air-dry wood for each specimen tested. The points on the graphs show the differences obtained with different specimens and different boards. It is very evident that the greatest differences in results in individual specimens and boards occurred in the region of 4 to 7 lb. of salt per 100 lb. of wood. Within this border-line range of absorptions the degree of effectiveness of the salt was just sufficient that the burning of the specimen might stop at the time the gas flame was removed or very shortly thereafter, giving a small loss in weight, or it might continue to burn slowly for some time, showing eventually a larger loss in weight. For material untreated or lightly treated (3 lb. or less per 100 lb. of wood) and for treatments of 5 lb. or more per cubic foot, the results are reasonably consistent. The results, obtained by averaging the four untreated boards and the four boards of each wood receiving similar absorptions, are shown in Fig. 7. It is quite evident that a similar degree of effectiveness was obtained in the two woods when the same percentage of diammonium phosphate per 100 lb. of air-dry wood (10 to 12 per cent moisture content) was used.[6]

The comparisons thus far made between the two woods and the different absorptions of salt have been on a basis of the total loss in weight when flaming stopped and on the maximum temperatures developed during test. From the data taken comparisons may also be made at other times during test, as for example, at the end of 2 min. In Fig. 8 the average losses in weight and maximum temperatures at the end of 2 min. of test are shown for diammonium phosphate and the two kinds of woods. Data shown in Fig. 8 are from the same specimens shown in Fig. 7.

In the test the ignition flame comes directly in contact with the lower one-fourth of the specimen, and that part of the specimen is largely destroyed even in treated wood. In the case of effectively treated material the actual loss in weight depends very largely upon the density of the wood in contact with the flame. For example, if a specimen weighs 100 grams and loses one-fourth, the loss is 25 grams, whereas in a 200-gram specimen the loss would be 50 grams. Two specimens of different weights therefore may show very different actual losses in weight, although one may not spread the flame any farther than the other. Percentage loss shows quite clearly the extent of burning beyond the ignition flame, irrespective of the density of the specimens.

EFFECT OF POSITION OF SPECIMEN IN THE BOARD

Surfaced and Unsurfaced. The results so far presented and discussed relate to nominal 1-in. boards impregnated with fire retardant throughout, dried to an air-dry condition, and then surfaced before test. Approximately $^1/_4$ in. was removed from the edges and $^1/_{16}$ in. from each of the faces before cutting the specimens (Fig. 3*A*). In order to determine the effect of the surfacing on the results, tests were made on adjacent surfaced and unsurfaced portions of Southern yellow pine boards. The unsurfaced portion came from approximately the center of the board, while the surfaced part was cut from one side.

The results of the tests are shown in Fig. 9. The average losses in weight were consistently higher in the surfaced treated boards than in the unsurfaced boards. The maximum temperatures developed during test were higher for the surfaced boards except for the three highest absorptions, where the unsurfaced boards gave slightly higher temperatures. In general, the results indicate that the concentration of salts was somewhat higher near the surface than in the interior of the boards and that surfacing had removed some of the most effectively treated material.

A comparison was also made between the first, second, third, and fourth specimens tested from each board (see Fig. 3*A*). The data for birch and Southern yellow pine, shown in Figs. 5 and 6, were averaged for the first specimens, second specimens etc., and the results are shown in Fig. 10. Although $^1/_4$ in. was cut away from the edge of each board before cutting the specimens, the first specimen still showed slightly greater fire resistance in the treated boards than the other specimens. No consistent difference was evident between the second, third, and fourth specimens.

A few tests were also made to compare specimens cut from the interior of boards with similar specimens cut near the edges. Boards of Southern pine treated with diammonium phosphate were used, and the specimens were cut as illustrated in the sketch in Fig. 11. As the curves indicate, the specimens cut from the interior of the board showed considerably less fire resistance than

[6] A more complete discussion of results obtained to date with the fire-tube apparatus is presented in the 1930 Proceedings of the American Wood Preservers' Association in a paper entitled "Fire Resistance of Wood Treated With Zinc Chloride and Diammonium Phosphate," by Hunt, Truax, and Harrison.

those cut through the board from face to face. Although the results for the first and second specimens cut from the edges were averaged, the first specimens showed slightly higher fire resistance (less loss in weight) than the second specimens. This indicates that there is a considerable difference in fire resistance between the center and the outside of thoroughly impregnated boards.

Moisture Content of Wood

Since the moisture content of wood is known to be a factor in the inflammability of wood, some tests were made to determine its effect in the fire-tube test. Matched specimens, cut from the same boards, were exposed to a temperature of 140 deg. fahr. (humidity undetermined) and to a temperature of 80 deg. fahr. at relative humidities of 30, 60, and 90 per cent until approximately constant in weight. These conditions brought the untreated wood to moisture contents of about 1 to 2, 6 to 7, 11 to 12, and 22 to 23 per cent, respectively.

The results of the tests are shown in Figs. 12 and 13. In Fig. 12 losses in weight and temperatures are plotted against time of test. It is evident that the moisture content affects the rate of burning in the untreated and the lightly treated material. It has less effect in the heavily treated material. In Fig. 13 the average results obtained with different absorptions of diammonium phosphate are shown. The total losses in weight at the time flaming ceased and the maximum temperatures are plotted against absorption. The differences in moisture content had the greatest effect in the range of 3 to 10 lb. absorption of dry salt per 100 lb. of wood. While the rate of burning was distinctly slower for material at a higher moisture content in the case of untreated or lightly treated wood (Fig. 12), the total loss and maximum temperatures are nearly the same as for the material with a lower moisture content (Fig. 13). Consequently, the results are less liable to be affected by a difference in moisture content if total losses in weight when flaming ceases are taken as the measure of the fire resistance than the losses at some earlier time during tests, such as 2 min.

Other Factors Affecting Test

Other factors, including the density of the wood, the presence of heartwood and sapwood, especially in some species, the presence of oils, resins, and the like, and the depth of penetration and uniformity of absorption of the fire retardant, are of importance in testing fire-resistant wood. Although information is inadequate on the influence and importance of these factors, some information is available on all of them. Density affects the rate at which a piece is destroyed by fire and the amount of heat evolved.

The presence of heartwood in otherwise all-sapwood material affects the test results. This has frequently been observed and may be due to a smaller proportional amount of fire retardant, incomplete impregnation, or to the wood itself being different in fire resistance. The difficulty of impregnating the heart-

(Each point on untreated wood is an average of twelve specimens and on treated wood of three specimens.)

wood of certain woods with water solutions is well known. It is also generally known that wood which contains considerable quantities of oil and pitch ignites and burns readily. Differences in inflammability of some species when untreated are measurable on the fire-tube apparatus.

It is felt that the fire-tube test will contribute materially in

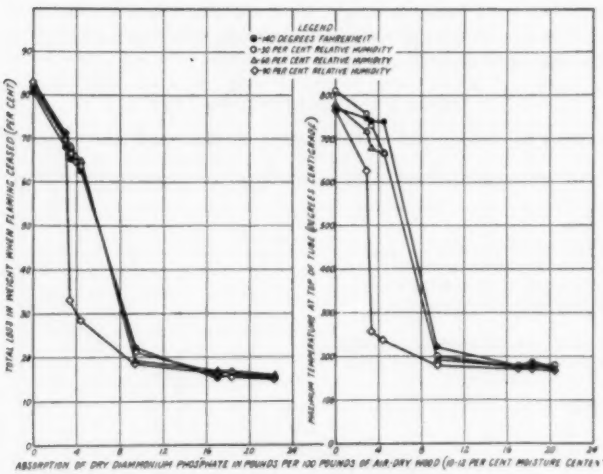

FIG. 13 EFFECT OF MOISTURE CONTENT ON TOTAL LOSS IN WEIGHT AND MAXIMUM TEMPERATURE. TESTS MADE ON SOUTHERN YELLOW PINE UNTREATED AND TREATED WITH DIAMMONIUM PHOSPHATE
(Each point on untreated wood is an average of twelve specimens and on treated wood of three specimens.)

further attempts to evaluate the factors and conditions which affect the fire resistance of wood. The test promises to be useful also as an acceptance test for fire-resistant wood for certain purposes as well as a means of working out some of the problems confronting those in the business of treating wood with fire retardants.

SUMMARY

The fire-tube test is believed to measure more accurately and in more definite terms the property of wood to resist the spread of flame and to contribute to an increase in temperatures than is possible under other test methods commonly employed. Results are shown to illustrate the significance of the fire-tube test and certain variables of test. By controlling known factors the test results can be duplicated with a reasonable degree of accuracy. The test is regarded as a useful and significant measure of the fire resistance of wood both in inspection and investigative work.

ACKNOWLEDGMENT

Acknowledgment is made of the financial assistance of the National Lumber Manufacturers Association in this study of the fire resistance of wood.

Discussion

FRANK P. CARTWRIGHT.[7] In my present capacity, and as Chairman of Sub-Committee II of A.S.T.M. Committee C-5, which is charged with developing a standard form of test for fire-retardant treated wood, progress in treatment effectiveness, and in methods of measuring, it has been of intense interest for several years. The holding of such a meeting on the subject of fire-retardant treatments seems to indicate that actual progress has been made and that it is being recognized by the engineering profession.

Mr. Storm has hit the proper keynote in terming the results of treatment as "Firesafe" lumber. The author should define a little more clearly what "firesafe" lumber must be. Studying the question from the viewpoint of fire control and public safety in building codes, it has been concluded that there are four important criteria of fire safety:

1 Firesafe wood should not support nor spread combustion.

2 It should not contribute materially to the heat of a fire in which it may be involved.

3 Used in doors, partitions, floors, for protection of structural members, or for other purposes for which a definite fire-resistance rating is prescribed, firesafe wood should be capable of sufficiently uniform control of the treatment so that dependable performance can be expected of the structural assemblies in which it is used.

4 It must be permanent in character under all ordinary use conditions.

It would be interesting in this connection if Mr. Storm can give the amount and character of chemicals which were put into samples 6805 to 6807 mentioned in the paper.

Other criteria of treated wood, mentioned by Mr. Storm, such as appearance, ease of working and finishing, hydroscopicity, wear resistance, etc., are also important, but from the viewpoint of fire resistance these four are really important.

The second and fourth of these criteria almost automatically eliminate painting or surface coating from available methods, since a coating is subject to removal and does not in any case affect the ability of the wood to add to fire temperature.

The third makes necessary some test method which will give definite quantitative results, so that the effectiveness of treated material going into a structural assembly can be anticipated. This yardstick of treatment Mr. Truax's method of test provides. The tendency of the wood to burn under applied heat, and thereafter to support its own combustion in a heated enclosure, is clearly and quantitatively shown (see left half of Fig. 4). Since the curves at the right of Fig. 4 indicate maximum tube temperatures against time, the area under each curve and above the horizontal line representing tube temperature without the specimen may be considered a fair measure of the heat which lumber so treated will contribute to a fire in which involved. Mr. Truax unfortunately has not shown this line, but it would run across the chart at an ordinate of 185 deg., well above the combined temperature of flame and specimen. In other words, well-treated wood not only does not contribute to the heat of a fire in which it is involved, but it subtracts from it.

As to the practical uses of fire-retardant treated wood, from a

[7] Chief Engineer, National Lumber Manufacturers Association, Washington, D. C. Assoc-Mem. A.S.M.E.

safety viewpoint it would seem that the use of fire-retardant treated wood for molding, trim, flooring, and other purely finish purposes in a building of reinforced concrete or protected steel construction is immaterial. A survey of office floor loads in a large New York City building some years since showed an average of 11.6 lb. per sq. ft. and in many cases exceeding 30 lb. per sq. ft., very largely of combustible material. In loft buildings the proportion of combustible contents is much greater. The addition of perhaps 3 or 4 lb. per sq. ft. of wood to the total has little effect on fire temperatures.

When it comes to wood for partitions, doors, shaft enclosures, or other devices for controlling the spread of fire, or to the use of treated wood as fire protection for structural members, of wood or other materials, the possibilities are endless. The building-code requirements of half a hundred cities are so drawn at this date that a door of fire-retardant treated wood which demonstrated a definite period of fire resistance would find acceptance automatically.

Treated scaffolding plank, mentioned by Mr. Storm, represents an example of use which confers actual fire safety. The boxing in of columns and beams in heavy timber construction and of important structural shapes in steel-framed industrial buildings probably will add from 50 to 100 per cent to their safety in case of fire, and may eventually come to be a more or less general practice.

When this time comes, and perhaps even in the near future, the need will be felt of two or three standard grades of treatment, adapted to the purposes for which the lumber will be used, as preservative treatments are now adapted to conditions of service. These degrees of treatment will need to be identified by distinguishing marks, behind which those treating lumber can stand; and for testing and control of treatment quality, a definite, quantitative method of test, such as Mr. Truax's method provides, will be necessary.

The fire-retardant possibilities of various well-known chemicals are being investigated systematically, and it is easily conceivable that treatment for this purpose will soon become a customary activity of concerns now devoting themselves solely to preservative treatment.

PROF. HENDERSON.[8] The subject is of importance to engineers and lumbermen because of the coming in of so-called substitutes. These were brought in primarily because they were thought to be fireproof or fire resistant. These demonstrations have brought out the fact that wood can be made more or less fireproof. There seems to be quite a fire resistance anyway, and it is going to overcome many of the supposed detriments to the use of wood.

DR. WINOGRADOW.[9] The writer would like to discuss one point about the temperatures, relating to Fig. 4. One item is not taken into consideration, and that is the elongation of the flame at the moment when the flame comes in contact with the specimen which hangs in the tube. It has been observed in experiments that at the moment a specimen is in contact with the flame, even a specimen of asbestos or porcelain, it is combustible, and there is an elongation of the flame sometimes over 50 per cent. So the longer the flame the closer it is to the top of the tube. There is an increase of temperature due to this elongation occurring automatically. It seems that this should be taken into consideration. It is suggested that in this case they measured the temperature on the top of this cylinder without the specimen and they found it to be about 180 deg. cent. It is suggested that they place a stick of asbestos and measure under this condition, and then there may be a different result. There will be a higher temperature at the end at the top of the tube and a lower temperature in case there is placed a highly saturated specimen, because the heat will be absorbed or transferred. . The calories will be transferred into work by the decomposition of the chemicals. So the curve will probably run a little differently. At the start it will be lower and it will go up.

MR. TRUAX. As to the points that Mr. Cartwright and Dr. Winogradow raised in reference to the temperature and the calibration of the apparatus as to the height and flame, the authors would say that, before we start a test, we calibrate the flame. We adjust the flame to get a height of 11 in. plus or minus $^1/_2$ in., and a temperature of 1000 deg. cent. plus or minus 25 deg. cent., or about 182 deg. fahr. That brings the temperature at the top of the tube to approximately 180 deg. cent.

Referring to Fig. 4 it may be noticed that in burning the specimens containing 5 lb. and over of salt, the temperature did not reach the calibration temperature of 180 deg. cent. That confirms the point that Dr. Winogradow made that there is an absorption of heat. There undoubtedly is some burning of gas, but also there is an absorption of heat. In other words, we did not build up temperatures as a result of any combustion which may have occurred.

With reference to the height of flame and elongation of the flame, we calibrate the flame out of the tube, and we know that it does spread when applied to the specimen. It is suspected that the spread on the specimen will be related to some extent to the inflammability of the material. It is not quite seen, however, how we could standardize that in the test method—that is, take account of the elongation of the flame. So long as we have a standard height flame, a standard temperature flame, and a standard temperature at the top of the tube to begin with, we are subjecting untreated specimens and the various treated specimens to substantially the same conditions.

We have a range in temperature; at the bottom of the specimen the temperature may be regarded as fairly severe, and at the top of the specimen the temperature is very close to the ignition point of wood if exposed for a long period. That was pointed out in the early part of the paper. The work of Prince and of others indicates that wood ignites eventually at about 180 to 200 deg. cent.

We believe we have a set of conditions in the fire tube which enables us to measure the property of wood to spread flames and to build up temperatures by combustion.

RALPH H. MANN.[10] I would like to point out the fact that all of the tested sticks which had been impregnated were sticks of sap timber, that portion of the wood which most readily will take up treatment. Is there any ready method by which the ordinary lumberman, contractor, or engineer can tell the difference between long-leaf pine and ordinary Southern pine.

MR. TRUAX. We selected the sapwood so that we could make certain of complete impregnation in the timber. If one is going to study the relationship between the amount of chemical in the board and the effectiveness, there must be a uniform distribution in each piece. There are many species in which it is difficult to thoroughly impregnate the heartwood, and the heartwood was purposely avoided for that reason.

I believe there is no way by which a lumberman can identify pine by ordinary vision and inspection and be sure whether a stick is longleaf pine or shortleaf pine.

MR. HARMON.[11] I would like to ask Mr. Truax what are the shortcomings of the present timber? Have you any results of

[8] Professor, Syracuse University, Syracuse, N. Y.

[10] Service Bureau, American Wood Preservers Association, New York, N. Y.
[11] Bureau of Buildings, New York, N. Y.

the crib and shavings test conducted at Columbia University?

MR. TRUAX. We have tested treated material by the New York tests and the firetube test. Our principal objections to the New York tests are that they leave too much to the judgment of the operator; for example, in the shavings test, as to the character and quantity of the shavings. The directions state that they should be packed moderately, but in that respect variations will be very great. Consequently, different results will be obtained on the same material in different testing laboratories. Another point is the thickness and form of shavings. It is almost impossible to get uniform shavings from different species of wood. Without uniform shavings the test cannot be duplicated.

I do not believe one can duplicate the New York test closely, with different operators and in different testing laboratories. Our test rather clearly indicates that there is a distinct relationship between the amount of chemical in the wood and its effectiveness. With the New York test we were unable to get a consistent relationship.

MR. STORM. I would like to ask Mr. Truax if any attention has been given to the corrosive effect, if any, of the chemicals used—the ammonia and zinc chloride?

MR. TRUAX. Chemicals vary enormously in corrosive action. Previous tests by Prince indicate that some chemicals are distinctly objectionable from a corrosion standpoint.

MR. STORM. Could you tell about the affinity of those chemicals to moisture?

MR. TRUAX. We have been making moisture-content determinations along with the fire-testing work, and we find that there is some additional moisture or something driven out at the time the moisture-content determination is made; whether it is moisture or whether it is chemical we do not know. With diammonium-phosphate there is not much difference from untreated wood. With zinc chloride there is a little higher moisture-content than one would expect from untreated wood.

MR. STORM. How would the absorption of a piece of wood so treated compare with the absorption in any given humidity of an untreated piece of wood—I mean with these two chemicals, zinc and diammonium-phosphate?

MR. TRUAX. The diammonium-phosphate is about the same as untreated wood. Zinc chloride is slightly higher than untreated wood.

MR. STORM. Do you feel that those chemicals would be practical as a treatment in lumber from that standpoint?

MR. TRUAX. Zinc chloride has been used for a long time in the wood-preservation industry. It is one of the principal chemicals used to treat wood for decay resistance. It does have considerable fire resistance. Whether it is practical to put as much zinc chloride into wood as one would need to get high fire resistance, I would not attempt to answer. It may be that the large amount of chemical that is necessary to get high fire resistance would injure the wood or bring about other disadvantages that would be objectionable.

ERNEST F. HARTMAN.[12] Within the course of a month, a paper on fire resistance of wood was presented before the American Wood Preservers' Association, an editorial on fireproofed wood appeared in *Wood Preserving News*, and now comes this valuable contribution on measuring the fire resistance of wood. Considering the scarcity of literature of the subject, this would seem to indicate considerable interest, and as the operator of the 35-year old Bachert process of fireproofing, this is indeed gratifying.

It is but proper to state that common acceptance of the designation "fireproofed wood" is here used in that sense and with a full recognition that the terms fire-retardant, fire-resistant, and non-inflammable are more suitable.

Flameproofing is considered as the partial impregnation of wood sufficient to withstand external flame. Fireproofing demands the complete penetration of the chemicals of the very core of the wood.

It should be noted that the reprint in Appendix 1 of Mr. Storm's paper does not cover the New York Building Department rules now in effect and fails to include the requirement adopted last March that, before testing, all samples must be oven-dried at 140 deg. fahr. to a constant weight.

Acknowledgment is made of the compliment paid by Mr. Storm that the old fireproofed wood has retained its efficiency and that records show this to be true after more than 30 years. It is on the development of this successful process that the writer has been working in an endeavor to secure progress by evolution. He is not a lumberman in the sense that he is not interested directly or indirectly in the sale of timber, lumber, or wood. The subject of fireproofing wood is approached as an engineering problem dealing with a structural material. The distinction between science and engineering is a difference both in purpose and method; it is the sharp contrast between dream and attainment. It is the engineer who is responsible for the development of the modern equipment used in wood impregnation. The forester, the pathologist, and the chemist must all collaborate, and so it is that separate chemical and plant laboratories are maintained as a matter of industrial research. Thus it has been possible to develop treatments satisfactory for what are called refractory woods, such as American walnut, white oak, etc. On one job for interior trim there may have teakwood, French walnut, and marmut. Thus, library and laboratory are necessary to provide answers to questions on suitable methods of treatment. Often the writer's experience of 30 years in the field of wood impregnation finds itself impotent. Those interested in the grouping of woods for treatment will find much valuable experience recorded in the proceedings of the American Wood Preservers' Association. Wood-using industries will likely find it to their advantage to utilize the accumulated experience of the more than a hundred-year-old wood-preserving industry, especially since the equipment now available will answer for all treating requirements for fireproofing.

Being the first to commercially flameproof scaffolding used in New York City is an acknowledgment that the writer favors the partial impregnation of wood. Here the condition of a short mechanical life makes possible the use of cheaper chemicals than are used in fireproofing to New York City Building Department requirements. Chestnut contains considerable tannin and so discolors the treating solution. Certain other woods also discolor the solution, and in consequence proper plant equipment calls for a considerable number of storage tanks for the varying solutions required for different woods or for different treatments.

In discussing the paper on "Fire Resistance of Wood" recently at Seattle, the writer took occasion to call attention to the vital importance of the chemistry of wood to the fireproofer. This will frequently necessitate changes in the chemicals. Of the various constituents of wood, those with the greatest calorific value demand first consideration. Lignin, which is incrustated material, possesses an excess of carbon and hydrogen and is soluble in acids. Compared with oxygen its combustion produces more heat than that of cellulose. Since lignin is present in large quantities in hardwoods and more abundant in the heart than in the sapwood, it will be apparent that thorough chemical treatment of the heartwood is absolutely essential if New York City Building Department requirements are to be met. Ingberg gives the calorific value of cellulose as 7570 B.t.u. per lb. In the case of Douglas fir the figures would be 10,550 B.t.u. per lb. for components other than cellulose.

[12] President, Protexol Corporation, Kenilworth, N. J.

Success in producing stainless fireproofed finished oak flooring that under proper humidity conditions in new buildings does not shrink or swell first induced experiments with milled stock and moldings. The drying of such stock produced new questions which are still being investigated. A fair number of jobs have been run through successfully, and these have included glued-up stock. This, it is hoped, will materially reduce the cost to the woodworker, and it is also hoped, by eliminating the difficulties of working fireproofed wood, to secure good will where today most woodworkers consider fireproofed wood an abomination that they must put up with because of the law. Incidentally, the writer does not favor legislation as a means of increasing a demand for fireproofed wood. A healthy demand can result only from supplying a need, and no industry can prosper that must depend on subsidy or legislation for an existence.

The greatest objection to fireproofed wood from architects has resulted from the staining of wood or the causing of discoloration. To overcome this prejudice of many years' standing will require much educational work, and exhibits of fireproofed wood should not be neglected whenever opportunity offers. Otherwise no prejudice has been found anywhere. The fact is that the public has not been informed by the fireproofer, and trade literature is practically unknown.

As the writer views the requirements of industry, it will be necessary to combine wood preservation with suitable flameproofing. If by so doing, there can be a reduction of the fire risk and the securing of consideration from insurance companies in a lower rate, it will be possible to maintain for wood its position as the best insulating roofing material. It is, however, not sufficient to accomplish this result unless it is at a cost somewhere near what is being paid at present for straight wood-preserving treatments. This, then, requires that there must be a one-movement process, since two movements add materially to the cost, as the wood preserver learned long ago when discarding the Wellhouse process. The chemist must supply chemicals of sufficient toxic strength with known fireproofing chemicals that will readily remain in solution during treatment, but which will combine and become insoluble after the watery menstruum dries out. The toxics to be used must be well known if one would avoid having to demonstrate their efficiency by the test of time. The flameproofing can be demonstrated, though its permanence may be questioned. It is along these lines that the writer is conducting research and experiment.

Messrs. Truax and Harrison have made a valuable contribution and have given another and a most accurate method of determining relative values in fireproofing. Peter Lochtin in 1893 probably gave the first comparable data. During 1914, when testing the inflammability and combustion loss of treated timber with engineers of the New York Connecting Railroad, the writer employed a sand bath in a closed muffle and in the absence of direct flame. At Vancouver, B.C., Banfield and Peck in 1922 used an electrical furnace.

While of inestimable value in the laboratory, the method suggested does not lend itself to the testing of commercial requirements of either flameproofed or fireproofed wood, since many of the sizes that occur will not permit of securing a sufficiently long test piece. It appears desirable to have information available on the behavior of the sample at comparatively low and high temperatures if one is to consider the temperature of a burning building at the values set by Woolsen and Weiss—i.e., 1700 deg. fahr. There therefore need be no concern over the temperature obtained with a welding torch and which, after all, being fed by air, does not reproduce any ordinary method of ignition. An acceptance test to evaluate flameproofed wood is indeed badly needed. It would possibly prove of interest to have comparative data on treatments for air-dried and kiln-dried material.

It may be worth while to record the information obtained from the New York Building Department tests.

The shavings test is intended to prove that wood properly fireproofed will not support flame, and in case flame should appear it should be of short duration and die out without materially consuming the shavings outside the flame area of the burner. The temperature for this test is approximately 800 deg. fahr.

The crib test at 1200 deg. fahr. measures the tendency of the material to transmit combustion. It indicates the action of the burning wood in contact with other wood and the tendency of the material to spread flame.

The timber test at 1700 deg. fahr. is important in determining the structural conditions. It determines the degree of incombustibility of the material, but is not conclusive as to its inflammability.

Summarized, then, the shavings test shows ignition, the crib test communication, and the timber test strength of the wood.

The veneer or splinter test has been discontinued. This at 1000 deg. fahr. aimed to determine the degree of incombustibility of veneering materials. This test was made on a hot plate, and only charring without flame should occur. It appears desirable because of the fact that conflagration may expose wood for some time to a strong heat without direct contact with flame; in fact, it may cause temperature equal to dry distillation without flame contact.

One other thought in this connection is suggested by fire-protection engineering. Due consideration must be given to the fumes and smoke given off by burning materials in order to safeguard the life of the fire fighter. Means for determining the kind and quantity of the fumes and smoke are therefore necessary. Again, smoke explosions are not uncommon and must be guarded against.

These comments are offered in the hope that they will stimulate further study and investigation.

WDI-52-5

End-Matching, Edge-Jointed and Surface-Laminated Wood Parts for Auto-Body Building

By G. G. WHITE,[1] DETROIT, MICH.

Advantages and savings from cutting lumber to final dimensions at the point of supply are discussed in this paper. Freight charges on waste and on the moisture removed in kiln drying are saved. In addition a lower grade of lumber can be used, and by cutting to size and shipping in bundles, the cost of handling is reduced and much less storage space is needed. The author describes various manufacturing processes used in the construction of wood frames for automobile bodies. Use of laminated woods has done much to conserve the timber supply because species of woods not previously used can be worked satisfactorily.

CONSTRUCTION of the wood frames of automobile bodies and methods of procuring this material have passed through some radical changes within the past four years. In 1929 the management of a large body plant, in studying costs, saw that the average waste in cutting body parts from all thicknesses of lumber between 1 in. and 3 in. was 35 per cent. Realizing that they had paid the freight on this waste, the question arose, "Why pay freight on 350 ft. of lumber and then burn it?" Also each 1000 ft. of air-dried lumber contains approximately 700 lb. of water that is removed in kiln drying. This weight together with that of the lumber scrapped amounted to 1925 lb. per 1000 ft. on which freight is paid. At 40 cents per 100 lb. this amounts to $7.70 that could be saved. From this calculation was born the idea of operation in the South, in the heart of lumber supply. The saving in freight added to low labor cost in the South made the idea very attractive.

A small plant was started in Arkansas and operations at this plant proved the calculations correct, and also disclosed other cost-reducing features not considered at first. It was found that a lower grade of lumber could be used. The lumber was kiln dried, cut to size, and shipped in bundles of convenient size for handling. This method effected a considerable saving in storage space, which is always at a premium in a body plant. Material handling costs were reduced by 70 per cent. Material received in this manner can be placed on mill trucks in the railroad car and taken direct to the machine room.

Hardwood Should Be Cut to Dimension Sizes

It is not possible to argue logically for the cutting of hardwood into board form for re-manufacturing operations. It is undoubtedly true that softwood was originally cut into boards for structural purposes where long lengths were the units of building. Apparently manufacturers of hardwood followed the procedure of the softwood manufacturers, and practice and precedent have carried forward the producing of hardwood lumber in board form.

Fig. 1 Lumber Storage at a Detroit Body Plant

There is no practical reason why hardwood logs cannot be sawn with reference to the final dimensions required for re-manufacturing operations, at least to some multiple of the same, or with some definite relation to the eventual sizes. It is usually more convenient to kiln dry and handle in multiple sizes. There seems to be no logical reason, however, for preserving the standard board lengths, widths, and thicknesses now in use.

A small part of a typical dimension specification for the lumber required for a medium-price sedan body is given in Table 1 preceded by a brief description of the grades. Table 2 is a recapitulation of the preceding table and shows in the right-hand column the proportion of the various final lengths that are required, and it is perfectly obvious that the large proportion of short lengths gives a better basis of sizing than the conventional board standards.

Ratio of Thickness Values

Several dimension manufacturing companies came into the field and the cost item was attacked in earnest. The first thing considered was the high prices paid for "thick lumber," meaning 2½ and 3 in. thick, which usually sells for $15 to $25 more per 1000 ft. than 1 in. thickness. Taking a lesson from the veneer manufacturers, experiments were started to use 1-in. lumber laminated to take the place of thick lumber. Most of the body engineers were not in favor of using laminated stock for various reasons, but after many experiments and laboratory tests

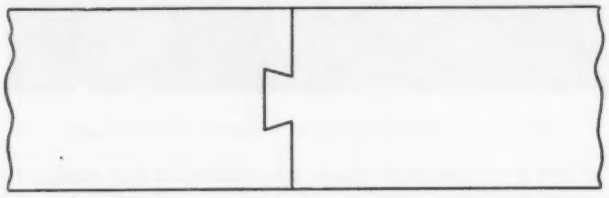

FIG. 2 DOVETAIL EDGE JOINT MADE ON A LINDERMAN MACHINE

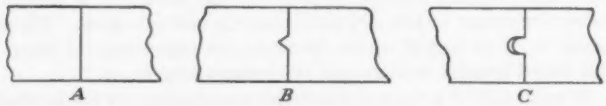

FIG. 3 THREE TYPES OF JOINTS—*A*, PLAIN JOINT; *B*, V JOINT; *C*, TONGUE AND GROOVE JOINT

this material was approved for use by most of them. This approval also included the use of oak, a wood not used extensively by body builders, because they had not been able to dry thick oak with any degree of speed, oak taking approximately 80 per cent more time in the kilns than other species of wood.

Oak 1 in. thick can be purchased at approximately 40 per cent of the cost of 2-in. Southern lumber suitable for body work. The 1-in. oak can be kiln dried to 6 per cent moisture content in approximately 8 days. The use of 1-in. lumber laminated enables one to more than double the output of the kilns.

METHODS OF MANUFACTURING

The lumber should be kiln dried to between 5 per cent and 6 per cent moisture content. Care should be exercised in stacking the lumber on kiln trucks to see that plenty of stacking sticks are used to prevent warping. Straight lumber is essential to secure proper lamination. The lumber passes from the kilns to dry storage for tempering or equalizing, and should not be cut until it has been out of the kilns at least 3 days. This gives it time to equalize any strains or stresses that may have developed in kiln drying. It is then taken through cut-off and rip saws, where it is cut to length and edges are straightened where necessary. It is then sized, i.e., passed through a single surfacer set at 15/16 in., which gives the lumber one surfaced side and a uniform thickness. At this point two methods are used to make up the blanks for laminating—first, linderman machine; second, edge-gluing on rotating glue clamps. These methods are as follows:

1 The lumber is put through the linderman machine, which makes up the blanks using a glue joint. (See Fig. 2.) When the glue has set it is put through a double surfacer set at 13/16 in., which is the standard thickness used by most manufacturers. It is now ready to be laminated

2 The lumber goes to a glue jointer, where three types of joints may be used. (See Fig. 3.) After jointing it goes to the glue room for edge-gluing on rotary clamps.[2] Most of the manufacturers have found a 39-section clamp the most economical, both in first cost and operation. Steam pipes are usually placed on the floor under these clamps to speed up the drying, which gets the same result that a 59-section clamp would produce. After the glue has set the panels are S2S (surfaced two sides) to 13/16 in. and are ready to be laminated.

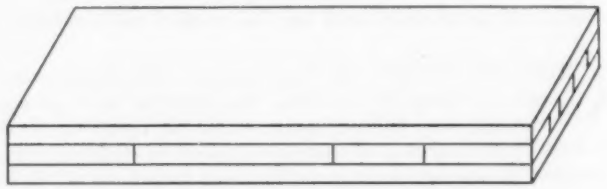

FIG. 4 USE OF SHORT NARROW PIECES IN CENTRAL PLIES

FIG. 5 REASON FOR AVOIDING SHORT-PIECE CONSTRUCTION IN BAND-SAWN AND SHAPED STOCK

In making up the panels another factor should be taken into consideration—that is, the use of narrow and short pieces of lumber. Previous to this time these have been considered waste. Most specifications today permit the use of narrow lumber (narrow lumber as used here means strips from 1 in. to 3 in. wide) in all panels, provided the narrow pieces are the full length of the finished panel. With low labor costs in the South it is possible to utilize this narrow lumber and show a substantial saving. In using narrow lumber it is better to make up the panels over a glue jointer and rotary clamp as the percentage of waste[3] is less than with a linderman machine, also labor is less.

Specifications issued by consumers now allow short-end glued lumber to be used, but only in the inside plies of panels having 3 or more plies (Fig. 4). The general reason given for not

[2] See "Design and Application of Clamp Carriers for Wood Gluing," by Raymond W. Burns of James L. Taylor Manufacturing Company, Poughkeepsie, N. Y., in *Mechanical Engineering*, May, 1926.

[3] See "Plywood Cores as a Foundation for Good Woodwork," by E. V. Knight and J. D. Perry, A.S.M.E. Transactions, WDI-51-13.

allowing this method of construction on outside of panels is that all shaper work is done on the outside plies and they do not think end-glued construction would give the desired results. There have been very few attempts to experiment along this line. In one experiment the shaper knives did throw a piece of end-glued stock from the piece, and this one failure seems to have determined the fate of end-glued stock on outside plies. However, the use of end-glued small pieces to make up panels for center plies has proved satisfactory both to manufacturers of wood parts and to consumers.

End-glued lumber in the body plant on parts such as side roof rails, rear belt rails, seat-back frames, and body hinge-pillar extensions have come into general use and have proved satisfactory both from a use and cost standpoint. A hydraulic press used for clamping up laminated lumber parts is shown in Fig. 6.

End-Jointing Lumber Parts

As an example take a side roof rail which has a sweep both horizontally and vertically. This is made from three pieces of

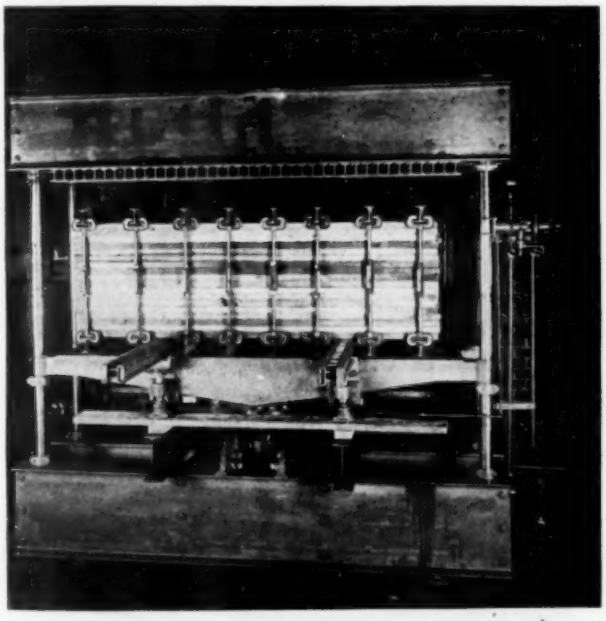

Fig. 6 Press and Method of Clamping Laminated-Lumber Parts

lumber end-glued to conform as near as possible to the final shape of the finished piece. This is done by using what is commonly known as a "finger joint." (Fig. 7.) This finger joint can be used to join two pieces of lumber at a vertical or horizontal angle, or a combination of both at the same time. A special machine and cutters are sold to do this work, and one can be found in nearly any body woodworking plant. This joint should be glued under pressure, furnished either by hand screw or compressed air. The compressed air is faster and gives a better quality of work. All joints should be clamped with a "C" clamp while under pressure, and should not be removed until the glue has set. Some mill men also used a dowel pin through the joint (Fig. 8) as an added factor of safety, but this is not generally practiced.

The preparation of these finger joints has been much facilitated by recent developments of several pneumatic-motored machines. These pneumatic-motored or air-turbined machines permit a much higher operating speed than has been practical with electric motors, and hence have permitted more efficient operation and smoother cutting. Several of the types of joints used in these machines, and also the cutter heads that are especially designed for such joints, are shown in Figs. 9, 10, and 11.

Finger jointing offers not only the opportunity of angling finger joints, as shown in Fig. 8, but also offers an opportunity of building up lengths from shorter pieces in order to obtain ultimate lumber strength in the final product. Tests have shown that while these finger joints may not produce full-strength lumber, yet their factor of strength is sufficient for most practical purposes. It is quite conceivable that four 6-in. pieces might be jointed together for a single 24-in. piece to be used in laminated work. Finger joints are already used in certain branches of other woodworking industries, such as the making of grand rims for pianos and the jointing of thin maple for piano backs.

Laminating Presses

The laminating should be done in a press, either hydraulic or electric, where a pressure of 100 lb. per sq. in. can be obtained over a large surface. (See Fig. 6.) The size generally used is 36 in. by 108 in. This size is most desirable because truck and bus-body sills are 8 ft. and longer. A motor-driven glue spreader is used and should be large enough to take 36 in. widths. Glue should be spread on both surfaces that are to be laminated. This is particularly desirable where oak is the wood to be laminated. On softer texture woods, such as gum, soft maple, and magnolia, glue spread on one surface might be sufficient, but on oak auto-

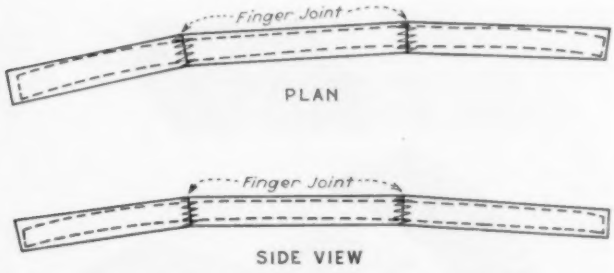

Fig. 7 Angles of End Jointing Required for Side Roof Rail

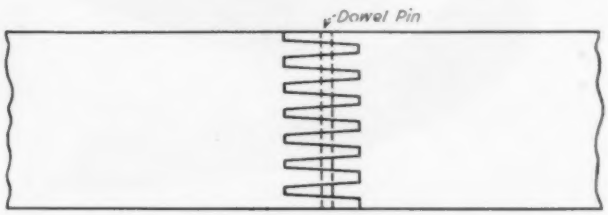

Fig. 8 Finger Joint With Wood or Metal Dowel

mobile body stock, where numerous operations are performed, including shaper cuts, the glue should be spread on both surfaces. Use of laminated stock in body work has proved that single spreading is not sufficient.

Glues Required

In laminating, both hot and cold glue are used. In using hot animal glue care should be exercised to regulate the temperature conditions in the glue room. The most satisfactory method developed up to this time is to have an annealing room adjoining the glue room. The temperature in this annealing room should be kept as near 100 deg. as possible at all times. The panels are on trucks or skids, and should have strips between them in order that the heat may penetrate the surface of the panels at all points. Panels should remain in the annealing room 48 hr. or longer. The glue room should be kept at a temperature between 80 and 90 deg. fahr. After the glue has been spread on the panel no air

draft or wind should be allowed to reach it; if it does it will cause a slight "skin" to form on the glue surface, and an inferior glue joint will be the result. While the panels are under pressure in the press the clamps are applied and pulled up tight. (Fig. 3.) The stock should remain in the clamps for at least 24 hr. In using cold glue it is recommended that a pressure slightly higher than 100 lb. per sq. in. should be used. Temperature conditions are not so important.

After the stock is taken from the clamp it should be taken to the rough mill and have the ends trimmed square, and in some cases the edge should also be squared in order that the straight edge can be used as a stop for making patterns. This is particularly true on sills and pillars.

Gluing Curved Surfaces

The work so far described has related wholly to flat gluing, but there is a vast field available for gluing curved shapes with thinner

Fig. 9 Types of Finger Joints Commonly Used

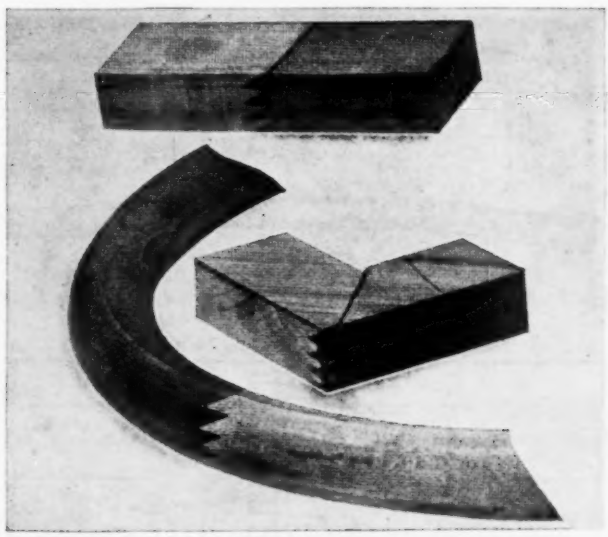

Fig. 10 Typical Straight, Miter, and Curved Joints

lumber so as to permit stronger and sturdier curved-piece construction. In fact, one body company is gluing up side roof rails to shape by using two or more pieces of 4/4 laminated to give the desired thickness. These roof rails are to exact curves, both horizontally and vertically, and several shaper operations are eliminated.

This involves the use of curved cauls in the glue presses, but will almost wholly eliminate the tendency of curved pieces to split and will largely increase the strength of the same over those that are band-sawn out of flat glued lumber.

This underlying policy also can be carried forward by the use of various kinds of rotary-cut veneer, which will permit an infinite variety of shapes and arrangements of parts with the minimum of weight and maximum of strength. Just how far economic conditions will justify the use of these curved forms is yet to be determined, but they offer a very interesting and intriguing field of research that should have early and complete investigation.

General Results

The use of laminated woods has done much to conserve the timber supply, because it permits the use of species of woods not previously used in body construction. It has done much to increase the use of lower grades of lumber and has brought about increase in woodworking plants in the South. Of course, the main object was cost reduction and this has been accomplished to an extent not thought of three years ago. Laminated woods have reduced the cost of medium-priced bodies by as much as $5 per body.

Appendix

GENERAL SPECIFICATIONS FOR DIMENSION STOCK

4/4 in.–8/4 in.–10/4 in.–12/4 in.

"A" *Clear Stock.* Free from defects of any description.

"B" *Sound Cuttings.* This grade permits sound tight knots as follows; Pieces 3 in. and wider knots up to 3/4 in. in diameter. Pieces 2 1/2 to 3 in. wide knots up to 1/2 in. diameter.

All other defects are excluded except small surface checks, stain, and similar defects that will dress out in surfacing as follows, 4/4 shall dress 1 7/16 in., 8/4 shall dress 1 15/16 in., 10/4 shall dress 2 7/16 in., 12/4 shall dress 2 15/16 in. Each piece may contain one defect per lineal foot, or the equivalent, provided the defects are not so situated as to decrease the strength of the piece.

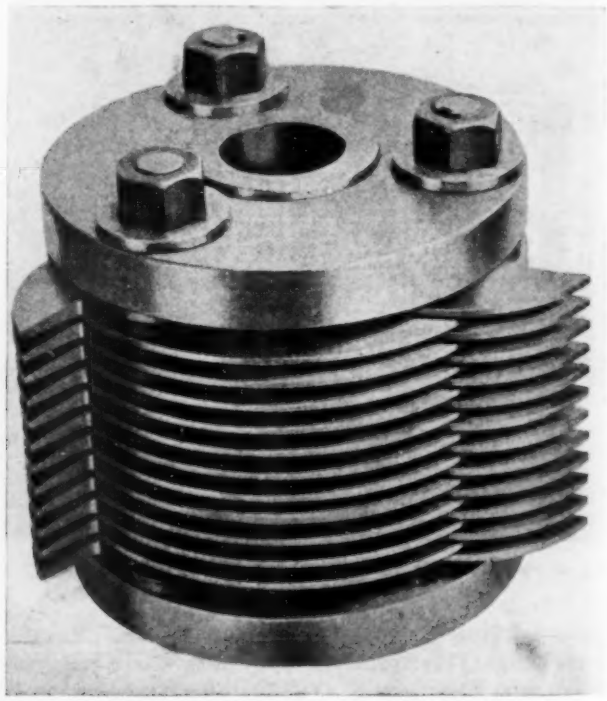

Fig. 11 A Patented Lock-Joint Grooving Head

"C" *Sill Stock Solid.* May contain sound tight knots up to 3/4 in. in diameter. Each piece may contain one defect per lineal foot, or the equivalent, provided the defects are not so situated as to decrease the strength of the piece. Stock must be free from warp or surface bend. If surfaced one side stock must be at least 1 7/8 in. thick. Scant stock will be rejected.

Linderman Sill Stock. Width of stock must be at least:

50 per cent—4 in. and wider
40 per cent—2 1/2 in. to 4 in. wide
not more than 10 per cent—2 in. to 2 1/2 in. wide.

Pieces 4 in. and wider may contain sound tight knots 3/4 in. in diameter.

Pieces 2 1/2 to 4 in. wide may contain sound tight knots up to 1/2 in. diameter.

Pieces 2½ in. wide must be clear.

Each piece may contain one defect per lineal foot, or the equivalent provided the defects are not so situated as to decrease the strength of the piece. Stock must be free from twist, warp, and all other defects that will not dress out in surfacing one side to standard thickness of 1 15/16 in. Thirty per cent of all sill stock under heading "C" must be Solid.

"D" *Sound Cutting* "B" except that knots must be at least 3 in. from ends.

"E" *Sound Cuttings* "B" except knots must be at least 6 in. from ends.

"F" *Sound Cuttings* "B" except knots must be at least 9 in. from ends.

GENERAL ITEMS

(1) Stock shall not contain more than 8 per cent or not less than 5 per cent moisture content at time of shipment.

(2) Species of lumber shown on cutting bill must be used.

(3) Dimensions shown on cutting bill have no minus allowance, the plus allowance is ¼ in. in width or thickness, a plus allowance of 1½ in. in length is permitted unless otherwise noted. Scant stock will be rejected.

(4) Stock to be bundled and marked with part number shown on cutting bill.

(5) Honeycomb is cause for rejection.

Airplane Spruce

By E. J. FISHBAUGH,[1] HOQUIAM, WASH.

The author seeks to prove that wood is a better material than metal in airplane construction where strength is required, airplane spruce being the material against which all other materials are checked for suitability. The paper indicates that airplane spruce gives the least possible weight with the greatest possible strength. There is a stand of Sitka spruce available for airplane manufacture, the author attempts to show by statistics, that will outlast the present generation of builders.

THIS paper might well be entitled Airplane Wood, as airplane spruce has become the standard against which all other wood, and in reality all other material in which strength is required, is judged as to its suitability for airplane construction. Thus far in the development of the aircraft industry, no material has been found superior to Sitka spruce in its ratio of strength to weight. As it is essential to have the least possible weight, and at the same time keep the greatest possible strength, Sitka spruce has become the chief material used for wing beams or spars in airplane construction.

The designers of the best-known planes and those making the great historical flights have understood this so well that their planes were designed to use spruce in their wing construction. In this connection uninformed men are often found who shake their heads in grave perplexity regarding the strength of spruce timbers of a given cross-section.

However, this very perplexity indicates two things. First of all is that they have not availed themselves of the accurately tabulated information to be had for the asking at the Forest Products Laboratory, Madison, Wisc. Here is to be found a fund of knowledge accumulated through years of painstaking laboratory experiments, by men thoroughly equipped, both technically and practically, to get results which are plain guides to the lumbermen and to the designing engineers.

The laboratory has made thousands of tests as to strength. It has ascertained that the average specific gravity, based on oven-dry weight and volume, of 0.40 will bear a reduction to 0.36 and still maintain its factor of strength and that an increase in specific gravity is an indication of added strength, although for purposes of airplane construction, keeping always in mind the desirability of lightness, the majority of lumber should keep somewhere within 10 per cent below and 10 per cent above the average of 0.40.

The second thing, indicated by perplexity in the mind of the designing engineer as to whether the strength factors can be accurately gaged in a timber, is that he is not familiar with the fact that men who have worked in timber and are experienced in this line of activity can tell by a surface examination of a piece of spruce whether it is what we call a live, strong piece or a brash, useless piece. Those who have studied the strength properties of spruce are able to read the indications put there by nature. Nature puts up its own signs, which have an unmistakable meaning to those who have learned the language.

Metal, being the result of chemical combination, cannot be judged thus accurately by any other than a laboratory test. Designers who have built planes around both materials are usually free to admit that the experience and data available concerning spruce and its properties leave in the mind of the designer less uncertainty as to the ultimate result than about any other material.

In this connection it is interesting to record a statement of one of the most prominent engineers connected with the aircraft industry, to the effect that in estimating the performance of newly designed ships it has been his experience that wood construction usually works out in actual practice at 5 to 10 per cent better than the original estimate and that metal usually has worked out in actual performance 5 to 10 per cent under the theoretical expectation.

The question is often asked, "How long before all the spruce will be used up?" And it is perhaps well to indicate here that there are three species of spruce which have been found to have equal value from the standpoint of the strength-weight ratio: Sitka spruce (*Picea sitchensis*), red spruce (*Picea rubra*), and white spruce (*Picea glauca*). Of the three species Sitka spruce has been found for all purposes to be by far the best, as it can be obtained in greater quantity and in more desirable sizes. The other species named are not capable of producing large timbers meeting Government specifications.

There is a stand of approximately 30 billion ft. of Sitka spruce timber available. Government statistics compiled show that there is approximately 2½ per cent of airplane lumber possible from spruce logs. At the present rate there is being produced about 300,000,000 ft. of Sitka spruce per year, which would give a yield of about 7,500,000 ft. of airplane spruce per year for the next 100 years. The present requirements of the airplane industry are about 2,500,000 ft. per year, based on last year's production. So it would seem that the present generation of designers and builders has little to worry about as to reliability of supply.

Another question frequently heard from purchasing agents and manufacturers is, "Do we have to use spruce—isn't there some other wood we can use?" They do not have to use spruce. There are two other woods which show approximately the same strength-weight ratio; viz., Port Orford cedar and old-growth yellow Douglas fir. (See Table 1, "Strength Values of Various Woods. . . for Use in Aircraft Design," which was prepared by the Forest Products Laboratory and has been adopted as standard by the Army Air Service, Bureau of Aeronautics, Navy Department, and the Department of Commerce.) The first of these looks very much like Sitka spruce, although it is slightly heavier and is found in only a very small area and, thinking in terms of an industry, in insufficient quantities to warrant making designs which would depend upon it for a supply. Old-growth yellow Douglas fir is a splendid wood and is found in large volume all along the Northwestern coast. It is considerably heavier than Sitka spruce, and if used would require special designs by reason of its greater weight. In case of a national emergency,

[1] The average values for fiber stress at elastic limit and modulus of rupture in static bending and fiber stress at elastic limit and maximum crushing strength in compression parallel to grain have been multiplied by two factors to obtain values for use in design. A statement of these factors and of the reasons for their use follows: It was thought best, in fixing upon strength values for use in design, to allow for the variability of wood and the fact that a greater number of values are below the average than above it, and the most probable value (as represented by the mode of the frequency curve) was accordingly decided upon as the basis for design figures. From a study of the ratios of most probable to average values for three species (Sitka spruce, Douglas fir, and white ash), 0.94 was adopted as the best value of this ratio for general application to the properties in question. The stress that wooden members can carry depend on its duration. A factor of 1.17 has been applied to test results to get values of the stress that can be sustained for a period of 3 seconds, it being assumed that the maximum load will not be maintained for a longer period.

[2] The values given are the most probable values (92 per cent of the average) of the apparent modulus of elasticity (E_c) as obtained by substituting results from tests of 2 by 2 in. beams on a 28-in. span with load at the center in the formula $E_c = P13/48\Delta I$. The use of these values of E_c in the usual formulas will give the deflection of beams of ordinary length with but small error. For exactness in the computation of deflections of I and box beams, particularly for short spans, the formula that takes into account shear deformations (see National Advisory Committee for Aeronautics Report No. 180, "Deflection of Beams With Special Reference to Shear Deformations") should be used. This formula involves E_T, the true modulus of elasticity in bending, and F, the modulus of rigidity in shear. Values of E_T may be obtained by adding 10 per cent to the values of E_C as given in the table. If the I or box beam has the grain of the web parallel to the axis of the beam, or parallel and perpendicular thereto, as in some plywood webs, the value of F may be taken as $E_T/16$ or $E_c/14.5$. If the web is of plywood with the grain at 45 deg. to the axis of the beam F may be taken as $E_T/5$ or $E_c/4.5$.

[3] Design values for fiber stress at elastic limit in compression parallel to grain were obtained by multiplying the values of maximum crushing strength as given in the next column by factors as follows: 0.75 for hardwoods, 0.80 for conifers. Values as given are to the nearest 10 lb.

[4] Wood does not exhibit a definite ultimate strength in compression perpendicular to grain, particularly when the load is applied over only a part of the surface, as it is at fittings. Beyond the elastic limit the load continues to increase slowly until the deformation and crushing become so severe as to seriously damage the wood in other properties. Figures in this column were obtained by applying a duration of stress factor of 1.17 (see Note 1) to the average elastic limit stress and then adding 33⅓ per cent to get design values comparable to those for bending, compression parallel to grain, and shear as listed in the table.

[5] Values in this column are for use in computing resistance of beams to longitudinal shear. They are obtained by multiplying average values by 0.75. This factor is used because of the variability in strength and in order that failure by shear may be less probable than failure from other causes. Furthermore, tests have shown that because of the favorable influence upon the distribution of stresses resulting from limiting shearing deformations the maximum strength-weight ratio and minimum variability in strength are attained when I and box beams are so proportioned that the ultimate shearing strength is not developed and failure by shear does not occur.

[6] Includes white ash (F. americana), green ash (F. pennsylvanica lanceolata), and blue ash (F. quadrangulata).

[7] Includes sweet birch (B. lenta) and yellow birch (B. lutea).

[8] Includes bigleaf shagbark hickory (H. laciniosa), mockernut hickory (H. alba), pignut hickory (H. glabra), and shagbark hickory (H. ovata).

[9] Includes material from Central America and Cuba.

[10] Includes white oak (Q. alba), bur oak (Q. macrocarpa), swamp chestnut oak (Q. prinus), post oak (Q. stellata), red oak (Q. borealis), southern red oak (Q. rubra), laurel oak (Q. laurifolia), water oak (Q. nigra), swamp red oak (Q. pagodafolia), willow oak (Q. phellos), yellow oak (Q. velutina).

[11] Includes red spruce (P. rubra), white spruce (P. glauca), and Sitka spruce (P. sitchensis).

this wood offers an unlimited supply to supplement the already large supply of Sitka spruce available. The chief obstacle to the use of this wood for aircraft, outside of the extra weight-strength ratio, is the fact that up to the present time this species has been manufactured largely upon a commercial volume basis rather than on a quality selection basis.

The production of wood for airplanes necessitates a high-grade remanufacturing plant with a personnel thoroughly experienced in selecting lumber for its strength qualities. Again, thinking in terms of economics, for the last 20 years engineering experts have been building up tables of experience, based upon the use of Sitka spruce, and at least one high-grade remanufacturing specialist, the Posey Manufacturing Company, Hoquiam, Wash., has been accumulating and supplying material for the airplane industry based upon practical as well as technical knowledge and experience. In view of this information and the unlimited supply, for practical purposes, of Sitka spruce (about which there is probably more known than about any other available material) it would not seem economically sound to venture into new fields for material.

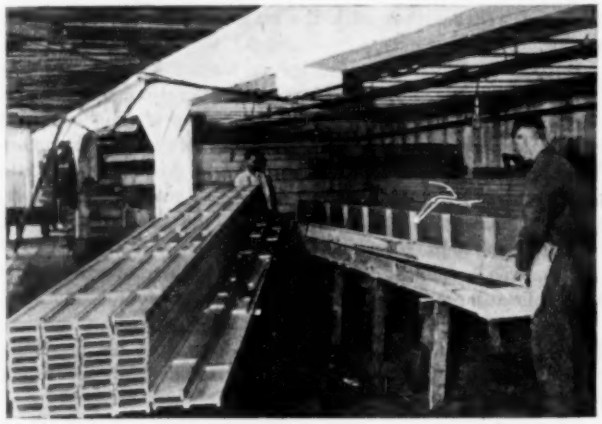

FIG. 1 PACKING SITKA SPRUCE AIRPLANE SPARS
(These are fully worked to blueprint dimension and are being shipped to the airplane manufacturer.)

The availability of dimension, laminated, and spliced spars, should not be overlooked in planning the production program for a new shop layout, and as a matter of fact it is well to consider the use of dimension stock in any of the present airplane factories using spruce parts because a thorough study of this matter will show that a dimension program is economically sound and fundamentally correct.

The automobile body manufacturers, refrigerator and piano manufacturers, and others have found that a tremendous saving is made by purchasing their wood requirements cut to net sizes and manufactured more or less ready for assembly. This eliminates a heavy investment for machines and the floor space necessary for manufacture, besides greatly reducing the amount of capital required, as well as taxes and insurance; the result is no sacrifice in quality and permits a greater potential machine production capacity. Furthermore, there is not only a saving of time in cost accounting, but more accurate costs are obtainable, because the problem of the cost of waste is virtually eliminated so far as the airplane manufacturer is concerned.

Many people make comparisons between the automobile and airplane industries, and in the mind of the public generally there seems to be the thought that airplanes will soon be as numerous as automobiles. Practically, this is not true, and there is no evidence at present that it ever will be true. Previous to the historic flight made by Colonel Lindbergh, very few planes were made except for use by the Army and Navy. Beginning immediately after that great flight, individual engineers, aviators, and the general public became wildly enthused over the possibilities in airplane manufacture and travel. The production ratio for the years following has been about in the proportion of 2 for the first year, 4 for the second, 8 for the third, and 12 for the last year. Up until last year, any plane built could be sold as soon as finished, and many were sold before they were started. But the airplane industry awoke suddenly last October to find that it needed to study its market, as already it had built enough planes to last well through the first quarter of 1930.

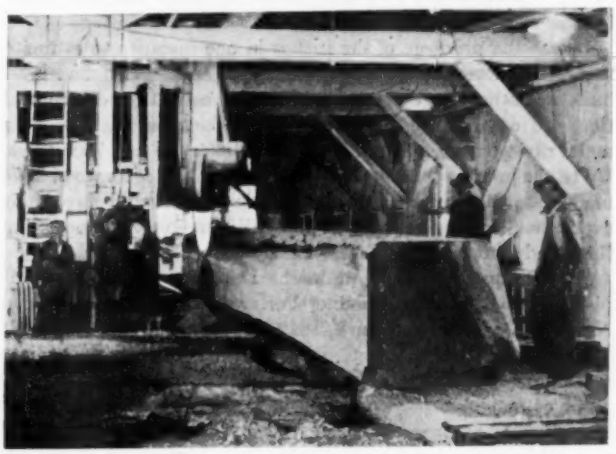

FIG. 2 SAWING A SITKA SPRUCE AIRPLANE LOG
(Squaring up of a No. 1 log, ready to saw off cants to make airplane lumber. It is the part nearest the bark from which airplane and other strength timber is procured.)

FIG. 3 "POSEY INSPECTED AERO" GRADE OF LUMBER
(Timber from a No. 1 log being examined to remanufacture, first being marked to save the airplane lumber in it.)

The fear in the minds of manufacturers and engineers as to the available supply of spruce, together with the vision of high production and the very splendid sales approach by the advocates of wood substitutes, has led to some use and considerable experimentation with metal.

Rapid progress in the airplane industry has made what seemed to be good usage in the first half of the year entirely out of date by the end of the year. In many instances, with engineering pans approved and ordered into production, they have been

changed, sometimes radically, before the first production planes were completed. Even in some of the largest production units of the country probably there is not over a half dozen who have made as high as a thousand planes of one type, and very few have made over a hundred of one type, without a radical change of some kind. Because of the small number made by any company of one type of plane and the great expense involved for dies for metal construction, for practical purposes wood unquestionably is the superior material and will maintain its position even though metal should be perfected to the point where it would become of equal value technically.

It was the privilege of the author in one instance to estimate the cost of wood ribs for a certain type ship which had been built in rather large quantity. The investigation determined that the cost of the equipment with which to begin making metal ribs would pay for all the wood ribs for the first 750 planes. Up to the present time, while makers of substitutes for wood have made great progress in perfecting their product and have done exceptional promotion work, wood still remains enthroned from the standpoint of utility and economy.

A paper entitled, "Factors in the Design of Commercial Airplanes," read by Charles Talbot Porter at the annual meeting in New York City, December 2, 1929, of The American Society of Mechanical Engineers, contained an interesting paragraph in this connection. In reviewing existing airplanes from the standpoint of materials used, it was stated that a great variation of thought was at once apparent. There had been much talk, it was said, of the fundamental advantage over wood of the all-metal rowboats, all-metal houses, etc., but the airplane engineer was urged to select his materials for each case with the best combination of safety, durability, cost, and performance; and while, for reasons of safety and cost, to some extent wood had been abandoned for body construction, the case of wood for wing-beam construction was still very strong.

In connection with the foregoing, it might be pointed out that one of the largest producers of automobiles in the world has recently carried out exhaustive tests looking toward safety, durability, cost, and performance in automobile bodies, and after the most painstaking tests he has decided to abandon largely the metal construction and revert to wood.

As to the fire risk, of course the recent deplorable accidents in the transport field with all-metal ships, which were consumed by fire, does away with any argument regarding the greater risk of wood construction. This is strikingly demonstrated also in automobiles, where the fire risk with wood-constructed bodies is considered no greater than with all-metal.

Referring again to Government statistics which indicate that about 2½ per cent of the total cut of spruce is all that has the requisite quality for use in airplane construction, it will be seen that there is a serious matter of inspection and selection necessary before a given piece can be placed in the wing of a finished plane. In this connection it is well to consider some of the specifications laid down by the Government relative to quality of airplane lumber, as follows:

Material:

1 The lumber shall be sound and clear on four sides, and free from all decay. Bright sap, knots, or equivalent burls ¼ in. or less in diameter, and narrow pitch pockets and bark seams 1½ in. in length, shall not be considered defects.

2 The grain shall be straight, that is, the angle of deviation from a line parallel to the edges shall not exceed 1 in. in 15 in. Vertical or flat grain will be accepted.

3 The rate of growth of any piece shall be not less than six annual rings to each inch when measured in a radial direction on either end section through the zone of maximum growth.

These are some of the specifications, but in actual practice their proper interpretation is the important thing, as here it is that experience counts.

It is to be said in behalf of the Department of Commerce in charge of commercial aeronautics that it is a group of young men, technically trained, industriously working with high ideals to accomplish the greatest possible good for the airplane industry and the public. When one says "airplane lumber" he should have in mind lumber that not only answers the foregoing specifications but lumber that has strength as its first characteristic.

The accompanying photographs show different operations in the production of airplane spruce.

Discussion

R. L. Hankinson.[2] The author has presented the subject largely from the standpoint of the lumber manufacturer who furnishes the airplane builder with spruce, either as a raw material or in a semi-manufactured form, such as wing beams, wing ribs, etc. From study of the use of spruce in airplane construction, the writer agrees with the statements presented by the author.

During the World War the spruce needed for airplanes was furnished by the Spruce Production Corporation, which functioned under Government supervision. For a time following the armistice some of the airplane spruce left over from manufacturing Government planes was sold and found its way into the manufacture of commercial planes. About 1922, however, airplane builders began to complain of the scarcity of spruce for airplane manufacture and to look for substitutes. The opinion was broadcast among the airplane manufacturers and the public at large that some substitute must be found for spruce.

Three causes were responsible for the prevailing opinion: First, the airplane manufacturer, not foreseeing his needs far enough in advance, attempted to obtain airplane spruce for quick delivery, the same as he would buy nails, bolts, etc., forgetting that it was not a commercial commodity. In the second place, a few lumber dealers attempted to supply commercial spruce in place of the higher-grade material needed for airplanes which was unsatisfactory to the airplane manufacturer. The third reason was that the market for airplane spruce was a negligible quantity and no manufacturer of spruce lumber could afford to gradually accumulate the very best of the run of his production to supply a very doubtful market where there were no size standards existing.

The paper points out that the existing stand of spruce is adequate to meet the needs of airplane manufacturers for years to come, even though no consideration is given to the yearly growth of spruce. Especially is this statement true if airplane manufacturers can be educated to the use of built-up beams and other spruce members which will allow the utilization of the pieces of smaller cross-section and shorter lengths which are of airplane grade. It may be stated that there is a scarcity of airplane spruce for wing beams of large cross-section and long lengths because nature grows but few trees which will produce such stock. An airplane manufacturer should in no way hesitate to use a wing beam or other highly stressed part which has been manufactured from several smaller pieces of spruce, using casein glue as an adhesive.

The writer was one of the very early advocates of this method of wing-beam construction, and after many experiments and tests made at the Matériel Division of the Army Corps at Dayton, Ohio, did everything possible to encourage manufacturers to adopt this type of construction, which construction was sanc-

[2] Wood Technologist and Research Engineer, U. S. Army Air Service, 1918 to 1929; present position Chief Engineer, Crescent Panel Company, Louisville, Ky.

t'oned for use on Air Corps contracts as early as 1921. It was the writer's privilege to follow the history of such construction until about one year ago, and he does not know of a structural failure which could be attributed to built-up spruce members.

There are a number of good designs for built-up wing beams which have been successfully used. One of the types most largely used is the so-called box-type beam, which consists of two spruce flanges and spruce planking for the beam sides.

The spruce flanges either can be laminated or made from a single piece in cross-section. Either type of flange may be spliced by means of a plane-scarfed splice to form the beams of the required lengths. The side members which resist the shear forces should be two-ply 45-deg. planking of either spruce or mahogany. Spruce planking for this purpose appears to be the favorite on account of its higher weight-strength ratio.

The writer would urge airplane manufacturers to place more reliance in reputable spruce and plywood manufacturers who stand ready to help the airplane manufacturer obtain the most suitable material for airplane construction. By such mutual cooperation some of the problems relating to the scarcity of spruce and unsatisfactory plywood will be satisfactorily settled to the mutual advantage of all parties concerned.

WDI-52-7

Manufacturing Upright- and Grand-Piano Cases

By JOSEPH T. LINDSEY,[1] ROCHESTER, N. Y.

In this paper the author tells of the various manufacturing operations that are necessary to complete piano cases, and describes the system of following work used by the Foster-Armstrong Company. Emphasis is placed on the fact that an efficient planing system is most essential to obtain best results. Operations carried out in the various departments together with the special machine tools used are described.

AN EFFICIENT drafting and planning system is one of the essential factors for obtaining best results in manufacturing piano cases. In the factory with which the author is connected a schedule sheet for every part is prepared. On this is given the part number, the kind of wood, the number of pieces, finished dimensions, cost-part numbers, operation numbers, and remarks telling what to do. Numbers are assigned for every operation from that of the swing-saw in the mill to the final operation at completion. As an illustration of the part-number system numbers from 1 to 100 are allotted to upright-piano cases and those from 101 to 200 to grand-piano cases. Practically every part number has a name. Drawings are made first, and are approved by the proper authorities, then the schedule sheet is made. When the schedule of operations is completed the sheet is filed in the case-shop office.

When a particular style appears on the layout, it is handled either by sheets or by tags. When a long run on a particular style is expected sheets are multigraphed. Blank spaces are provided for the lot number, kind of wood, veneer or stock to be used, etc. The tag system is used for slow-moving styles where it does not pay to put them on sheets. Layout check lists are distributed to all departments. The mill department received tags at this time. The foreman sorts the tags and checks them off on his check list as they are given out to the different swing-saws. When parts are completed they are checked out of the mill and into the department that receives them. This system continues until the work is completed.

Approximately 1,250,000 ft. of lumber is kept in the storage yard. This consists of 10 different kinds of wood varying in thickness from $^1/_8$ to $2^1/_2$ in. To keep a sufficient quantity of all kinds and dimensions, and to take care of a fluctuating layout, a schedule called the "minimum quantity" for the lumber yard is used. That quantity is based on an estimated amount so that no lumber will need to be delivered to kilns that has not been air dried for at least nine months.

The purchasing department receives a report the first and fifteenth of every month showing shortages. By following this scheme there is no excuse for not having ample air-dried lumber at all times regardless of the layout.

The mill foreman has charge of the kilns. He in turn gives the yard foreman orders as to the kind of lumber and amount needed. This is governed somewhat by the particular styles going through. The company with which the author is connected uses a box-type kiln with a conditioning shed between the kiln and the millroom. This layout is about the best for real results. It is the practice to keep all lumber in the conditioning shed for at least five days before cutting. That is ample time for cooling off and for taking on moisture necessary for a balanced condition equal to the average amount throughout the case shop.

FIG. 1 A HOME-MADE VENEER JOINTER

The tag system starts at the swing-saw. Each part has a tag to work by. With this system the department has a check list. This list calls for all parts that are used on this particular style. As a rule no two styles would ever have the same number of tags; therefore, check lists are different on every style. The list shows what has been delivered and what needs attention. It is a very simple scheme but very important.

The mill delivers to four departments. They are the veneer laying, back frame, machine assembling, and cleaning departments. The machine tools include a swing-saw, band-resaw, jointers, automatic jointer, planers, linderman, glue jointer, sticker, cylinder sander, dowel machine, tenoner, and continuous glue clamps.

VENEER CUTTING DEPARTMENT

Veneers are cut by schedule with part numbers as already mentioned. In the space for remarks are entered the number of pieces, single veneer on one side or two sides, double veneer on one side, etc. Otherwise, it is understood that it is to be double veneered on both sides. When special veneers are to be used that information also appears on the schedule. In fact, the schedule takes care of all details.

It is very important that veneers should be dried properly

[1] General Superintendent, Case Shop, Foster-Armstrong Co. Mem. A.S.M.E. Mr. Lindsey started work in a builder's finishing factory at the age of 16, remained in that line of work for 5 years and changed to mechanical pattern making for $10^1/_2$ years. He spent 2 years in designing and pattern making in piano-case work.

Presented at the Rochester Meeting, Rochester, N. Y., May 13 to 15, 1929, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

before cutting and taping. Lack of proper drying causes warping, twisting, checking, and open joints. When veneers are prepared properly, as a rule the percentage of replacement parts is very small. Cross-banding should never be dried any more after it has been taken care of by the manufacturer. Material is not used from a car that has just been unloaded. It is uncrated, piled, and in about two or three weeks' time, the moisture content is the same as that being used, or 8 to 10 per cent.

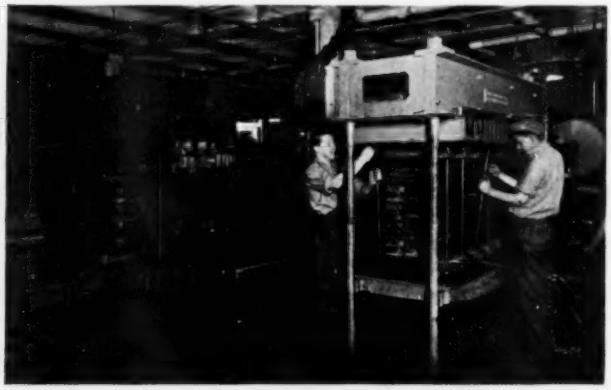

FIG. 2 HYDRAULIC PRESS IN THE VENEER LAYING DEPARTMENT

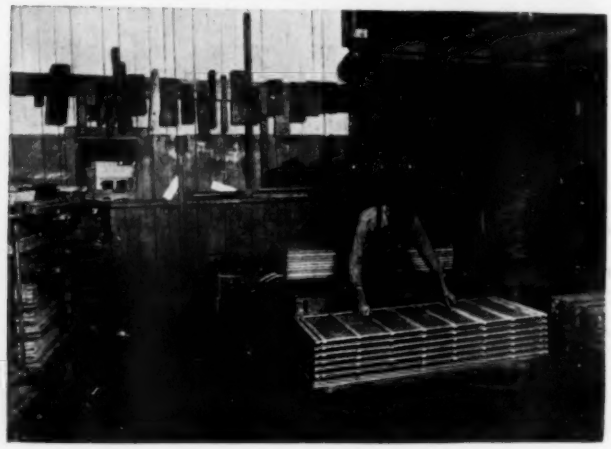

FIG. 3 OPERATION OF UNLOADING AND RACKING

FIG. 4 HAND-BLOCK BELT SANDER

Fig. 1 shows a veneer jointer. This is a home-made machine consisting of a bench, portable bench top, and an electric saw. A strip of steel is screwed to the entire length of the portable bench top to serve as a guide. A recess is cut in the electric saw frame that fits the strip that is on the portable bench top. Veneers are placed on the bench so as to work from the front edger. The portable table is placed on top of the veneers, and is held in place by guides at both ends of the bench and the portable bench top. The operator places the electric saw on the portable table, turns on the switch, and then pushes the saw the full length of the veneer. The current is then turned off and the saw is drawn back to the shelf. The portable bench top is then removed and is placed on its hangers. The veneers are then turned over as per the dimension required and then the procedure is repeated. This jointer is unlimited as to its capacity and can be used to advantage particularly in small shops that use veneers.

VENEER LAYING DEPARTMENT

Core-stock veneers and cross-banding are checked in and out as to lot number and part number by a check list. Three kinds of glue are used, vegetable, hide, and monite. Vegetable glue is used on at least 98 per cent of the flat work; on the remaining 2 per cent hide glue is used.

Hide glue is used on practically all circle work; that is, falls, moldings, etc. Monite is used on some parts when the layout is too great for the caul capacity as where two layings per day are obtained in the hydraulic press; that is, parts that pass through the sticker or molder.

Templets are made for the sticker. Cauls are made from the templet by a first-class trained mechanical pattern maker. By employing such a mechanic there are no loose veneers. In fact, all patterns, cauls, forms, jigs, and such tools are built by the pattern maker.

Great care is taken when unloading the presses and racking stock. About 85 per cent passes through the kiln. It is not necessary to put the thick stock through as moisture is absorbed in a very short time.

Fig. 2 shows a hydraulic press in the veneer-laying department. A batch of back falls is being clamped in retainers. All circle work is handled in this manner as it eliminates hand press work. At the left of the hydraulic press there is a truck with a batch of back falls of a different shape. The real success of handling circle work in the hydraulic press is through the use of the templet and by maintaining accuracy.

Fig. 3 shows the unloading and racking operation. Care in this is necessary to obtain good straight stock. Several sizes of racks are used so the combination is generally great enough to take care of the varied sizes. All veneered parts pass through this operation. Veneer dry-kiln stock remains in the kiln about 14 hr.

GRAND PIANO RIM DEPARTMENT

This department works by layouts, style, and lot number. Monite glue is used. Rims and skeletons are laid starting at 7:30 a.m. They are taken out of the presses at about 2 p.m. the same day. The second laying starts at that time. Rims that come from the press are taken to a bandsaw, the ends are cut off plus final length and then the bottom edge is jointed.

Retainers are placed on the treble and base sides. The next day they are put in the kiln for 48 hr. Final jointing of the bottom edge then takes place, cheeks are glued on, band-sawed to shape, and sawed to width. From this operation they are piled in the conditioning room for four to five weeks. Then they are taken to the machine department, cheeks are shaped, and other machine operations take place at this time. When com-

pleted they are delivered to the assembling and cleaning department, where they are completed, ready for inspection.

Machine Department

This department receives stock from the mill, veneer laying, and grand-rim laying departments. All work is carried through by tags and by the check-list system. This department is called the "Second Mill." The term "machine" is used because all parts are completed ready for assembling. The machine used in this department are: Jointers, saw benches, shapers, band- and jig-saws, boring machines, cylinder sander, stroke sanders, automatic lathe, hand lathe, carving machine, and edge veneering machine. Special equipment such as patterns, forms, cauls, etc., are furnished by the pattern makers. All completed parts are delivered to the assembling and cleaning department.

Fig. 5 Grand Skeleton Leveling Machine

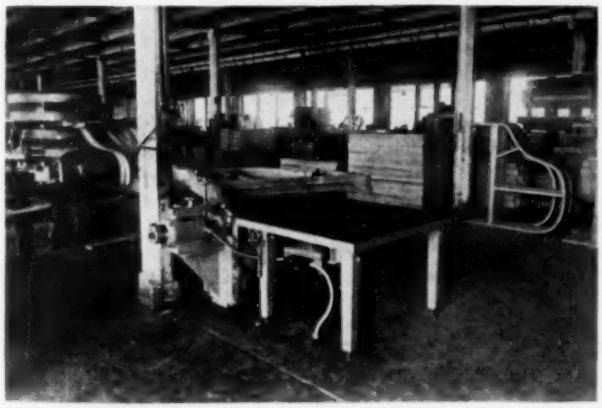

Fig. 6 Skeleton After Leveling Operation Has Been Completed

Cleaning Department

Practically all parts are delivered to this department by the machine department. Very few parts are delivered by the mill department. All work is carried through with the tag and check-list system. The tags furnish complete information as to operation. Drawings are not found necessary except possibly for the first lot going through. By eliminating the drawings production is somewhat larger than it was before the tag system was used. All the assembling or cabinet work is completed in this department.

It is necessary to return some parts to the machine department before they are machine sanded or hand sanded. All edge sanding, circle falls, moldings, and small parts are machine sanded in this department. The machines used are the edge belt, spindle, disk, and hand block. All work such as vein lining, fluting, small depressions, and cutting in leg plates are handled by small routers. They are very efficient.

Fig. 4 shows a hand-block belt sander. This machine has some special equipment. There is a vertical table and a pit is built in the floor. In this pit there is a platform that can be raised or lowered by the hand wheel shown at the left end just above the floor in the illustration. Parts up to 68 in. square are handled.

When sanding a square back-end, grand-piano rim or case, the rim rests on two arms which hook on to the top edge of the vertical table. They are long enough so the operator is able

Fig. 7 Crowning the Skeleton for the Sounding Board

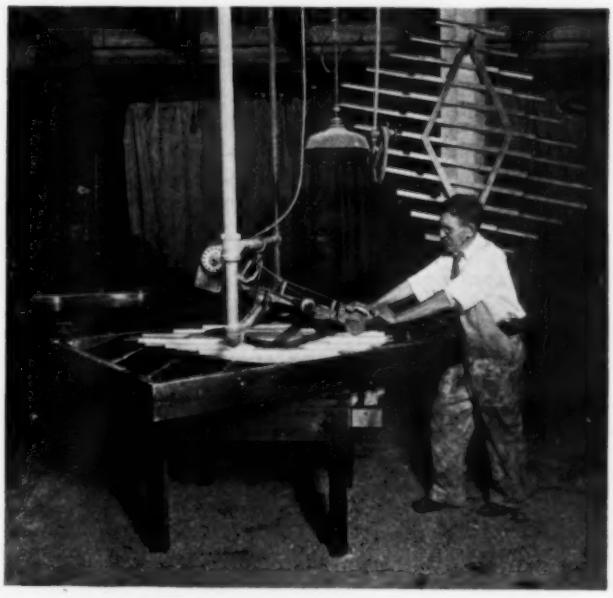

Fig. 8 Sounding-Board Scooping Machine

to slide the rim backward and forward. This enables him to sand the full width of the treble base and back end. The circle part is sanded by hand.

Fig. 5 shows a grand-piano skeleton-leveling machine. At the right is a form to assemble grand-piano skeleton parts. When completed in this form they are placed on a three-point bearing form on the leveling machine. In Fig. 5 the operator is passing a skeleton over the cutters. About $^1/_8$ in. is allowed on the bottom edge for leveling. As a rule this is sufficient. If not, the operator can raise the head enough to clean whatever is necessary.

Fig. 6 shows the skeleton completed as far as leveling is concerned. It is cleaned by the cabinet maker and in the machine department it is shaped on a form to exact shape and size.

The next operation shown in Fig. 7 is the operation of crowning the skeleton for the sounding board. This operation is very important. In order to eliminate the human element the electric planer is arranged so that the operator takes two cuts. About $^3/_{32}$ in. is left for the last cut. When completed by this operator, they are inspected and then delivered to the belly department where the sounding board is glued on, plate fitted, and the bearing taken. From this point they are delivered to the stringing department.

Fig. 8 shows the sounding-board scooping machine. This is a home-made machine of four parts. The base is a revolving frame. Over this is a swinging pipe frame. On this frame a machine on wheels rotates back and forth so as to cover the entire size of the sounding board. The sounding board is placed on a revolving frame, rib side up. Then the form is placed on the rib side of the sounding board. One of these can be seen hanging just back of the operator on a post. The operator can start on either end. When he has finished one side, he swings the frame that is on top of the base one-half around and then proceeds as before. This scheme eliminates any chance of error, and in turn insures a first-class job. All finished parts are inspected, checked, and delivered to the staining and filling department.

WDI-52-8

Mass Production of Radio Cabinets

By ARCHER W. RICHARDS,[1] CHICAGO, ILL.

The great demand for radio cabinets made it necessary for manufacturers to arrange their methods and machinery on a highly productive basis. The author in this paper tells of the production methods and machinery used by the Grigsby-Grunow Company. Lumber is purchased already dried and cut to exact dimensions for standard designs of cabinets. The material is received in matched sets, so parts are started through the mill immediately upon receipt and much storage space is saved and several handlings are eliminated. More rigid inspection is necessary with this method than with others so specifications for material were given careful attention. The paper describes the plant equipment, inspection methods, plant layout, and handling methods.

RADIO cabinets, in the beginning, were merely boxes to house the various component parts of the radio receivers, speakers, etc., and it is only within the past few years that the radio industry conceived the idea of a complete piece of furniture to house all of the mechanism of the radio receiver. The tremendous demand created for these compact, artistic outfits, as well as the low-selling price, called for deep study and intensive experimenting in the manufacture of well-made low-priced cabinets.

The furniture industry is one of the oldest in existence, and while low-priced furniture has been made, the lesson learned in mass production of other products did not seem to be accepted by the industry. Hence the Grigsby-Grunow Company found it necessary to build a complete cabinet plant which would combine the most modern production methods and machinery.

Rather strangely the development was made, not by experienced woodworkers of the old school, but by ingenious and resourceful production engineers, who were inspired by their chiefs to undertake and creditably to master the best way of producing attractive, efficient, and salable radio outfits. It is one of the instances that demonstrates that trade knowledge is much less essential to success than is the thorough production experience of technical engineers combined with a tremendous market demand for the product.

The First Steps

In May, 1928, a plant consisting of four buildings with approximately 375,000 sq. ft. of manufacturing floor space was leased from one of the General Motors subsidiaries in Chicago, and rapidly during the subsequent 60 days, woodworking machinery and equipment was installed, and the production of cabinets was under way while the previous tenants were moving out. By the first of July production had reached 1500 complete radio cabinets per day, which was increased at the rate of 500 per day every two or three weeks until by the first of September the maximum possible production of 3500 cabinets per day was reached.

A number of far-reaching decisions were made at this particular time, and the wisdom of these decisions has been fully justified by the subsequent success and efficiency of the cabinet plant In the first place although the plant, which was leased, contained the necessary dry kilns and storage space for handling rough lumber it was decided to purchase the lumber already dried and cut to the exact dimensions and size necessary for the particular cabinet designs which had already been decided upon. As this material is received in matched sets in each car, a great deal of storage space is saved because the parts can be started through the mill immediately upon receipt. The purchase of dimension stock makes necessary a rigid inspection of incoming materials, to be certain that each piece is exactly suitable for the particular part of the cabinet for which it is intended, and to eliminate at least half of the mill operations, allowing them to be performed nearer the sawmill in a cheaper labor market, thus saving freight on all waste material.

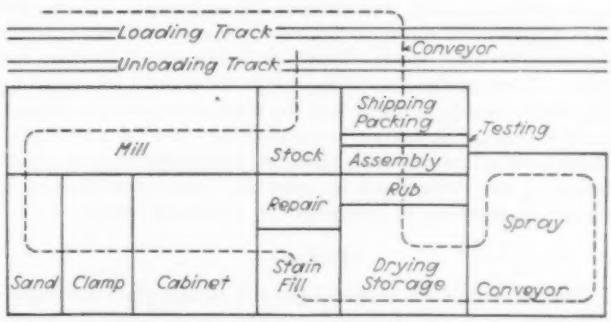

Fig. 1 Plant Layout of Grigsby-Grunow Company, Chicago, Ill.

Plywood specifications were also carefully developed so that the exact sizes required could be shipped in matched sets, and immediately be started through the manufacturing department, with a minimum amount of waste and machine work.

Sources of Supply

At the time these decisions were made there were no manufacturing units large enough to handle the quantity of material required so that specifications were scattered among a number of manufacturers. It soon became obvious that it was necessary to minimize the number of suppliers, and the best of the suppliers were inspired to increase their facilities to a point which in some cases meant three or four times their previous maximum production.

Every piece of material used in the cabinet is specified exactly, not only as to size and manufacturing tolerances, but as to kind and quality of wood, kind of glue used, amount of moisture, as well as other requirements.

Working with the plywood manufacturer reasonable limits were also developed for the veneer figures, so as not to limit the purchase of materials while still obtaining the beautiful effects necessary to make the cabinets a work of art.

This required close cooperation with the suppliers and a tremendous amount of work by all organizations, but this has been thoroughly justified by the results as evidenced by the fact that production was stepped up to 5000 units per day the first of May, 1929, without it becoming necessary to increase the number of suppliers or enlarge the plant.

---

[1] Factory Manager, Grigsby-Grunow Co.

Presented at the Fourth National Meeting of the Wood Industries Division, Rockford, Ill., Oct. 16 to 18, 1929, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Plant Equipment

Inasmuch as the cabinets were designed before production was started, it was possible to select the exact equipment required to perform each operation, and to arrange so that this equipment would be in operation 22 hr. per day. The economy of this continuous operation is obvious. In the majority of cases the operators are working on the same piece and operation day after day, which makes for quality and low cost. Material is brought to them and taken from them in a steady flow, and in most cases passes through an inspection before moving from one department to the next for further operations. All material thrown out by the inspection department is taken to a separate department, and is either brought up to standard or discarded by this department. This eliminates all delays and congestion that would result from "backtracking" material for salvage in the manufacturing department. It also puts the salvaging under the supervision of an expert whose whole thought is to prevent waste of material.

All machines are individually driven by electric motors so that shafting and belts are entirely eliminated. This permits great flexibility in the arrangement of machines, preserves headroom for mechanical handling, distributes natural and artificial light more advantageously, and reduces dirt and noise. A complete blower system of the most improved type and ample capacity has been installed so that there is a minimum of shavings and dust. Every machine and operator in the plant is scheduled by the production department and the production of every department is checked each hour to see that the "rate" is maintained. Reports are submitted to the operating heads each hour, and upon failure of any department to make its "rate," investigation is started immediately to determine the cause and remedy.

Inspection

Ten per cent of the employees of the cabinet plant are inspectors reporting to a chief inspector, who reports only to the factory manager, and no foreman or department head other than the chief inspector and the factory manager is authorized to override the inspector's rejection. Inspection is based on the standards set up by the engineering department. It is obvious that it requires close cooperation between the production, operating, and inspection departments in order that harmonious relations, as well as the highest efficiency, be maintained. In all departments the battery system of production is used so that intensive supervision and intelligent inspection is possible.

Plant Layout

The various departments of the plant are classified as follows:

Stock Room. In this department is vested the responsibility for the unloading and storing of all raw and semi-raw materials used, and also from this department issue the "rations" of raw materials according to the time schedule set up by the production department.

Mill Room. This department is responsible for all necessary machine work, on dimension lumber and plywood.

Sanding Department. The work of this department is to polish (in the white) each part separately so that there is required the minimum amount of hand-sanding after assembly.

Clamp Department. In this department all individual parts are assembled and clamped into a case or cabinet.

Cabinet Room. Here all of the doors are fitted and hung, hardware put on, and all necessary hand finishing and sanding of molding, trim, etc., is done.

Finishing Department. To this department come all assembled units and parts in the "white," where they are stained, filled, sprayed, rubbed, and polished. Following this operation, each cabinet is inspected carefully, and is gone over by a trained finisher, and if found necessary, each cabinet is polished up by hand.

Assembly Department. The cabinet is then carefully re-inspected and turned over to the assembly department, where are installed the radio receiver, speaker, and hardware fittings on the exterior and in the interior of the cabinet.

Testing Department. The final test and inspection of the receiver and speaker after assembly are under the direction of the engineering department, and each completed job is checked carefully to see that every part functions properly.

Packing Department. The assembled and tested units are then turned over to the packing department, where the complete assembly is packed in a special packing case, and is again inspected and forwarded to the shipping department.

Shipping Department. In this department is installed a 1500-ft. mechanical conveyor which has a capacity for loading 35 cars per day.

Handling of Materials

All material is handled on trucks up to the clamp department, after which it is slid over specially prepared hardwood floors or carried by overhead conveyors from one operation to the next.

Warehouse Unnecessary

It is of interest that the manufacturers have no large warehouse for raw materials. A continuous inflow of materials is maintained and used at such a rate that many items of these materials are shipped out in the finished product within a few hours after they are received. Practically no item is kept in an unfinished state more than two days.

Volume Capacity

To the furniture manufacturer and woodworker, the figures below will be of interest. In the present production of 5000 radio sets per day approximately the following materials are used weekly:

18 carloads of plywood
18 carloads of dimension lumber
3 carloads of lacquer
1 carload of nails and screws
48 carloads of packing cases
5 tons of glue
2500 yards of silk grill cloth
150,000 lineal feet of molding

There are 40 cars required for each day's shipment of finished radio receivers.

A.S.M.E. Record and Index, 1930

THIS section of the Transactions contains a record of the Society's activities for the year 1930, together with an index of its publications. Since 1926 when the original form of printing the Transactions was abandoned, the Record and Index has been issued in book form. After further study of the publication program, the Council voted to issue the Record and Index so that it would be uniform in size and general appearance with other sections containing the technical papers, thus returning this material to the Transactions where it was formerly to be found. It thus becomes possible to bind the Record and Index with the technical papers for the use of libraries and official depositories throughout the world, and for members to file or bind their copies with the sections of Transactions they have received during the year.

The Record and Index Section of Transactions includes all the reference material likely to be of permanent value and of interest to future searchers. As an index it provides a means of locating the technical information in the Society's publications. It includes the separate indexes of the Transactions and *Mechanical Engineering*, together with a miscellaneous index to reports or other technical publications of the Society that have appeared during the year.

A considerable part of this section is devoted to memorial notices of members who have died during the year. Special care has been given to the preparation of the necrology with the idea in mind that fitting notice and attention should be given to significant events in the lives of deceased members, even though they may fall outside the immediate field of mechanical engineering.

Charles Piez

THE career of Charles Piez, President of The American Society of Mechanical Engineers for the term 1929–1930, has been characteristically American. Born in Germany in 1866, of naturalized American parents, he grew up in this country and became a typical American. He personifies progressive Americanism of the sort typified by the late President Roosevelt. Mr. Piez received his technical education as a mining engineer at the School of Mines, Columbia University. Like many other men who later became leaders in the business world, his own earnings contributed largely toward paying for his education.

Immediately after his graduation in 1889, he entered the employ of the Link-Belt Engineering Company, in Philadelphia, as an engineer draftsman at $65 a month. Seventeen years later (in 1906), after he had attained to the position of chief engineer and general manager of the Philadelphia works of that concern, he was elected president of a consolidated organization of the three related companies, the Link-Belt Machinery Company (Chicago), the Ewart Manufacturing Company (Indianapolis), and the Link-Belt Engineering Company (Philadelphia). The consolidation was thereafter known as the Link-Belt Company. The consolidated corporation under Mr. Piez's management became widely known as an efficiently operated and successful engineering and manufacturing enterprise.

Largely as a result of his fame as an organizer and manager of industry, Mr. Piez was selected in November, 1917, to be vice-president and general manager of the United States Shipping Board Emergency Fleet Corporation, to carry out the nation's shipbuilding program. Charles M. Schwab, later chosen director-general of this corporation, "the greatest business organization in the world's history," and Mr. Piez were inseparable associates and friends in their titanic efforts to "bridge the seas with ships." On May 1, 1919, Mr. Piez resigned as director-general, to return to his private business. He continued as president of the Link-Belt Company until 1924, when he became chairman of the board, with full executive control of the company and its various subsidiaries.

He is also president of the Commercial Club of Chicago; a director of the State Bank of Chicago and of the Drexel State Bank of Chicago; a member of the executive committee of the Museum of Science and Industry founded by Julius Rosenwald; and a member of the following engineering societies: The American Society of Mechanical Engineers, American Institute of Mining and Metallurgical Engineers, Society of Naval Architects and Marine Engineers, and Western Society of Engineers.

CHARLES PIEZ

PRESIDENT OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS
1929–1930

The American Society of Mechanical Engineers

THE personnel records and other information presented in this first section of the Record and Index refer, except where otherwise noted, as in the case of Local Section and Student Branch chairmen, to the official year beginning in December, 1929. Such information is purely of historical nature and is included here as a permanent record. For the names of those in office or serving the Society in any way in 1931, the Membership List for 1931 should be consulted.

Worcester	O. V. Payne
Youngstown	R. J. Wean

[5] Term of office, July, 1929–July, 1930.

Student Branches

For further information consult 1930 Membership List

Name and Location	Honorary Chairmen[6]
Akron, Univ. of, Akron, Ohio	F. S. Griffin
Alabama Polytechnic Inst., Auburn, Ala.	Solon Dixon
Arkansas, Univ. of, Fayetteville, Ark.	L. C. Price
Armour Inst. of Technology, Chicago, Ill.	Daniel Roesch
Brooklyn, Polytechnic Inst. of, Brooklyn	Joseph Lambertine
Brown Univ., Providence, R. I.	J. A. Hall
Bucknell Univ., Lewisburg, Pa.	Frank E. Burpee
California Inst. of Technology, Pasadena	W. H. Clapp
California, Univ. of, Berkeley, Calif.	H. B. Langille
Carnegie Inst. of Tech., Pittsburgh, Pa.	T. G. Estep
Case School of Applied Science, Cleveland	C. L. Tuve
Catholic Univ. of America, Washington	Wm. Karsunky
Cincinnati, Univ. of, Cincinnati, Ohio	C. A. Joerger
Clarkson College of Tech., Potsdam, N. Y.	Jess H. Davis
Clemson College, Clemson College, S. C.	C. P. Philpot
Colorado Agricultural College, Fort Collins	L. D. Crain
Colorado, Univ. of, Boulder, Colo.	Frank S. Bauer
Columbia Univ., New York, N. Y.	Carl F. Kayan
Cooper Union, New York, N. Y.	G. F. Bateman
Cornell Univ., Ithaca, N. Y.	S. S. Garrett
Delaware, Univ. of, Newark, Del.	R. L. Spencer
Detroit, Univ. of, Detroit, Mich.	F. J. Linsenmeyer
Drexel Inst., Philadelphia, Pa.	C. V. Hahn
Florida, Univ. of, Gainesville, Fla.	P. O. Yeaton

[6] In office December 31, 1930.

Name and Location	Honorary Chairmen
George Washington Univ., Washington, D. C.	Walter B. Lawrence
Georgia School of Technology Atlanta, Ga.	Ray M. Matson
Harvard Univ., Cambridge, Mass.[7]	
Idaho, Univ. of, Moscow, Idaho	Barton Cruikshank
Illinois, Univ. of, Urbana, Ill.	C. W. Ham
Iowa State College, Ames, Ia.	J. G. Hummel
Iowa, State Univ. of, Iowa City, Ia.	Ralph M. Barnes
Johns Hopkins Univ., Baltimore, Md.	F. W. Kouwenhoven
Kan. State Agricultural College, Manhattan	J. P. Calderwood
Kansas, Univ. of, Lawrence, Kan.	Ralph S. Tait
Kentucky, Univ. of, Lexington, Ky.	Carter C. Jett
Lafayette College, Easton, Pa.	Paul B. Eaton
Lehigh Univ., Bethlehem, Pa.	Fred V. Larkin
Louisiana State Univ., Baton Rouge, La.	Hamilton Johnson
Louisville, Univ. of, Louisville, Ky.	H. H. Fenwick
Lowell Textile Inst., Lowell, Mass.	H. J. Ball
Maine, Univ. of, Orono, Me.	Harry Watson
Marquette Univ., Milwaukee, Wis.	John E. Schoen
Mass. Inst. of Technology, Cambridge	C. E. Fuller
Michigan College of Mining and Technology, Houghton, Mich.	R. R. Seeber
Michigan State College, East Lansing, Mich.	Lawrence N. Field
Michigan, Univ. of, Ann Arbor, Mich.	R. S. Hawley
Minnesota, Univ. of, Minneapolis, Minn.	B. J. Robertson
Mississippi A. & M. College, A. & M. College	O. D. M. Varnado
Missouri School of Mines and Metallurgy, Rolla, Mo.	R. O. Jackson
Missouri, Univ. of, Columbia, Mo.	G. D. Newton
Montana State College, Bozeman, Mont.	Eric Therkelsen
Nebraska, Univ. of, Lincoln, Neb.	A. A. Luebs
Nevada, Univ. of, Reno, Nev.	F. H. Sibley
Newark College of Engineering, Newark, N. J.	J. Ansel Brooks
New Hampshire, Univ. of, Durham, N. H.	Edward T. Donovan
New York, College of City of, New York	Frederick Kuhlen
New York Univ., New York, N. Y.	Arthur C. Coonradt
North Carolina State College, Raleigh, N. C.	J. M. Foster
North Carolina, Univ. of, Chapel Hill, N. C.	E. G. Hoefer
North Dakota Agri. College, Fargo, N. D.	Robert M. Dolve
North Dakota, Univ. of, Grand Forks, N. D.	A. J. Diakoff
Northeastern Univ., Boston, Mass.	J. W. Zeller
Notre Dame, Univ. of, Notre Dame, Ind.	(To be appointed)
Ohio Northern Univ., Ada, Ohio	John A. Needy
Ohio State Univ., Columbus, Ohio	W. T. Magruder
Oklahoma A. & M. College, Stillwater, Okla.	E. C. Baker
Oklahoma, Univ. of, Norman, Okla.	J. H. Felgar
Oregon State Agricultural College, Corvallis	R. E. Summers
Pennsylvania State College, State College	C. L. Allen
Pennsylvania, Univ. of, Philadelphia, Pa.	John A. Prior
Pittsburgh, Univ. of, Pittsburgh, Pa.	John A. Dent
Porto Rico, Univ. of, Mayaguez, P. R.	Ramon Gil
Pratt Inst., Brooklyn, N. Y.	A. C. Harper
Princeton Univ., Princeton, N. J.	A. M. Greene, Jr.
Purdue Univ., W. Lafayette, Ind.	H. L. Solberg
Rensselaer Polytechnic Inst., Troy, N. Y.	Howard E. Stevens
Rhode Island State College, Kingston, R. I.	Royal L. Wales
Rice Inst., Houston, Tex.	J. V. Pennington
Rose Polytechnic Inst., Terre Haute, Ind.	Carl Wischmeyer
Rutgers Univ., New Brunswick, N. J.	H. Lea Mason
Santa Clara, Univ. of, Santa Clara, Calif.	G. L. Sullivan
Southern California, Univ. of, Los Angeles	T. T. Eyre
Stanford Univ., Stanford University, Calif.	A. B. Domonoske
Stevens Inst. of Technology, Hoboken, N. J.	F. D. Furman
Swarthmore College, Swarthmore, Pa.	G. A. Bourdelais
Syracuse Univ., Syracuse, N. Y.	S. T. Hart
Tennessee, Univ. of, Knoxville, Tenn.	Leo Holdridge
Texas, A. & M. College of, College Station	V. M. Faires
Texas Technological College, Lubbock, Tex.	C. L. Svensen
Texas, Univ. of, Austin, Tex.	Carl J. Eckhardt
Tufts College, Tufts College, Mass.	W. E. Farnham
U. S. Naval Academy, P. G. Sch., Annapolis	P. J. Kiefer
Utah, Univ. of, Salt Lake City, Utah	W. J. Cope
Vanderbilt Univ., Nashville, Tenn.	P. A. Cushman
Vermont, Univ. of, Burlington, Vt.	E. L. Sussdorff
Villanova College, Villanova, Pa.	J. S. Morehouse
Virginia Polytechnic Inst., Blacksburg, Va.	J. B. Jones
Virginia, Univ. of, Charlottesville, Va.	A. F. Macconochie
Washington, State College of, Pullman, Wash.	Howard H. Langdon
Washington Univ., St. Louis, Mo.	Edward H. Sager
Washington, Univ. of, Seattle, Wash.	R. H. G. Edmonds
West Virginia Univ., Morgantown, W. Va.	C. R. Jones
Wisconsin, Univ. of, Madison, Wis.	J. W. McNaul
Worcester Polytechnic Inst., Worcester	Kenneth G. Merriam
Wyoming, Univ. of, Laramie, Wyo.	Robt. Rhoads
Yale Univ., New Haven, Conn.	S. W. Dudley

[7] Established November, 1930.

A.S.M.E. Representatives on Joint Activities

Dates in parentheses denote expiration of term

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

SECTION M, ENGINEERING

James H. Herron — M. P. Cleghorn

Representatives or alternates appointed according to geographical location of meetings

AMERICAN ENGINEERING COUNCIL

Terms expire January 1, 1931	*Terms expire January 1, 1932*
D. Robert Yarnall, *Vice-Chairman*, Philadelphia, Pa.	Charles Piez, *Chairman*, Chicago, Ill.
E. O. Eastwood, Seattle, Wash.	L. P. Alford, New York, N. Y.
Dean E. Foster, Tulsa, Okla.	Thomas D. Campbell, Hardin, Mont.
O. P. Hood, Washington, D. C.	William B. Ferguson, Newport News, Va.
W. P. Hunt, Moline, Ill.	Charles E. Ferris, Knoxville, Tenn.
Charles Penrose, Philadelphia, Pa.	John Lyle Harrington, Kansas City, Mo.
Frank A. Scott, Cleveland, Ohio	William H. Kenerson, Providence, R. I.
Elmer A. Sperry, Brooklyn, N. Y.	John H. Lawrence, New York, N. Y.
Max Toltz, St. Paul, Minn.	Richard C. Marshall, Jr., Chicago, Ill.
Edward N. Trump, Syracuse, N. Y.	A. A. Potter, Lafayette, Ind.

AMERICAN SOCIETY OF SAFETY ENGINEERS

ENGINEERING SECTION, NATIONAL SAFETY COUNCIL

H. W. Mowery — Ernest Hartford

AMERICAN STANDARDS ASSOCIATION

Cloyd M. Chapman (1930) — H. Birchard Taylor (1932)
Collins P. Bliss (1931)[8] — K. H. Condit (*alternate*)
C. B. LePage (*alternate*)

ENGINEERING FOUNDATION, INC.

Formerly United Engineering Society

E. R. Fish (1931) — H. Hobart Porter (1932)
Harold V. Coes (1933)

ENGINEERING SOCIETIES RESEARCH BOARD

D. Robert Yarnall (1931) — H. Hobart Porter (1932)[9]
A. E. White (1933)

GANTT MEDAL BOARD OF AWARD

W. L. Conrad — Conrad N. Lauer
Dexter S. Kimball

GUGGENHEIM MEDAL BOARD OF AWARD

Elmer A. Sperry[10] (May, 1931) — Edwin E. Aldrin (May, 1933)
W. F. Durand (May, 1932) — George W. Lewis (May, 1934)

HERBERT HOOVER MEDAL BOARD OF AWARD

Ambrose Swasey — Dexter S. Kimball
Calvin W. Rice

INTERNATIONAL ELECTROTECHNICAL COMMISSION

U. S. NATIONAL COMMITTEE

F. R. Low — C. Harold Berry
W. F. Durand — H. Birchard Taylor
Francis Hodgkinson

[8] Represents the A.S.M.E. on the Executive Committee of the A.S.A.
[9] A.S.M.E. representative from Board of Trustees of Engineering Foundation, Inc.
[10] Deceased, June 16, 1930. H. I. Cone appointed to fill vacancy.

JOHN FRITZ MEDAL BOARD OF AWARD

The terms of office expire in October of each year

DEXTER S. KIMBALL (1930) — ALEX DOW (1932)
C. M. SCHWAB (1931) — ELMER A. SPERRY (1933)[11]

JOSEPH A. HOLMES SAFETY ASSOCIATION

O. P. HOOD

NATIONAL RESEARCH COUNCIL

DIVISION OF ENGINEERING

B. H. BLOOD (June, 1930) — R. J. S. PIGOTT (June, 1931)
A. E. WHITE (June, 1932)

ALFRED NOBLE PRIZE

L. P. ALFORD

SPIRIT OF ST. LOUIS MEDAL BOARD OF AWARD

(To be appointed)

WESTERN SOCIETY OF ENGINEERS

WASHINGTON AWARD

CHARLES PIEZ (June, 1930) — J. D. CUNNINGHAM (June, 1931)

[11] Deceased, June 16, 1930. W. L. Abbott appointed to fill vacancy.

GENERAL ASSIGNMENTS[12]

American Bureau of Welding, Advisory Board of the National Research Council, JAMES PARTINGTON.
American Bureau of Welding, Advisory Committee on Structural Steel Welding, GEO. A. ORROK.
American Bureau of Welding, Gas Welding Committee, JAMES PARTINGTON and C. W. OBERT.
George Washington Bicentennial Commission, GANO DUNN.
International High Commission, Advisory Committee to the U. S. Section, concerned with a preliminary study and compilation of a report on the use of Uniform Weights and Measures, RALPH E. FLANDERS.
National Screw Thread Commission, LUTHER D. BURLINGAME.
Standardization Survey Committee, C. M. SCHWAB, H. BIRCHARD TAYLOR (alternate).
U. S. Department of Commerce, National Committee on Metals Utilization, STANLEY G. FLAGG, JR.
U. S. Department of Commerce, National Conference on Street and Highway Safety, E. J. POSSELT.
U. S. Shipping Board, Fuel Conservation Board, H. L. SEWARD.

[12] The Society is also represented on a number of technical committees sponsored by other organizations. These committees are listed as follows: Research, p. 12; Standardization, p. 14; Safety, p. 15.

Honorary Members

HONORARY MEMBERS IN PERPETUITY

ALEXANDER LYMAN HOLLEY, Founder of the Society. Died 1882.
JOHN EDSON SWEET, Founder of the Society. Died 1916.
HENRY ROSSITER WORTHINGTON, Founder of the Society. Died 1880.

DECEASED HONORARY MEMBERS

	ELECTED	DIED
HORATIO ALLEN	1880	1889
SIR WILLIAM ARROL	1905	1913
SIR BENJAMIN BAKER	1886	1907
JOHANN BAUSCHINGER	1884	1893
SIR HENRY BESSEMER	1891	1898
SIR FREDERICK JOSEPH BRAMWELL	1884	1903
JOHN ALFRED BRASHEAR	1908	1920
GUSTAVE CANET	1900	1908
ANDREW CARNEGIE	1907	1919
DANIEL KINNEAR CLARK	1882	1896
RUDOLPH JULIUS EMMANUEL CLAUSIUS	1882	1888
SIR JOHN COODE	1889	1892
PETER COOPER	1882	1883
CARL GUSTAF PATRIK DE LAVAL	1912	1913
RUDOLPH DIESEL	1912	1913
JAMES DREDGE	1886	1906
VICTOR DWELSHAUVERS-DERY	1886	1913
ALEXANDRE GUSTAVE EIFFEL	1889	1923
MARSHAL FERDINAND FOCH	1921	1929
SIR CHARLES DOUGLAS FOX	1900	1921
JOHN FRITZ	1900	1913
MAJOR - GENERAL GEORGE WASHINGTON GOETHALS	1917	1928
FRANZ GRASHOF	1884	1893
OTTO HALLAUER	1882	1883
CHARLES HAYNES HASWELL	1905	1907
FRIEDRICH GUSTAV HERRMANN	1884	1907
GUSTAV ADOLPH HIRN	1882	1890
JOSEPH HIRSCH	1889	1901
IRA N. HOLLIS	1928	1930
ROBERT WOOLSTON HUNT	1920	1923
BENJAMIN FRANKLIN ISHERWOOD	1894	1915
HENRI LÉAUTÉ	1891	1916
ERASMUS DARWIN LEAVITT	1915	1916
ANATOLE MALLET	1912	1919
CHARLES H. MANNING	1913	1919
REAR-ADMIRAL GEORGE WALLACE MELVILLE	1910	1912
CHARLES TALBOT PORTER	1890	1910
AUGUSTE C. E. RATEAU	1919	1930
SIR EDWARD J. REED	1882	1906
FRANZ REULEAUX	1882	1905
HENRI ADOLPHE - EUGENE SCHNEIDER	1882	1898
C. WILLIAM SIEMANS	1882	1883
HENRY ROBINSON TOWNE	1921	1924
HENRI TRESCA	1882	1885
FRANCIS A. WALKER	1886	1897
WORCESTER REED WARNER	1925	1929
SIR WILLIAM HENRY WHITE	1900	1913
GEORGE WESTINGHOUSE	1897	1914

LIVING HONORARY MEMBERS

	ELECTED
SIR JOHN AUDLEY FREDERICK ASPINALL	1911
WILLIAM WALLACE ATTERBURY	1925
MORTIMER ELWYN COOLEY	1928
CHARLES DE FRÉMINVILLE	1919
THOMAS ALVA EDISON	1904
REAR-ADMIRAL ROBERT STANISLAUS GRIFFIN	1920
NATHANAEL GREENE HERRESHOFF	1921
HONORABLE HERBERT CLARK HOOVER	1925
MASAWO KAMO	1929
HENRI LE CHATELIER	1927
THE HONORABLE SIR CHARLES ALGERNON PARSONS	1920
GRANDE UFFICIALE ING. PIO PERRONE	1920
CHARLES M. SCHWAB	1918
VISCOUNT EIICHI SHIBUSAWA	1929
AMBROSE SWASEY	1916
ELIHU THOMSON	1930
WILLIAM CAWTHORNE UNWIN	1898
SAMUEL MATTHEWS VAUCLAIN	1920
OSKAR VON MILLER	1912
RIGHT HONORABLE LORD WEIR	1920
ORVILLE WRIGHT	1918
SIR ALFRED FERNANDEZ YARROW	1914

Past Officers

ALEXANDER LYMAN HOLLEY, Chairman of the Preliminary Meeting for Organization of The American Society of Mechanical Engineers. Died January 29, 1882

PRESIDENTS

1880–1882	ROBERT HENRY THURSTON	Died October 25, 1903
1883	ERASMUS DARWIN LEAVITT	Died March 11, 1916
1884	JOHN EDSON SWEET	Died May 8, 1916
1885	JOSEPHUS FLAVIUS HOLLOWAY	Died September 1, 1896
1886	COLEMAN SELLERS	Died December 28, 1907
1887	GEORGE H. BABCOCK	Died December 16, 1893
1888	HORACE SEE	Died December 14, 1909
1889	HENRY ROBINSON TOWNE	Died October 15, 1924
1890	OBERLIN SMITH	Died July 19, 1926
1891	ROBERT WOOLSTON HUNT	Died July 11, 1923
1892	CHARLES HARDING LORING	Died February 5, 1907
1893–1894	ECKLEY BRIXTON COXE	Died May 13, 1895
1895	EDWARD F. C. DAVIS	Died August 6, 1895
1895	CHARLES ETHAN BILLINGS	Died June 4, 1920
1896	JOHN FRITZ	Died February 13, 1913
1897	WORCESTER REED WARNER	Died June 25, 1929
1898	CHARLES WALLACE HUNT	Died March 27, 1911
1899	GEORGE WALLACE MELVILLE	Died March 17, 1912
1900	CHARLES HILL MORGAN	Died January 10, 1911
1901	SAMUEL T. WELLMAN	Died July 11, 1919
1902	EDWIN REYNOLDS	Died February 19, 1909
1903	JAMES MAPES DODGE	Died December 4, 1915
1904	AMBROSE SWASEY	Cleveland, Ohio
1905	JOHN RIPLEY FREEMAN	Providence, R. I.
1906	FREDERICK WINSLOW TAYLOR	Died March 21, 1915
1907	FREDERICK REMSEN HUTTON	Died May 14, 1918
1908	MINARD LAFEVER HOLMAN	Died January 4, 1925
1909	JESSE MERRICK SMITH	Died April 1, 1927
1910	GEORGE WESTINGHOUSE	Died March 12, 1914
1911	EDWARD DANIEL MEIER	Died December 15, 1914
1912	ALEXANDER CROMBIE HUMPHREYS	Died August 14, 1927
1913	WILLIAM FREEMAN MYRICK GOSS	Died March 23, 1928
1914	JAMES HARTNESS	Springfield, Vt.
1915	JOHN ALFRED BRASHEAR	Died April 8, 1920
1916	DAVID SCHENCK JACOBUS	New York, N. Y.
1917	IRA NELSON HOLLIS	Died August 15, 1930
1918	CHARLES THOMAS MAIN	Boston, Mass.
1919	MORTIMER ELWYN COOLEY	Ann Arbor, Mich.
1920	FRED J. MILLER	Center Bridge, Pa.
1921	EDWIN S. CARMAN	Cleveland, Ohio
1922	DEXTER SIMPSON KIMBALL	Ithaca, N. Y.
1923	JOHN LYLE HARRINGTON	Kansas City, Mo.
1924	FREDERICK ROLLINS LOW	New York, N. Y.
1925	WILLIAM FREDERICK DURAND	Stanford Univ., Calif.
1926	WILLIAM LAMONT ABBOTT	Chicago, Ill.
1927	CHARLES M. SCHWAB	New York, N. Y.
1928	ALEX DOW	Detroit, Mich.
1929	ELMER AMBROSE SPERRY	Died June 16, 1930
1930	CHARLES PIEZ	Chicago, Ill.

NOTE: According to the Constitution, Article C7, Sec. 2, the last five surviving Past-Presidents are members of the Council.

VICE-PRESIDENTS

HENRY ROSSITER WORTHINGTON	April, 1880–December, 1880
COLEMAN SELLERS	April, 1880–November, 1881
ECKLEY B. COXE	April, 1880–November, 1881
QUINCY A. GILMORE	April, 1880–December, 1880
WM. H. SHOCK	April, 1880–November, 1882
ALEXANDER L. HOLLEY	April, 1880–January, 1882
FRANCIS A. PRATT	December, 1880–November, 1881
THEO. N. ELY	1881–November, 1882
WASHINGTON JONES	1881–November, 1882
WM. P. TROWBRIDGE	1881–November, 1883
E. D. LEAVITT	1881–December, 1882
CHAS. E. EMERY	1881–1883
S. B. WHITING	1882–1883
JOHN FRITZ	1882–1884
HENRY MORTON	1882–1884
WM. METCALF	1882–1884
A. B. COUCH	1883–1885
W. R. ECKART	1883–1885
J. V. MERRICK	1883–1885
CHAS. W. COPELAND	1884–1886
HENRY R. TOWNE	1884–1886
COLEMAN SELLERS	1884–1885
OLIN H. LANDRETH	1885–1886
ALLAN STIRLING	1885–1887
HORACE SEE	1885–1887
CHAS. H. LORING	1885–1887
JOS. MORGAN, JR.	1886–1888
CHAS. T. PORTER	1886–1888

E. E. Keller 1913–1915
H. G. Reist 1913–1915
Henry Hess 1914–1916
Geo. W. Dickie 1914–1916
James E. Sague 1914–1916
Wm. B. Jackson 1915–1917
J. Sellers Bancroft 1915–1917
Julian Kennedy 1915–1917
Charles H. Benjamin 1916–1918
Arthur M. Greene, Jr. 1916–1918
Charles T. Plunkett 1916–1918
Spencer Miller 1917–1919
Max Toltz 1917–1919
John Hunter 1917–1919
Fred R. Low 1918–1920
Henry B. Sargent 1918–1920
John A. Stevens 1918–1920
John R. Allen[13] 1920–1921
William B. Gregory[14] 1920–1921
Robert H. Fernald 1919–1921
Edward C. Jones 1919–1921
Leon P. Alford 1920–1922
John L. Harrington 1920–1922
Robert B. Wolf 1920–1922
E. A. Deeds 1921–1923
Robert Sibley 1921–1923
L. E. Strothman[15] 1921–1922
Arthur L. Rice[16] 1922
H. H. Vaughan[17] 1923
Walter S. Finlay, Jr. 1922–1924
Wm. H. Kenerson 1922–1924
Earl F. Scott 1922–1924
George I. Rockwood 1923–1925
W. J. Sando 1923–1925
H. Birchard Taylor 1923–1925
Robert W. Angus 1924–1926
Sherwood F. Jeter 1924–1926
Thos. L. Wilkinson 1924–1926
A. G. Christie 1925–1927
Wm. T. Magruder 1925–1927
Roy V. Wright 1925–1927
H. V. Coes[18] 1927
Charles L. Newcomb 1926–1928
E. O. Eastwood 1926–1928
Edwards R. Fish 1926–1928
John H. Lawrence 1927–1929
E. A. Muller 1927–1929
Newell Sanders 1927–1929
Paul Wright 1927–1929
Robert L. Daugherty 1928–1930
William Elmer 1928–1930
Charles E. Gorton 1928–1930
Paul Doty 1929–1931
Ernest L. Jahncke 1929–1931
Conrad N. Lauer 1929–1931
Ralph E. Flanders 1929–1931

MANAGERS

Wm. P. Trowbridge
April, 1880–November, 1881
Theo. N. Ely . April, 1880–November, 1881
J. C. Hoadley . April, 1880–November, 1881

Fred J. Miller 1904–1907
Richard H. Rice 1904–1907
Walter Laidlaw 1905–1908
Fred. M. Prescott 1905–1908
Frank G. Tallman 1905–1908
G. M. Basford 1906–1909
Andrew J. Caldwell 1906–1909
Andrew L. Riker 1906–1909
Wm. L. Abbott 1907–1910
Alex. C. Humphreys 1907–1910
Henry G. Stott 1907–1910
H. L. Gantt 1908–1911
I. E. Moultrop 1908–1911
W. J. Sando 1908–1911
J. Sellers Bancroft 1909–1911
James Hartness 1909–1912
H. G. Reist 1909–1912
Henry G. Stott 1911–1912
D. F. Crawford 1910–1913
Stanley G. Flagg, Jr. 1910–1913
E. B. Katte 1910–1913
Charles J. Davidson 1911–1914
Henry Hess 1911–1914
George A. Orrok 1911–1914
Alfred Noble 1912–1914
Morris L. Cooke 1914–1915
W. B. Jackson 1912–1915
H. M. Leland 1912–1915
Arthur M. Greene, Jr. 1913–1916
John Hunter 1913–1916
Elliott H. Whitlock 1913–1916
Charles T. Main 1914–1917
Spencer Miller 1914–1917
Max Toltz 1914–1917
John H. Barr 1915–1918
H. de B. Parsons 1915–1918
John A. Stevens 1915–1918
Robert H. Fernald 1916–1919
William B. Gregory 1916–1919
C. R. Weymouth 1916–1919
Fred A. Geier 1917–1920
Fred. N. Bushnell 1917–1920
D. Robert Yarnall 1917–1920
Charles L. Newcomb 1918–1921
Charles Russ Richards 1918–1921
Frank O. Wells 1918–1921
Elbert C. Fisher 1919–1922
Earl F. Scott 1919–1922
Dexter S. Kimball 1919–1921
L. C. Nordmeyer 1920–1923
Henry M. Norris 1920–1923
Carl C. Thomas 1920–1923
Sherwood F. Jeter 1921–1924
Horace P. Liversidge 1921–1924
Hollis P. Porter 1921–1924
A. G. Christie 1922–1925
James H. Herron 1922–1925
Roy V. Wright 1922–1925
E. O. Eastwood 1923–1926
E. R. Fish 1923–1926
Frank A. Scott 1923–1926
John H. Lawrence 1924–1927
Edward A. Muller 1924–1927
Paul Wright 1924–1927
Robt. L. Daugherty 1925–1928
Wm. Elmer 1925–1928
Chas. E. Gorton 1925–1928
Paul Doty 1926–1929
Ralph E. Flanders 1926–1929
Conrad N. Lauer 1926–1929
Frederick H. Dorner 1927–1930
William A. Hanley 1927–1930
L. B. McMillan[19] 1927–1929
Harvey N. Davis[20] 1929–1930
Charles M. Allen 1928–1931
Robert M. Gates 1928–1931
Ely C. Hutchinson 1928–1931
James D. Cunningham 1929–1932
Clarence F. Hirshfeld 1929–1932
Harold V. Coes 1929–1932

[13] Deceased, October 26, 1920.
[14] Elected to fill unexpired term of John R. Allen.
[15] Deceased, May 8, 1922.
[16] Elected to fill vacancy caused by death of L. E. Strothman.
[17] Elected to complete term of L. E. Strothman, deceased.
[18] Under Amendments to Constitution, providing for seven Vice-Presidents (formerly only six).
[19] Deceased, August 10, 1929.
[20] Elected to fill unexpired term of L. B. McMillan.

TREASURERS

Lycurgus B. Moore	April, 1880–December, 1881
Chas. W. Copeland	December, 1881–November, 1884
William H. Wiley	1884–1925
Erik Oberg	1925–date

SECRETARIES

Sam S. Webber, Jr.	Secretary, Organization Meeting, 1880
Lycurgus B. Moore	Acting Secretary, April–November, 1880
Thos. Whiteside Rae	November, 1880–March, 1883
Frederick R. Hutton	1883–1906
Calvin W. Rice	1906–date

Technical Committees

Revised to December 31, 1930. For the personnel of these committees refer to the Membership List

RESEARCH

A.S.M.E. Research Committee (Standing) (5) *
Special Committee on Lubrication (10)
Special Committees on Fluid Meters (7)
- Subcommittee on Description of Flow Meters and Water Meters—Part 2 (4)
- Subcommittee on Influence of Installation—Part 3 (8)
- Subcommittee on Revision of Part 1—Report on Fluid Meters (9)

Special Committee on Thermal Properties of Steam (15)
- Technical Subcommittees (11)

Special Committee on Strength of Gear Teeth (9)
Special Committee on Cutting of Metals (19)
- Executive Committee (3)
- Subcommittee on Physics of Cutting Metals (2)
- Subcommittee on Hard Cutting Tool Materials (9)
- Subcommittee on Properties of Materials (3)
- Subcommittee on Bibliography and Correlation (3)
- Subcommittee on Cutting Fluids (7)

Special Committee on Mechanical Springs (9)
- Executive Committee (5)
- Subcommittee on Present Status of the Art (7)
- Subcommittee on Program (10)
- Subcommittee on Spring Materials (1)
- Subcommittee on Bibliography (1)

Joint Committee on Effect of Temperature on the Properties of Metals (13)
- Subcommittee on Constitution, By-Laws, and Membership (1)
- Subcommittee on Finances (1)
- Subcommittee on Projects and Prosecution (1)
- Subcommittee on Correlation of Test Data (1)

Special Committee on Condenser Tubes (20)
- Executive Committee (6)
- Subcommittee on Questionnaire (2)
- Subcommittee on Finance (1)
- Subcommittee on Bibliography (2)

Joint Committee on Boiler Feedwater Studies (61)
- Executive Committee (21)
- Finance Committee (6)
- Subcommittee on Sedimentation With and Without Chemicals, Pressure and Gravity Filters and Deconcentrators, Continuous Blow-Down Apparatus (5)
- Subcommittee on Water Softened by Chemicals (External Treatment) (9)
- Subcommittee on Zeolite Softeners, Internal Treatment, Priming and Foaming, Electrolytic Scale Prevention (13)
- Subcommittee on Surface Condensers, Evaporators, and Deaerators (8)
- Subcommittee on Corrosion of Boilers and the Effect of Treated Water in Accelerating or Relieving These Troubles (15)
- Subcommittee on Embrittlement of Metals (12)
- Subcommittee on Municipal Water Supply in Relation to Boiler Use (12)
- Subcommittee on Standardization of Water Analysis (12)
- Subcommittee on Bibliography (8)

Special Committee on Boiler Furnace Refractories (20)
Special Committee on Elevators (9)
- Technical Program Subcommittee

Special Committee on Worm Gears (8)
Joint Committee on Welding of Pressure Vessels (49)
- Executive Committee (8)
- Subcommittee on Methods of Test (11)
- Subcommittee on Procedure of Specifications (12)
- Subcommittee on Ways and Means (1)

Special Committee on Saws and Knives (10)
Special Committee on Existing Supplies of Hardwood (9)
Special Committee on Strength of Vessels Under External Pressure (10)
Special Committee on Absorption of Radiant Heat in Boiler Furnaces (7)
Special Committee on Velocity Measurement of Fluid Flow (3)
Special Committee on Measures of Management (6)
Joint Committee on Physical Constants of Refrigerants ( )
Special Committee on Diesel Fuel Oil Specifications (35)
- Subcommittee on Physical Research (6)
- Subcommittee on Chemical Tests Research (4)
- Subcommittee on Tests and Field Data (9)

Special Committee on Airplane Vibration With Special Reference to Instruments (14)
Special Committee on Heavy Duty Anti-Friction Bearings (8)
Special Committee on Removal of Ash as Molten Slag From Powdered-Coal Furnaces (8)
Special Research Committee on Automatic Oil Pipe Line Pumping Stations (24)
Special Research Committee on Methods and Apparatus for Noise Measurement (13)
Special Research Committee on Wire Rope (11)
Representatives on Engineering Foundation (3)
Representatives on Engineering Societies Research Board (3)
Representatives on National Research Council (3)
Representatives on the Following Research Committees Sponsored by Other Organizations (6)
- Corrosion Committee (American Society of Refrigerating Engineers)
- Fatigue Phenomena of Metals (American Society for Testing Materials)
- Highway Research (Advisory Board of National Research Council)
- National Committee on Wood Utilization (Department of Commerce, Bureau of Standards)
- Non-Ferrous Metals and Alloys (Advisory to the Bureau of Standards Committee)
- Properties of Refractory Materials (Advisory to the Bureau of Standards Committee)

Approved Research Publications of the A.S.M.E.

Bibliography on Riveted Joints
Report on Fluid Meters—Their Theory and Application, Part 1 (Third Edition)
Bibliography on Mechanical Springs
Bibliography on Effect of Temperature on Properties of Metals
Bibliography on Woods of the World—Exclusive of the Temperate Region of North America and with Emphasis on Tropical Woods
Bibliography on Cutting of Metals
Research Reports and Papers, 1929 and 1930

STANDARDS

A.S.M.E. Standardization Committee (Standing) (5)
Sectional Committee on Shafting (17)
- Subcommittee on Shafting Dimensions (4)
- Subcommittee on Stock Key Sizes (5)
- Subcommittee on Code for Design of Transmission Shafting (7)
- Subcommittee on Taper Keys (3)
- Subcommittee on Woodruff Keys (15)

Allowances and Tolerances for Cylindrical Parts and Limit Gages (32)
Sectional Committee on Ball and Roller Bearings (16)
- Subcommittee on Annular Ball Bearings (7)
- Subcommittee on Annular Ball Bearings (Light, Medium, and Heavy Series) (3)

Sectional Committee on Gears (35)
- Executive Committee (3)
- Subcommittee No. 1 on Program (3)
- Subcommittee No. 2 on Editing Reports (3)
- Subcommittee No. 3 on Nomenclature (6)

* Note.—The figures in parentheses indicate the number of men serving on each committee.

Subcommittee No. 4 on Tooth Form (Spur Gear) (4)
Subcommittee No. 5 on Helical Gears (10)
Subcommittee No. 6 on Worm Gears (6)
Subcommittee No. 7 on Bevel Gears (5)
Subcommittee No. 8 on Materials (6)
Subcommittee No. 9 on Inspection (3)
Subcommittee No. 10 on Horse Power Rating (4)
Sectional Committee on Pipe Flanges and Fittings (56)
Subcommittee No. 1 on Cast Iron Flanges and Flanged Fittings (35)
Subgroup on Cast Iron Flanges for Pressures Under 100 Lb. (8)
Subgroup on Ammonia Fittings (7)
Subcommittee No. 2 on Screwed Fittings (27)
Working Committee (5)
Subcommittee No. 3 on Steel Flanges and Flanged Fittings (22)
Working Committee (10)
Subgroup on Flange Standards for 1350 Lb. Steam Pressure (4)
Subgroup on Flange Standards for Higher Than 1500 Lb. Steam Pressure (3)
Subgroup on Bolting of Flanges (5)
Subgroup on Steel Companion Flanges (6)
Subcommittee No. 4 on Materials and Stresses (7)
Subcommittee No. 5 on Face-to-Face Dimensions of Ferrous Flanged Valves (14)
Subcommittee No. 6 on Malleable Iron or Steel Brass Seat Unions (25)
Manufacturers' Subgroup (13)
Subgroup on Tolerances and Marking (7)
Subgroup on Tests and Material Requirements (3)
Subcommittee No. 7 on Rating of Pipe Fittings (9)
Subcommittee No. 8 on Marking of Pipe Fittings (7)
Sectional Committee on Bolt, Nut, and Rivet Proportions (56)
Subcommittee No. 1 on Large and Small Rivets (10)
Subcommittee No. 2 on Wrench Head Bolts and Nuts (25)
Subgroup on Nomenclature (5)
Subgroup on Large Nuts for Piping Industry (7)
Subgroup on Stud Bolts (3)
Subgroup on Wrench Openings (3)
Subgroup on Reduction of Thickness of Jam Nuts ( )
Subcommittee No. 3 on Slotted Head Proportions (10)
Subcommittee No. 4 on Track Bolts and Nuts (9)
Subcommittee No. 5 on Round Unslotted Head Bolts (Carriage Bolts) (7)
Subcommittee No. 6 on Plow Bolts (5)
Subcommittee No. 7 on Body Dimensions and Material (11)
Subcommittee No. 8 on Nomenclature (10)
Subcommittee No. 9 on Socket Head Cap and Set Screws (10)
Sectional Committee on Scheme for Identification of Piping Systems (32)
Executive Committee (5)
Subcommittee on Identification by Colors (6)
Subcommittee on Classification (4)
Subcommittee on Identification Markings Other Than Color (5)
Subcommittee on Editing (8)
Sectional Committee on Small Tools and Machine Tool Elements (17)
Executive Committee (5)
Technical Committee No. 1 on T-Slots (13)
Technical Committee No. 2 on Tool Holder Shanks and Tool Post Openings (15)
Technical Committee No. 3 on Machine Tapers (21)
Subgroup on Taper Series (8)
Subgroup on Standard Dimensions (3)
Subgroup on Detailed Dimensions, Tolerances and Gages (10)
Technical Committee No. 4 on Spindle Noses and Collets for Machine Tools (27)
Subgroup on Milling Machines, Small and Medium (3)
Subgroup on Large Milling Machines (8)
Subgroup on Grinding Machine Spindles (7)
Subgroup on Drilling Machines and Horizontal Boring Machines (7)
Subgroup on Cutting Off Machines (3)
Subgroup on Turning Machines, Including Automatic Screw Machines, Lathes, Automatic Lathes, Turret Lathes, and Automatic Chucking Machines (14)
Subgroup on Cutting and Hobbing Machines (6)
Subgroup on Correlation of Counter Proposals for Spindle Noses (5)
Technical Committee No. 5 on Milling Cutters (23)
Subgroup on Profile Cutters (4)
Subgroup on Keyways (4)
Subgroup on Nomenclature (4)
Subgroup on Limits (4)
Subgroup on Formed Cutters (4)
Subgroup on Hobs (4)
Subgroup on Inserted Tooth Cutters (4)
Technical Committee No. 6 on Designations and Working Ranges of Machine Tools (23)
Technical Committee No. 7 on Twist Drill Sizes (9)
Subgroup on Lengths and Diameters of Drills (3)
Technical Committee No. 8 on Drill Bushings (9)
Subgroup on Liner Outer Diameters and Tolerances (3)
Technical Committee No. 9 on Punch and Die Holders (12)
Subgroup on Sizes, Styles, and Materials (6)
Technical Committee No. 10 on Circular Forming Tools and Holders ( )
Technical Committee No. 11 on Chucks and Chuck Jaws (9)
Subgroup on Master Chuck Jaws (5)
Subgroup on Adapters for Air Cylinders (4)
Technical Committee No. 12 on Cut and Ground Thread Taps (7)
Technical Committee No. 13 on Splines and Splined Shafts (12)
Subgroup on Machine Tools (1)
Subgroup on Automotive Splines (1)
Technical Committee No. 14 on Electric Welding Dies and Electrode Holders (9)
Technical Committee No. 15 on Standardization of Milling Machine Tables (5)
Subgroup on Tee Slot Spacing (1)
Sectional Committee on Scientific and Engineering Symbols and Abbreviations (33)
Executive Committee (7)
Subcommittee No. 1 on Symbols for Mechanics, Structural Engineering and Testing Materials (12)
Subcommittee No. 2 on Symbols for Hydraulics (13)
Subgroup on Theoretical Hydraulics (3)
Subgroup on Hydrology (2)
Subgroup on Water Power (2)
Subgroup on Pumps and Pumping Equipment (2)
Subgroup on Sanitary Engineering and Water Piping (2)
Subgroup on Irrigation (1)
Subgroup on Turbines (2)
Subcommittee No. 3 on Symbols for Heat and Thermodynamics (30)
Subcommittee No. 4 on Photometry and Illumination (15)
Subcommittee No. 5 on Aeronautical Symbols (11)
Subcommittee No. 6 on Mathematical Symbols (14)
Subcommittee No. 7 on Electrotechnical Symbols, Including Radio (15)
Subgroup on Letter Symbols (4)
Subgroup on Symbols for Electric Power, Including Interior Wiring (7)
Subgroup on Graphical Symbols for Radio (7)
Subgroup on Supply Material ( )
Subgroup on Traction, Including Railway Signaling (4)
Subgroup on Graphical Symbols for Telephone and Telegraph Use (5)
Subcommittee No. 8 on Navigational and Topographical Symbols (3)
Subcommittee No. 9 on Abbreviations for Engineering and Scientific Terms (5)
Sectional Committee on Plain and Lock Washers (27)
Subcommittee No. 1 on Plain Washers (9)
Subcommittee No. 2 on Lock Washers (21)
Sectional Committee on Machine Pins (14)
Subcommittee No. 1 on Straight, Taper, and Dowel Pins ( )
Subcommittee No. 2 on Split Pins ( )
Sectional Committee on Code for Pressure Piping (68)
Subcommittee No. 1 on Plan and Scope (6)
Subcommittee No. 2 on Power Piping (23)
Subgroup on Code for District Heating Piping (8)
Subcommittee No. 3 on Hydraulic Piping (8)
Subgroup on Penstock Work (1)
Subgroup on Hydraulic High Pressure Piping (1)
Subgroup on Water Works Piping (1)
Subcommittee No. 4 on Gas and Air Piping (18)
Subcommittee No. 5 on Refrigerating Piping (9)
Subcommittee No. 6 on Oil Piping (7)
Subcommittee No. 7 on Piping Materials and Identification (13)
Subcommittee No. 8 on Fabrication Details (18)
Subgroup on Hangers, Supports, and Anchors (1)
Subgroup on Joints Other Than Welded (1)
Subgroup on Pipe Bends (1)
Subgroup on Power Piping (1)
Subgroup on Welding (1)

TREASURERS

LYCURGUS B. MOORE . . . . . April, 1880–December, 1881
CHAS. W. COPELAND. . . . . December, 1881–November, 1884
WILLIAM H. WILEY 1884–1925
ERIK OBERG 1925–date

SECRETARIES

SAM S. WEBBER, JR. . . . Secretary, Organization Meeting, 1880
LYCURGUS B. MOORE . . . Acting Secretary, April–November, 1880
THOS. WHITESIDE RAE. . . . . November, 1880–March, 1883
FREDERICK R. HUTTON 1883–1906
CALVIN W. RICE 1906–date

Technical Committees

Revised to December 31, 1930. For the personnel of these committees refer to the Membership List

RESEARCH

A.S.M.E. Research Committee (Standing) (5) *
SPECIAL COMMITTEE ON LUBRICATION (10)
SPECIAL COMMITTEES ON FLUID METERS (7)
- Subcommittee on Description of Flow Meters and Water Meters—Part 2 (4)

Bibliography on Riveted Joints
Report on Fluid Meters—Their Theory and Application, Part 1 (Third Edition)
Bibliography on Mechanical Springs
Bibliography on Effect of Temperature on Properties of Metals
Bibliography on Woods of the World—Exclusive of the Temperate Region of North America and with Emphasis on Tropical Woods
Bibliography on Cutting of Metals
Research Reports and Papers, 1929 and 1930

STANDARDS

A.S.M.E. Standardization Committee (Standing) (5)
SECTIONAL COMMITTEE ON SHAFTING (17)
- Subcommittee on Shafting Dimensions (4)
- Subcommittee on Stock Key Sizes (5)
- Subcommittee on Code for Design of Transmission Shafting (7)
- Subcommittee on Taper Keys (3)
- Subcommittee on Woodruff Keys (15)

ALLOWANCES AND TOLERANCES FOR CYLINDRICAL PARTS AND LIMIT GAGES (32)
SECTIONAL COMMITTEE ON BALL AND ROLLER BEARINGS (16)
- Subcommittee on Annular Ball Bearings (7)
- Subcommittee on Annular Ball Bearings (Light, Medium, and Heavy Series) (3)

SECTIONAL COMMITTEE ON GEARS (35)
- Executive Committee (3)
- Subcommittee No. 1 on Program (3)
- Subcommittee No. 2 on Editing Reports (3)
- Subcommittee No. 3 on Nomenclature (6)

* NOTE.—The figures in parentheses indicate the number of men serving on each committee.

Subcommittee No. 4 on Tooth Form (Spur Gear) (4)
Subcommittee No. 5 on Helical Gears (10)
Subcommittee No. 6 on Worm Gears (6)
Subcommittee No. 7 on Bevel Gears (5)
Subcommittee No. 8 on Materials (6)
Subcommittee No. 9 on Inspection (3)
Subcommittee No. 10 on Horse Power Rating (4)
Sectional Committee on Pipe Flanges and Fittings (56)
Subcommittee No. 1 on Cast Iron Flanges and Flanged Fittings (35)
Subgroup on Cast Iron Flanges for Pressures Under 100 Lb. (8)
Subgroup on Ammonia Fittings (7)
Subcommittee No. 2 on Screwed Fittings (27)
Working Committee (5)
Subcommittee No. 3 on Steel Flanges and Flanged Fittings (22)
Working Committee (10)
Subgroup on Flange Standards for 1350 Lb. Steam Pressure (4)
Subgroup on Flange Standards for Higher Than 1500 Lb. Steam Pressure (3)
Subgroup on Bolting of Flanges (5)
Subgroup on Steel Companion Flanges (6)
Subcommittee No. 4 on Materials and Stresses (7)
Subcommittee No. 5 on Face-to-Face Dimensions of Ferrous Flanged Valves (14)
Subcommittee No. 6 on Malleable Iron or Steel Brass Seat Unions (25)
Manufacturers' Subgroup (13)
Subgroup on Tolerances and Marking (7)
Subgroup on Tests and Material Requirements (3)
Subcommittee No. 7 on Rating of Pipe Fittings (9)
Subcommittee No. 8 on Marking of Pipe Fittings (7)
Sectional Committee on Bolt, Nut, and Rivet Proportions (56)
Subcommittee No. 1 on Large and Small Rivets (10)
Subcommittee No. 2 on Wrench Head Bolts and Nuts (25)
Subgroup on Nomenclature (5)
Subgroup on Large Nuts for Piping Industry (7)
Subgroup on Stud Bolts (3)
Subgroup on Wrench Openings (3)
Subgroup on Reduction of Thickness of Jam Nuts ( )
Subcommittee No. 3 on Slotted Head Proportions (10)
Subcommittee No. 4 on Track Bolts and Nuts (9)
Subcommittee No. 5 on Round Unslotted Head Bolts (Carriage Bolts) (7)
Subcommittee No. 6 on Plow Bolts (5)
Subcommittee No. 7 on Body Dimensions and Material (11)
Subcommittee No. 8 on Nomenclature (10)
Subcommittee No. 9 on Socket Head Cap and Set Screws (10)
Sectional Committee on Scheme for Identification of Piping Systems (32)
Executive Committee (5)
Subcommittee on Identification by Colors (6)
Subcommittee on Classification (4)
Subcommittee on Identification Markings Other Than Color (5)
Subcommittee on Editing (8)
Sectional Committee on Small Tools and Machine Tool Elements (17)
Executive Committee (5)
Technical Committee No. 1 on T-Slots (13)
Technical Committee No. 2 on Tool Holder Shanks and Tool Post Openings (15)
Technical Committee No. 3 on Machine Tapers (21)
Subgroup on Taper Series (8)
Subgroup on Standard Dimensions (3)
Subgroup on Detailed Dimensions, Tolerances and Gages (10)
Technical Committee No. 4 on Spindle Noses and Collets for Machine Tools (27)
Subgroup on Milling Machines, Small and Medium (3)
Subgroup on Large Milling Machines (8)
Subgroup on Grinding Machine Spindles (7)
Subgroup on Drilling Machines and Horizontal Boring Machines (7)
Subgroup on Cutting Off Machines (3)
Subgroup on Turning Machines, Including Automatic Screw Machines, Lathes, Automatic Lathes, Turret Lathes, and Automatic Chucking Machines (14)
Subgroup on Cutting and Hobbing Machines (6)
Subgroup on Correlation of Counter Proposals for Spindle Noses (5)
Technical Committee No. 5 on Milling Cutters (23)
Subgroup on Profile Cutters (4)
Subgroup on Keyways (4)
Subgroup on Nomenclature (4)
Subgroup on Limits (4)
Subgroup on Formed Cutters (4)
Subgroup on Hobs (4)
Subgroup on Inserted Tooth Cutters (4)
Technical Committee No. 6 on Designations and Working Ranges of Machine Tools (23)
Technical Committee No. 7 on Twist Drill Sizes (9)
Subgroup on Lengths and Diameters of Drills (3)
Technical Committee No. 8 on Drill Bushings (9)
Subgroup on Liner Outer Diameters and Tolerances (3)
Technical Committee No. 9 on Punch and Die Holders (12)
Subgroup on Sizes, Styles, and Materials (6)
Technical Committee No. 10 on Circular Forming Tools and Holders ( )
Technical Committee No. 11 on Chucks and Chuck Jaws (9)
Subgroup on Master Chuck Jaws (5)
Subgroup on Adapters for Air Cylinders (4)
Technical Committee No. 12 on Cut and Ground Thread Taps (7)
Technical Committee No. 13 on Splines and Splined Shafts (12)
Subgroup on Machine Tools (1)
Subgroup on Automotive Splines (1)
Technical Committee No. 14 on Electric Welding Dies and Electrode Holders (9)
Technical Committee No. 15 on Standardization of Milling Machine Tables (5)
Subgroup on Tee Slot Spacing (1)
Sectional Committee on Scientific and Engineering Symbols and Abbreviations (33)
Executive Committee (7)
Subcommittee No. 1 on Symbols for Mechanics, Structural Engineering and Testing Materials (12)
Subcommittee No. 2 on Symbols for Hydraulics (13)
Subgroup on Theoretical Hydraulics (3)
Subgroup on Hydrology (2)
Subgroup on Water Power (2)
Subgroup on Pumps and Pumping Equipment (2)
Subgroup on Sanitary Engineering and Water Piping (2)
Subgroup on Irrigation (1)
Subgroup on Turbines (2)
Subcommittee No. 3 on Symbols for Heat and Thermodynamics (30)
Subcommittee No. 4 on Photometry and Illumination (15)
Subcommittee No. 5 on Aeronautical Symbols (11)
Subcommittee No. 6 on Mathematical Symbols (14)
Subcommittee No. 7 on Electrotechnical Symbols, Including Radio (15)
Subgroup on Letter Symbols (4)
Subgroup on Symbols for Electric Power, Including Interior Wiring (7)
Subgroup on Graphical Symbols for Radio (7)
Subgroup on Supply Material ( )
Subgroup on Traction, Including Railway Signaling (4)
Subgroup on Graphical Symbols for Telephone and Telegraph Use (5)
Subcommittee No. 8 on Navigational and Topographical Symbols (3)
Subcommittee No. 9 on Abbreviations for Engineering and Scientific Terms (5)
Sectional Committee on Plain and Lock Washers (27)
Subcommittee No. 1 on Plain Washers (9)
Subcommittee No. 2 on Lock Washers (21)
Sectional Committee on Machine Pins (14)
Subcommittee No. 1 on Straight, Taper, and Dowel Pins ( )
Subcommittee No. 2 on Split Pins ( )
Sectional Committee on Code for Pressure Piping (68)
Subcommittee No. 1 on Plan and Scope (6)
Subcommittee No. 2 on Power Piping (23)
Subgroup on Code for District Heating Piping (8)
Subcommittee No. 3 on Hydraulic Piping (8)
Subgroup on Penstock Work (1)
Subgroup on Hydraulic High Pressure Piping (1)
Subgroup on Water Works Piping (1)
Subcommittee No. 4 on Gas and Air Piping (18)
Subcommittee No. 5 on Refrigerating Piping (9)
Subcommittee No. 6 on Oil Piping (7)
Subcommittee No. 7 on Piping Materials and Identification (13)
Subcommittee No. 8 on Fabrication Details (18)
Subgroup on Hangers, Supports, and Anchors (1)
Subgroup on Joints Other Than Welded (1)
Subgroup on Pipe Bends (1)
Subgroup on Power Piping (1)
Subgroup on Welding (1)

SECTIONAL COMMITTEE ON STANDARDS FOR DRAWINGS AND DRAFTING ROOM PRACTICE (50)
- Subcommittee No. 1 on Specifications for Paper and Cloth (14)
  - Subgroup on Materials Specification (3)
- Subcommittee No. 2 on Method of Indicating Dimensions (10)
- Subcommittee No. 3 on Lettering (9)
  - Subgroup on Questionnaire (2)
- Subcommittee No. 4 on Layout (11)
- Subcommittee No. 5 on Line Work (10)
- Subcommittee No. 6 on Graphical Symbols for Drawings (10)
- Subcommittee on Editing (6)

SECTIONAL COMMITTEE ON STANDARDS FOR GRAPHIC PRESENTATION (42)
- Subcommittee No. 1 on Plan and Scope (9)
- Subcommittee No. 2 on Terminology (7)
- Subcommittee No. 3 on Time Series Charts (7)
- Subcommittee No. 4 on Non-Time Series Charts (8)
- Subcommittee No. 5 on Survey of Current Practice (8)
- Subcommittee No. 6 on Engineering and Scientific Graphs (9)

SECTIONAL COMMITTEE ON TRANSMISSION CHAINS AND SPROCKETS (17)
- Subcommittee on Roller Chain Standardization (7)
- Subcommittee on Silent Chain Standardization (7)

SECTIONAL COMMITTEE ON WIRE AND SHEET METAL GAGING SYSTEMS (27)
- Technical Committee on Flat Stocks (8)
- Technical Committee on Wires and Rods (9)
- Technical Committee on Tubing, Piping, Conduit, and Casing (4)

SECTIONAL COMMITTEE ON ELECTRIC MOTOR FRAME DIMENSIONS (32)
- Working Committee (7)

SECTIONAL COMMITTEE ON PIPE THREADS (45)
- Subcommittee No. 1 on Editing and Gaging (14)
- Subcommittee No. 2 on Taper Pipe Threads (10)
- Subcommittee No. 3 on Straight Pipe Threads (11)
  - Working Committee (2)
- Subcommittee No. 4 on Plumbers' Threads, Etc. (13)
  - Subgroup on Thread Pitch Diameters and Characteristics (1)
  - Subgroup to Study Existing Thread Dimensions of Cocks and Stops (3)
  - Subgroup on Fine Threads for Tubing Larger Than 2 Inches (1)
- Subcommittee No. 5 on Screw Threads for Rigid Electrical Conduit (6)
- Subcommittee No. 6 on Special Threads for Thin Tubes (8)

SECTIONAL COMMITTEE ON WROUGHT IRON AND WROUGHT STEEL PIPE AND TUBING (39)
- Subcommittee No. 1 on Plan, Scope, and Editing (5)
- Subcommittee No. 2 on Pipe and Tubing for Low-Temperature Service (16)
- Subcommittee No. 3 on Pipe and Tubing for High-Temperature Service (17)
  - Subgroup on Basic Formulas and Stresses (9)
- Subcommittee No. 4 on Materials (17)

SECTIONAL COMMITTEE ON SPEEDS OF MACHINERY (32)
- Subcommittee No. 1 on Plan and Scope (7)
- Subcommittee No. 2 on Questionnaire and Canvas to Industry (7)

SECTIONAL COMMITTEE ON SCREW THREADS FOR FIRE HOSE COUPLINGS ( )

SECTIONAL COMMITTEE ON SCREW THREADS FOR HOSE COUPLINGS (26)
- Special Subcommittee to Draft Recommended Specifications (3)
- Subcommittee on Basic Thread Dimensions (3)

SECTIONAL COMMITTEE ON PLUMBING EQUIPMENT (32)
- Subcommittee No. 1 on Plumbing Code (6)
- Subcommittee No. 2 on Staple Vitreous China Plumbing Fixtures (11)
- Subcommittee No. 3 on Staple Porcelain (All Clay) Plumbing Fixtures (19)
- Subcommittee No. 4 on Enameled Sanitary Ware ( )
- Subcommittee No. 5 on Traps (24)
  - Subgroup on Brass Lavatories and Sink Traps (8)
  - Subgroup on Brass Traps (5)
  - Subgroup on Cast Iron Traps (18)
  - Subgroup on Lead Traps (1)
  - Subgroup on Vitreous China Traps (1)
  - Subgroup on Interceptors, Catch Basins, and Miscellaneous Traps (1)
- Subcommittee No. 6 on Standardization of Brass Plumbing Products (13)
  - Subgroup on Compression Cocks, Washer Screws, Faucets, and Tail Piece Parts (2)
  - Subgroup on Flushing Tank Mechanism and Flush Valves, Supply Pipes and Connections, and Escutcheons (2)
  - Subgroup on Fixture Connections and Fixture Valves, Waste Holes, Plugs, and Connections; Overflows (3)
  - Subgroup on Valves (2)
  - Subgroup on Shower Heads, Diameter Connections, and Sizes (3)
  - Subgroup on Water Works Brass (1)
  - Subgroup on Nomenclature (7)
- Subcommittee No. 7 on Copper Water Tube Fittings (6)
- Subcommittee No. 8 on Cast Iron Soil Pipe and Fittings (9)

SECTIONAL COMMITTEE ON STANDARDIZATION AND UNIFICATION OF SCREW THREADS (38)
- Subcommittee No. 1 on Scope, Arrangement, and Editing of American National Standards (8)
- Subcommittee No. 2 on Terminology and Thread Specifications, Except Gages (13)
  - Subgroup on Minor Diameter of Nuts (4)
- Subcommittee No. 3 on Special Threads and Twelve Pitch Series, Except Gages (11)
  - Subgroup on Eight Pitch Thread Series (1)
  - Subgroup on Screw Thread Tolerances for Track Bolts and Nuts (1)
- Subcommittee No. 4 on Acme and Other Similar Threads, Except Gages (7)
- Subcommittee No. 5 on Screw Thread Gages and Inspection (9)
  - Subgroup on Drafting Report (3)
  - Subgroup on Tolerances for Different Classes of Gages ( )
- Subcommittee No. 6 on Lag Screws (2)
- Subcommittee No. 7 on Survey of Present Practice (3)

SECTIONAL COMMITTEE ON ROLLED THREADS FOR SCREW SHELLS OF ELECTRIC SOCKETS AND LAMP BASES (18)
- Subcommittee No. 1 (9)

SECTIONAL COMMITTEE ON STOCK SIZES, SHAPES, AND LENGTHS FOR HOT AND COLD FINISHED IRON AND STEEL BARS (18)
- Subcommittee No. 1 on Hot Rolled Steel (6)
- Subcommittee No. 2 on Cold Finished Steels (4)
- Subcommittee No. 3 on Hot Rolled Iron (1)

SECTIONAL COMMITTEE ON PRESSURE AND VACUUM GAGES (35)

REPRESENTATIVES ON AMERICAN STANDARDS ASSOCIATION (3)

REPRESENTATIVES ON THE FOLLOWING STANDARDIZATION COMMITTEES SPONSORED BY OTHER ORGANIZATIONS (31)
- Building Code Committee (Advisory Committee of Department of Commerce)
- Classification of Coal (American Society for Testing Materials)
- Drainage of Coal Mines (American Mining Congress)
- Electrical Definitions (American Institute of Electrical Engineers)
- Electric Welding (American Institute of Electrical Engineers and the National Electrical Manufacturers Association)
- Fire Test Building Construction and Materials (American Society for Testing Materials and Bureau of Standards, Fire Protection Group)
- Manhole Frames and Covers (American Society of Civil Engineers and Telephone Group)
- Methods for Testing Wood (American Society for Testing Materials and the Forest Service)
- Methods of Rating of Rivers (U. S. Geological Survey)
- Methods of Testing Petroleum Products and Lubricants (American Society for Testing Materials)
- Miscellaneous Outside Coal-Handling Equipment (American Mining Congress)
- National Fire Waste Council
- Petroleum Specifications (Advisory Board of Bureau of Mines)
- Rotating Electrical Machinery (American Institute of Electrical Engineers and the National Electrical Manufacturers Association)
- Specifications for and Recommended Practice in the Use of Wire Rope for Mines (American Mining Congress)
- Specification for Fuel Oils (American Society for Testing Materials)
- Specifications for Cast-Iron Pipe (American Gas Association, American Society for Testing Materials, American Water Works Association, and New England Water Works Association)
- Specifications for Materials for Use in Manufacture of Special Trackwork (American Electric Railway Association)
- Specifications for Tool Steel (Subcommittee No. XIV of A.S.T.M. Committee A-1 on Steel)
- Steel Railway and Movable Railway Bridges (Special American Standards Association Committee)

APPROVED STANDARDS PUBLISHED BY THE A.S.M.E.

Cold Finished Shafting, Standard Diameters and Lengths
Square and Flat Stock Keys, Standard Widths and Heights
Plain Taper Stock Keys, Square and Flat
Gib Head Taper Stock Keys, Square and Flat

Code for Design of Transmission Shafting
Tolerances, Allowances, and Gages for Metal Fits
Spur Gear Tooth Form, 14½ Degree Composite System, 20 Degrees Stub Involute System
American Standard Screw Threads for Bolts, Machine Screws, Nuts, and Commercially Tapped Holes
Cast Iron Pipe Flanges and Flanged Fittings; All Sizes for Maximum Working Saturated Steam Pressure of 125 Lb. per Sq. In. (Gage); Sizes 12 Inches and Smaller for Maximum Non-Shock Working Hydraulic Pressure of 175 Lb. per Sq. in. (Gage) at or Near the Ordinary Range of Air Temperatures
Cast Iron Pipe Flanges and Flanged Fittings; All Sizes for Maximum Working Saturated Steam Pressure of 250 Lb. per Sq. In. (Gage); Sizes 10 Inches and Smaller for Maximum Non-Shock Working Hydraulic Pressure of 400 Lb. per Sq. In. (Gage) at or Near the Ordinary Range of Air Temperatures
Cast Iron Screwed Fittings, for Maximum Working Saturated Steam Pressure of 125 and 250 Lb. per Sq. In. (Gage)
Malleable Iron Screwed Fittings, for Maximum Working Saturated Steam Pressure of 150 Lb. per Sq. In. (Gage)
Cast Iron Long Turn Sprinkler Fittings (Screwed and Flanged) for Maximum Hydraulic Working Pressures of 150 and 250 Lb. per Sq. In. (Gage)
Steel Pipe Flanges and Flanged Fittings for Maximum Working Steam Pressures of 250, 400, 600, 900, and 1350 Lb. per Sq. In. (Gage) at a Temperature of 750 Deg. Fahr.
Small Rivets, 7/16 Inch Nominal Diameter and Under
Tinners', Coopers', and Belt Rivets
Wrench Head Bolts and Nuts and Wrench Openings
Round Unslotted Head Bolts (Carriage, Step, and Machine Bolts)
Slotted Head Proportions; Machine Screws, Cap Screws, and Wood Screws
Plow Bolts
Track Bolts
Scheme for Identification of Piping Systems
T-Slots, Their Bolts, Nuts, Tongues, and Cutters
Tool Holder Shanks and Tool Post Openings
Taps—Cut and Ground Thread
Milling Cutters—Nomenclature, Diameters, Thickness, and Other Important Dimensions
Symbols for Hydraulics
Aeronautical Symbols
Mathematical Symbols
Symbols for Photometry and Illumination
Fire Hose Coupling Screw Thread for All Connections Having Nominal Inside Diameters of 2½, 3, 3½, and 4½ Inches

SAFETY

A.S.M.E. Safety Committee (Standing) (5)
Sectional Committee on Safety Code for Mechanical Power Transmission Apparatus (28)
- Subcommittee No. 1 for Detail Classification of Belts (5)
- Subcommittee No. 2 for Modification of Rule 223 for Cone Pulley Belts (3)
- Subcommittee No. 3 on Mechanical Power Control (13)
- Subcommittee No. 4 on Use of A.S.A. Code Versus State Codes (5)
- Subcommittee No. 5 on Statistics on Place of Occurrence of Accidents (8)

Sectional Committee on Safety Code for Elevators (38)
- Subcommittee on Research, Recommendations, and Interpretations (10)
- Subcommittee on Inspectors Handbook (9)
- Subcommittee on Elevator Systems Safe Against Fire (6)
- Subcommittee on Interlocks and Hoistway Enclosures (6)

Sectional Committee on Safety Code for Machinery for Compressing Air (28)
Sectional Committee on Safety Code for Conveyors and Conveying Machinery (46)
- Subcommittee No. 1 on All Types of Chain Conveyors and Elevators; Also Cable Flight Conveyors, Omitting Track Scraper Conveyors (6)
- Subcommittee No. 2 on Belt Conveyors and Belt Elevators, Including Steel Belt (11)
- Subcommittee No. 3 on Gravity Conveyors and Chutes, Live Roll Conveyors (8)
- Subcommittee No. 4 on Spiral and Track or Scraper Conveyors (9)
- Subcommittee No. 5 on Cable Conveyors (5)
- Subcommittee No. 6 on Air, Steam, or Liquid Conveyors (6)

- Executive Committee (6)
- Subcommittee No. 1 on Overhead and Gantry Cranes (22)
- Subcommittee No. 2 on Locomotive and Tractor Cranes (17)
- Subcommittee No. 3 on Derrick and Hoists (17)
- Subcommittee No. 4 on Miscellaneous Equipment for Cranes and Hoists (21)
- Subcommittee No. 5 on Jacks (8)

Editing Committee (3)
Representatives on the Following Safety Code Committees Sponsored by Other Organizations (33)
- Abrasive Wheels (Grinding Wheel Manufacturers Association of the U. S. and Canada, and International Association of Industrial Accident Boards and Commissions)
- Aeronautics (Society of Automotive Engineers)
- Amusement Parks (National Association of Amusement Parks and the National Bureau of Casualty and Surety Underwriters)
- Coal Mine Ventilation (American Mining Congress and the Bureau of Mines)
- Colors for Gas Mask Canisters (National Safety Council)
- Correlating Committee
- Floor Openings, Railings, and Toe Boards (National Safety Council)
- Forging and Hot Metal Stamping (American Drop Forging Institute and the National Safety Council)
- Industrial Sanitation (U. S. Public Health Service)
- Ladders (National Safety Council)
- Laundry Machinery and Operation (Association of Governmental Officials in Industry of the United States and Canada, Laundry Owners National Association, and the National Association of Mutual Casualty Companies)
- Lighting Factories, Mills, and Other Work Places (Illuminating Engineering Society)
- Logging and Sawmill Machinery (Bureau of Standards)
- Low Voltage Electrical Hazard (Special Committee of the American Society of Safety Engineers—Engineering Section, National Safety Council)
- Machine Tools (National Bureau of Casualty and Surety Underwriters and the National Machine Tool Builders Association)
- Mechanical Refrigeration (American Society of Refrigerating Engineers)
- Metal Mine Ventilation (American Mining Congress and the Bureau of Mines)
- Paper and Pulp Mills (National Safety Council)
- Power Presses and Foot and Hand Presses (National Safety Council)
- Rubber Machinery (International Association of Industrial Accident Boards and Commissions and the National Safety Council)
- Textiles (National Safety Council)
- Underground Power Transmission and Power Equipment for Metal Mines (American Mining Congress, National Standardisation Division)
- Ventilation (American Society of Heating and Ventilating Engineers)
- Walkway Surfaces (American Institute of Architects and the National Safety Council)
- Window Washing (National Safety Council)

Approved Safety Codes Published by the A.S.M.E.

A Safety Code for Elevators, Dumbwaiters, and Escalators
Safety Code for Mechanical Power-Transmission Apparatus

POWER TEST CODES

Main Committee on Power Test Codes (Standing) (25)
Individual Committee No. 1 on General Instructions (4)
Individual Committee No. 2 on Definitions and Values (5)
Individual Committee No. 3 on Fuels (15)
Individual Committee No. 4 on Stationary Steam-Generating Units (5)
Individual Committee No. 5 on Reciprocating Steam Engines (6)
Individual Committee No. 6 on Steam Turbines (8)
Individual Committee No. 7 on Reciprocating Steam-Driven Displacement Pumps (9)
Individual Committee No. 8 on Centrifugal and Rotary Pumps (7)
Individual Committee No. 9 on Displacement Compressors and Blowers (6)
Individual Committee No. 10 on Centrifugal and Turbo-Compressors and Blowers (10)
Individual Committee No. 11 on Complete Steam Power Plants (8)
Individual Committee No. 12 on Condenser, Water-Heating and Cooling Equipment (7)
Individual Committee No. 13 on Refrigerating Systems (6)
Individual Committee No. 14 on Evaporating Apparatus (5)
Individual Committee No. 15 on Steam Locomotives (7)
Individual Committee No. 16 on Gas Producers (5)
Individual Committee No. 17 on Internal-Combustion Engines (6)
Individual Committee No. 18 on Hydraulic Power Plants and Their Equipment (13)

Individual Committee No. 19 on Instruments and Apparatus (17)
Individual Committee No. 20 on Speed-Responsive Governors (4)
Representatives on U. S. National Committee of the International Electrotechnical Commission (8)

APPROVED TEST CODES PUBLISHED BY THE A.S.M.E.

General Instructions
Definitions and Values
Liquid Fuels
Solid Fuels
Stationary Steam-Generating Units
Reciprocating Steam Engines
Steam Turbines
Reciprocating Steam-Driven Displacement Pumps
Centrifugal and Rotary Pumps
Displacement Compressors and Blowers
Condensing Apparatus
Feedwater Heaters
Atmospheric Water-Cooling Equipment
Refrigerating Systems
Evaporating Apparatus
Steam Locomotives
Gas Producers
Internal-Combustion Engines
Hydraulic Power Plants and Their Equipment
Speed-Responsive Governors
Instruments and Apparatus:
- Part 1, General Considerations
- Part 2, Pressure Measurement; Chapter 1, Barometers and Chapter 6, Tables, Multipliers and Standards for Barometers, Mercury and Water Columns and Pressure Measurements
- Part 21, Leakage Measurement; Chapter 1, Condenser Leakage Tests

BOILER CODE

Main Committee on Boiler Code (23)
- Executive Committee (7)
- Subcommittee on Boilers of Locomotives (4)
- Subcommittee on Care of Steam Boilers in Service (11)
- Subcommittee on Heating Boilers (6)

Awards

The Committee on Awards, given on page 5, has supervision of the awards of the Society under the direction of the Council. Awards and special funds are administered as specified in the deeds of gift or as may be determined by the Council from time to time. The following awards come within the jurisdiction of the Society:

Honorary Membership, to which persons of acknowledged professional eminence are elected by unanimous vote of Council under the provisions of the By-Laws and Rules. A list of honorary members is given on page 9.

Life Membership, which may be conferred by the Council for distinguished service to the Society.

A.S.M.E. Medal, established by the Society in 1920 to be presented for distinguished service in engineering and science. May be awarded

for general service in science having possible application in engineering.

Holley Medal, instituted and endowed in 1924 by George I. Rockwood, Past Vice-President of the Society, to be bestowed for some great and unique act of genius of engineering nature that has accomplished a great and timely public benefit.

Melville Medal, established in 1914 by the bequest of Rear-Admiral George W. Melville, Honorary Member and Past-President of the Society, to be presented for an original paper or thesis of exceptional merit, presented to the Society for discussion and publication, to encourage excellence in papers. May be presented annually.

Spirit of Saint Louis Medal, endowed by members of the Society and citizens residing in St. Louis, Mo., to be awarded for meritorious service in the field of aeronautical engineering. This medal will be awarded at the discretion of the Council of the Society at approximately three-year periods upon the recommendation of a Spirit of Saint Louis Medal Board of Award made up of six members, each appointed for a term of nine years and the terms of two members expiring at each three-year period.

Junior Award, annual cash award of $50, established in 1914, from a fund created by Henry Hess, Past Vice-President of the Society, to be presented, together with an engraved certificate, for the best paper or thesis submitted by a Junior Member.

Student Awards, two annual cash awards of $25 each, established in 1914, from a fund created by Henry Hess, Past Vice-President of the Society, to be presented, together with engraved certificates, for the best papers or theses submitted by Student Branch Members.

Charles T. Main Award, annual cash award of $150, established in 1919 from a fund created by Charles T. Main, Past-President of the Society, to be awarded to a student of engineering, preferably a member of a Student Branch of the Society, for the best paper within the general subject of the "Influence of the Profession upon Public Life." The exact subject is assigned by the Committee on Awards, subject to the approval of the Council, and is announced each year through the Honorary Chairmen of the Student Branches.

SCHOLARSHIPS AND LOAN FUNDS

Max Toltz: Loan Fund of $15,000 established by Major Max Toltz, former member of the Council of the Society, the income to be used for assistance to students.

John R. Freeman: Fund of $25,000 established in 1926 by John R. Freeman, Past-President of the Society, the income to be used for travel scholarships and research.

Woman's Auxiliary: Scholarship or Fellowship offered by the Woman's Auxiliary to the Society to assist sons and daughters of members or worthy students of mechanical engineering.

RECIPIENTS OF AWARDS

The names of the recipients of the different awards to date are given in the following lists, together with the dates of presentation, and the services or papers for which the awards were made. There were no awards for the years not listed.

A.S.M.E. Medal

1921 Hjalmar Gotfried Carlson, in recognition of the services rendered the Government because of his invention and part in the production of 20,000,000 Mark III drawn steel booster casings used principally as a component of 75-mm. high-explosive shells, but also extensively in gas shells and bombs

1923 Frederick Arthur Halsey, for his paper describing the premium system of wage payments presented before the Society at the Providence Meeting in 1891, as the adoption of the methods there proposed has had a profound effect toward harmonizing the relations of worker and employer

1923 John Ripley Freeman, for his eminent service in engineering and manufacturing by his meritorious work in fire prevention and the preservation of property

1926 R. A. Millikan, in recognition of his contributions to science and engineering

1927 Wilfred Lewis, for his contributions to the design and construction of gear teeth

1928 Julian Kennedy, for his services and contributions to the iron and steel industry

1929 William LeRoy Emmet, for his contributions in the development of the steam turbine, electric propulsion of ships, and other power-generating apparatus.

Holley Medal

1924 Hjalmar Gotfried Carlson, for his inventions and processes which made possible the timely production of drawn steel booster casings for artillery ammunition, thereby aiding victory in the World War

1928 Elmer Ambrose Sperry, for achievements and inventions that have advanced the naval arts, including the gyroscope that has freed navigation from the dangers of the fluctuating magnetic compass

1929 Baron Chuzaburo Shiba, for his contributions to knowledge through fundamental research, including the field of aerodynamics, by the development of ultra-rapid kinematographic methods.

Melville Medal

1927 Leon P. Alford, "Laws of Manufacturing Management"

1929 Joseph Wickham Roe, "Principles of Jig and Fixture Practice"

1930 Herman Diederichs and William D. Pomeroy, "The Occurrence and Elimination of Surge or Oscillating Pressures in Discharge Lines From Reciprocating Pumps."

Spirit of Saint Louis Medal

1929 Daniel Guggenheim, founder of the Guggenheim Fund for the Promotion of Aeronautics.

Junior Award

1915 Ernest O. Hickstein, "Flow of Air Through Thin Plate Orifices"

1916 L. B. McMillan, "The Heat Insulating Properties of Commercial Steam-Pipe Coverings"

1919 E. D. Whalen, "Properties of Airplane Fabrics"

1921 S. Logan Kerr, "Moody Ejector Turbine"

1922 R. H. Heilman, "Heat Losses From Bare and Covered Wrought-Iron Pipe at Temperatures up to 800 Degrees Fahrenheit"

F. L. Kallam, "Preliminary Report on the Investigation of the Thermal Conductivity of Liquids"

1923 S. S. Sanford and S. Crocker, "The Elasticity of Pipe Bends"

1924 R. H. Heilman, "Heat Losses Through Insulating Material"

1925 Gilbert S. Schaller, "An Investigation of Seattle as a Location for a Synthetic Foundry Industry"

1927 Wm. M. Frame, "Stresses Occurring in the Walls of an Elliptical Tank Subjected to Low Internal Pressure"

1928 M. D. Aisenstein, "A New Method of Separating the Hydraulic Losses in a Centrifugal Pump"

1929 Arthur M. Wahl, "Stresses in Heavy Closely Coiled Helical Springs"

1930 Ed Sinclair Smith, Jr., "Quantity-Rate Fluid Meters."

Student Award

1916 Boynton M. Green, Stanford University, "Bearing Lubrication"

Howard Stevens, Rensselaer Polytechnic Institute, "An Investigation of the Dynamic Pressure on Submerged Flat Plates"

M. Adam, Louisiana State University, "The Adaptability of the Internal Combustion Engine to Sugar Factories and Estates"

1917 H. R. Hammond and C. W. Holmberg, Pennsylvania State College, "Study of Surface Resistance With Glass as the Transmission Medium"

1919 C. F. Leh and F. G. Hampton, Stanford University, "An Experimental Investigation of Steel Belting"

W. E. Helmick, Stanford University, "An Experimental Investigation of Steel Belting"

1920 Howard G. Allen, Cornell University, "Wire Stitching Through Paper"

1921 Karl H. White, University of Kansas, "Forces in Rotary Motors"

Richard H. Morris and Albert J. R. Houston, University of California, "A Report Upon an Investigation of the Herschel Type of Improved Weir"

1923 Charles F. Olmstead, University of Minnesota, "Oil Burning for Domestic Heating"

H. E. Doolittle, University of California, "The Integrating Gate: A Device for Gaging in Open Channels"

1924 George Stuart Clark, Stanford University, "Two Methods Used for the Determination of the Gasoline Content of Absorption Oils in Absorption Plants"

L. J. Franklin and Charles H. Smith, Stanford University, "The Effect of Inaccuracy of Spacing on the Strength of Gear Teeth"

1925 Harry Pease Cox, Jr., Rensselaer Polytechnic Institute, "A Study of the Effect of End Shape on the Towing Resistance of a Barge Model"

W. S. Montgomery, Jr., and E. Ray Enders, Jr., Pennsyl-

vania State College, "Some Attempts to Measure the Drawing Properties of Metals"

1926 R. E. Peterson, University of Illinois, "An Investigation of Stress Concentration by Means of Plaster of Paris Specimens"
Cecil G. Heard, University of Toronto, "Pressure Distribution over U. S. A. 27 Aerofoil with Square Wing Tips Model Tests"

1927 Alfred H. Marshall, Princeton University, "Evaporative Cooling"
Roger Irwin Eby, University of Washington, "Measurement of the Angular Displacement of Flywheels"

1928 Clarence C. Franck, Johns Hopkins University, "Condition Curves and Reheat Factors for Steam Turbines"

1929 Frank Vernon Bistrom, University of Washington, "An Investigation of a Rotary Pump"
William Wallace White, University of Washington, "An Investigation of a Rotary Pump"

1930 Gerard Eden Claussen, Polytechnic Institute of Brooklyn, "High-Temperature Oxidation of Steel"
Harold L. Adams and Richard L. Stith, University of Washington, "A Wind Tunnel for Undergraduate Laboratory Experiments."

Charles T. Main Award

1925 Clement R. Brown, Catholic University of America. Subject: "The Influence of the Locomotive on the Unity of the United States"

1926 W. C. Saylor, Johns Hopkins University, Subject: "The Effect of the Cotton Gin Upon the History of the United States During Its First Seventy Years"

1927 No award. Subject: "Scientific Management and Its Effect Upon the Industries"

1928 Robert M. Meyer, Newark College of Engineering. Subject: "Scientific Management and Its Effect Upon Manufacturing"

1930 Jules Podnossoff, Polytechnic Institute of Brooklyn. Subject: "The Value of the Safety Movement in the Industries."

JOINT AWARDS

The A.S.M.E. participates in three joint awards, the Herbert Hoover Medal, the John Fritz Medal, and the Washington Award.

The Herbert Hoover Medal

The Hoover Gold Medal was instituted in 1930 to commemorate the civic and humanitarian achievements of Herbert Hoover and the first award was made to Herbert Hoover on April 8, 1930. From time to time the medal will be awarded by engineers to a fellow engineer for distinguished public service.

The trust fund creating the award was the gift of Conrad N. Lauer, of Philadelphia. The American Society of Mechanical Engineers is the custodian of the fund which is administered by a Board of Award composed of representatives appointed by the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers, The American Society of Mechanical Engineers, and the American Institute of Electrical Engineers.

The John Fritz Medal

The John Fritz Medal was established in August, 1902, by the professional associates and friends of the late John Fritz, Past-President and Honorary Member of the A.S.M.E., to perpetuate the memory of his achievement in industrial progress.

The medal is awarded not more than once each year for notable scientific or industrial achievement, with no restrictions on account of sex or nationality. The award is made by a Board of sixteen, four representatives from each of the four national engineering societies, the A.S.C.E., A.I.M.E., A.S.M.E., and A.I.E.E.

The recipients of the John Fritz Medal are given in the following list; there were no awards for the years not listed.

1902 John Fritz, for scientific and industrial achievement

1905 Lord Kelvin, for work in cable telegraphy and other general scientific achievements

1906 George Westinghouse, for the invention and development of the air brake

1907 Alexander Graham Bell, for the invention and introduction of the telephone

1908 Thomas Alva Edison, for the invention of the duplex and quadruplex telegraph; the phonograph; the development of a commercially practical incandescent lamp; the development of a complex system of electric lighting, including dynamos, regulating devices, underground system, protective devices, and meters

1909 Charles Talbot Porter, for his work in advancing the knowledge of steam engineering and improvements in engine construction

1910 Alfred Noble, for notable achievements as a civil engineer

1911 Sir William Henry White, for notable achievements in naval architecture

1912 Robert Woolston Hunt, for his contributions to the early development of the Bessemer process

1914 John Edson Sweet, for his achievements in machine design; and for his pioneer work in applying sound engineering principles to the construction and development of the high-speed steam engine

1915 James Douglas, for notable achievements in mining, metallurgy, education, and industrial welfare

1916 Elihu Thomson, for achievements in electrical invention, in electrical engineering and industrial development, and in scientific research

1917 Henry Marion Howe, for his investigations in metallurgy, especially in the metallography of iron and steel

1918 J. Waldo Smith, for achievement as an engineer in providing the City of New York with a supply of water

1919 George W. Goethals, for achievement as builder of the Panama Canal

1920 Orville Wright, for achievement in the development of the airplane

1921 Sir Robert A. Hadfield, for the invention of manganese steel

1922 Charles Prosper Eugene Schneider, for achievement in metallurgy of iron and steel, for development of modern ordnance, and for notable patriotic contribution to the winning of the World War

1923 Senator Guglielmo Marconi, for the invention of wireless telegraphy

1924 Ambrose Swasey, for achievement as a designer and manufacturer of instruments and machines of precision, a builder of great telescopes, a benefactor of education, the founder of the Engineering Foundation

1925 John Frank Stevens, for great achievements as a civil engineer, particularly in planning and organizing for the construction of the Panama Canal; as a builder of railroads, and as administrator of the Chinese Eastern and Siberian Railways

1926 Edward Dean Adams, for great achievements as engineer, financier, scientist, whose vision, courage and industry made possible the birth at Niagara Falls of hydroelectric power

1927 Elmer Ambrose Sperry, for the development of the gyrocompass and application of the gyroscope to the stabilization of ships and aeroplanes

1928 John Joseph Carty, for pioneer achievement in telephone engineering and in development of scientific research in the telephone art

1929 Herbert Hoover, engineer, scholar, organizer of relief to war-stricken peoples, public servant.

1930 Ralph Modjeski, for notable achievement as an engineer of great bridges combining the principles of strength and beauty

1931 Admiral David Watson Taylor, for outstanding achievement in marine architecture, for revolutionary results of persistent research in hull design, for improvement in many types of warships, and for distinguished service as Chief Constructor of the United States Navy during the World War.

The Washington Award

The Washington Award was founded in 1916 by John Watson Alvord, to be awarded annually by the Western Society of Engineers upon the recommendation of a Commission composed of nine representatives of that society and two representatives of each of the four national engineering societies, the A.S.C.E., A.I.M.E., A.S.M.E., and A.I.E.E. It is bestowed in recognition of devoted, unselfish, and preeminent service in advancing human progress through engineering. The recipients have been as follows:

1919 Herbert C. Hoover, for his preeminent services in behalf of the public welfare

1922 Robert W. Hunt, for his pioneer work in the development of the steel industry, and for a life devoted to the advancement of the engineering profession

1923 Arthur N. Talbot, for his life work as a student and teacher, investigator and writer, and for his enduring contribution to the science of engineering

1925 Jonas Waldo Smith, for the rare combination of vision, technical skill, and administrative ability and courageous leadership in engineering

1926 John Watson Alvord, for his pioneer work in developing the fundamental principles of public utility valuation and his marked contributions to sanitary science

1927 ORVILLE WRIGHT, for fundamental scientific research and the resultant successful airplane flight

1928 MICHAEL I. PUPIN, for devotion to scientific research leading to his inventions which have materially aided the development of long-distance telephony and radio broadcasting

1929 BION JOSEPH ARNOLD, for pioneering work in the engineering and economics of electrical transportation

1930 MORTIMER ELWYN COOLEY, for vision and constructive leadership in the education of the engineer.

Report of Council

THE Council presents its report for the administrative year 1930. The personnel of the Council for 1930 is given on page 5 of this Section of Transactions.

The Council records with deep regret the death of Elmer A. Sperry, President of the Society in 1929, and Dr. Ira N. Hollis, President in 1917, and Honorary Member of the Society, as well as Chairman of the Committee on Awards.

Fiftieth Anniversary of the Society

Outstanding in events of the year was the celebration of fifty years of the organization of the A.S.M.E. This was held April 5–9 in New York, Hoboken, and Washington, D. C. The message from your President, Charles Piez, in the April, 1930, issue of *Mechanical Engineering*, gives not only a brief and splendid review of the past, but a challenge to the future interpreting the motto on the anniversary medal, "What is not yet, may be." This anniversary brought out our honor roll of the living founders, whose names are here recorded, several of whom were able to be present at the Founders' Luncheon in Washington on Tuesday, April 8. They are John W. Cloud, London, England, John S. Coon, Atlanta, Georgia, Robert F. Grimshaw, New York, N. Y., Francis H. Richards, New York, N. Y., Eugene H. Robbins, Pittsfield, Mass., and Ambrose Swasey, Past-President and Honorary Member, Cleveland, Ohio.

Hoover Medal. The Hoover Medal, made possible through the generous gift of Conrad N. Lauer, Vice-President of the Society, was instituted on the occasion of the Anniversary Dinner, Tuesday evening, to commemorate the civic and humanitarian achievements of an engineer; the medal is "to be awarded by engineers to a fellow engineer for distinguished public service," and was awarded to Herbert Hoover, as the first recipient, "whose humanitarism knew no national lines."

The Fiftieth Anniversary brought to this country, as a part of our program, a group of distinguished engineers from foreign countries.

The convocation ceremonies, at which were presented the fiftieth anniversary medalists, were held on Tuesday, April 8, in the assembly hall of the U. S. Chamber of Commerce, Washington, D. C. The chief diplomatic officer of each country represented on this occasion, presented to the Society for the conferring of the medal, the distinguished engineer who had been selected for this honor by the engineering profession of his country.

Membership

The chart on this page shows the changes in membership corresponding to the fiscal year of the Society. At the close of the administrative year of 1930 and the time of the writing of this report, the membership totals 20,047.

Standing and Special Council Committees

An outstanding accomplishment in this year's activities has grown out of the petroleum industry in Oklahoma, centering around the Mid-Continent Section at Tulsa. Through the combined efforts of the Local Sections Committee, the Professional Divisions, and a special research committee the Society began a service to the industry by the establishment of an educational laboratory for automatic pumping-station equipment. This represents on the part of industry, an investment of $50,000, and is the first automatic crude oil pumping station for pipe-line companies to be maintained as a permanent proving ground for the development of this type of apparatus. The Boiler Code Committee conferred with the representatives of this industry preparatory to a revision of the Code of Unfired Pressure Vessels to meet the needs of the petroleum industry. The Special Research Committee on Fluid Meters held a meeting in Norman, Okla., for the expressed purpose of studying the special needs of this industry in the measurement of natural gas. The A.S.M.E., through the cooperation of the Publications Committee, issued a special publication, *Petroleum Mechanical Engineering.* The Petroleum Division's Section of Transactions will hereafter be called *Petroleum Mechanical Engineering.* A part-time staff representative has been set up at Tulsa.

The reports of the Standing Committees, together with the report of the Boiler Code Committee, form an appendix to this record. "Fifty Years of the A.S.M.E.," as given on the occasion of our Fiftieth Anniversary, and printed in the April, 1930, issue of *Mechanical Engineering*, is an inclusive statement of the development of our various committees. Other special Council committees reporting this year are the Revenues Committee appointed in 1929 to study the possibilities of increasing the Society's income, of decreasing its expenditures, and of making such recommendations as might arise out of this study, looking toward the Society's operating efficiency. This resulted in the recommendation of a slight increase in the initiation fees in certain grades with the purpose of (1) increasing the income from initiation fees, and (2) providing a greater distinction between the grades of Associate Member and Member. The income from initiation fees becomes a part of the invested reserve of the Society. The result of the ballot on amendments shows a favorable ballot of 4762 for, and 1376 against. The amendments become effective on announcement at this Annual Meeting.

MEMBERSHIP CHANGES—OCTOBER 1, 1929, TO SEPTEMBER 30, 1930

	Membership			Losses			Additions			Totals

Finances. The report of the auditors for the fiscal year of the Society, October 1, 1929, to September 30, 1930, follows as part of the Finance report. Attention is called to the bequests of $23,250 of the late Worcester Reed Warner, Past-President and Honorary Member of the Society, and of C. B. F. Waller, member of the Society, who left the residue of his estate of some $7000 to the Society.

All trust funds are carefully invested by the Council under the legal requirements for trust funds in the State of New York, and the interest on the respective fund in most cases provides for the awards made under such gifts.

Each year's summing-up reveals an increase in industrial support for the experimental programs in research and the expenditures during the past year from cash contributions made by industry have totaled approximately $50,000, or more than three times the Society's research budget for the same period. At the present time the Society is custodian for the funds of

thirty-three (33) research committees, these funds being contributed by industry and The Engineering Foundation.

Student Branches. There are now 106 Student Branches. The conferences held at the Annual and Semi-Annual Meetings with delegates coming from the various branches, show an intensive interest in Society work. From the ranks of these young engineers, much of the membership of the future A.S.M.E. will be recruited.

Budgeting Policy Committee. This Committee since its formation has focused its discussion on the need for formulation of a definite program of Society activity in distinction from a financial program and the translation of the work program into expenditures.

The Committee on Economic Status of the Engineer was formed in May, 1928. This Committee is actively at work but has before it a most difficult, involved, and extended study and task. The Employment Service and Local Sections are cooperating in certain phases of the study which the Economic Status Committee is making.

Joint Activities and Representation

Employment Service. The Employment Service shows quite marked geographical development. For years it has had to function without the guidance of a committee. Now we are gratified to have the watchful care of the Committee on Local Sections. This service is a joint undertaking of the four national engineering societies and offices are maintained in New York, San Francisco, and Chicago.

A consultation of the membership list will give some idea of the varied general activities and the largely diversified appointments, both geographically and professionally, which are covered during a Society year. With the adherence last year of the American Society of Civil Engineers, the American Engineering Council is now a body representative of the profession. The A.S.M.E. has twenty representatives.

Other organizations in which we have joint interest and representation are the American Standards Association, the Engineering Foundation, the Engineering Societies Trustees, Inc. (the latter the holding corporation for the founder societies of the Engineering Building), the A.A.A.S., the Museums of the Peaceful Arts, Gantt Medal Board of Award, Guggenheim Medal Board, the U. S. National Committee of the International Electrotechnical Commission, John Fritz Medal Board of Award, the Hoover Medal Board, Joseph A. Holmes Safety Association, the Division of Engineering of the National Research Council, National Safety Council, the Alfred Noble Prize, the Spirit of St. Louis Medal Board of Award, and the Washington Award of the Western Society of Engineers.

We also have assignments on federal and civic organizations having to do with engineering problems. Both in our committee work and in general the President and Council are called on to make appointments for a great variety of occasions. This year, at home and abroad, the Society has been represented at many international congresses and special celebrations. For these latter events Honorary Vice-Presidents are chosen by the Council to represent the Society.

In the summary of the year's activity, the Council has touched only briefly. Your attention is especially called to the splendid reports of our Committees accompanying this summary to give you the more detailed accounts, and Council would again record its gratitude and appreciation to the Committeemen and to authors who have given of their time and talents and the benefits of their experience for the general good and for the advancement of our profession.

Calvin W. Rice,
Secretary.

FINANCE

The year 1929–1930 was a successful financial period in the Society's operation. The excess of income over expenditures was $39,069.33, of which $5000 went into the Retirement Fund. Five thousand dollars was added to the special reserve for Engineering Index Development and the total reserves were therefore increased by $44,069.33.

The Engineering Index passed through the third year of its development period and is at a point where, barring possibility of general loss in income due to business conditions, it will become self-supporting and may possibly produce a small amount of income.

$120,000 was borrowed to tide over the end of the fiscal year as compared to $80,000 for the same purpose the previous year. It should be explained that this financing is usually necessary as Mechanical Catalog billings are not made until September 30, the last day of the fiscal year, while expenditures against that income are incurred uniformly throughout the year. The increase this year was largely due to the expense for the Fiftieth Anniversary which is to be financed over a period of years.

The accompanying table giving the condensed comparison of the balance sheet for the year ending September 30, 1929, with that of the year just closed reveals increases in all of the items except one. These increases are explained in the following paragraphs.

CONDENSED STATEMENT OF INCOME AND EXPENDITURES
1928-1929 AND 1929-1930

	1928-1929	1929-1930
Income		
Initiation Fees	$ 29,769.02	$ 30,430.17
Membership Fees	303,272.09	314,815.87
Accounts Receivable (Members and Non-Members)	411,878.96	445,233.18
Interest	22,655.50	23,601.18
	$767,575.57	$814,080.40
Appropriated from 1927-1928 Excess Income.	10,000.00	
	$777,575.57	
Expenditures		
Administration and General	$119,068.38	$104,152.33
Initiation Fees Account	25,595.37	21,802.81
Service to Members Account	282,086.38	319,381.46
Income Producing and Professional	271,032.63	300,018.64
Reserve for Engineering Index Development.	20,000.00	5,000.00
Service to Public Account	24,659.42	24,676.49
	$742,442.18	$775,031.73
Preceding year's liability for Mechanical Catalog: Underexpended	521.84	20.66
	$741,920.34	$775,011.07
Balance of Income over Expenditures	$ 35,655.23	$ 39,069.33

CONDENSED COMPARISON OF BALANCE SHEETS

	Sept. 30, 1929	Sept. 30, 1930	Net Charge During Fiscal Year
Assets			
Cash	$ 4,367.49	$ 6,965.99	$+ 2,598.50
Accounts Receivable	160,412.58	166,150.97	+ 5,738.39
Inventory	101,378.05	114,873.36	+13,495.31
Deferred Charges	107,942.06	171,201.14	+63,259.08
Investment for Trust Funds	134,315.85	164,035.45	+29,719.60
Investment for Capital Account	332,381.25	343,381.25	+11,000.00
Fixed Assets	514,673.80	515,682.34	+ 1,008.54
Total Assets	$1,355,471.08	$1,482,290.50	$ 126,819.42
Liabilities			
Current Liabilities	$ 133,578.11	$ 184,803.95	$+51,225.84
Contributions for Research	22,453.48	23,757.09	+ 1,303.61
Dues Paid in Advance	4,473.09	4,349.81	− 123.28
Trust Funds	134,315.85	164,035.45	+29,719.60
Capital	1,060,650.55	1,105,344.20	+44,693.65
Total Liabilities	$1,355,471.08	$1,482,290.50	$ 126,819.42

Accounts Receivable. The increase in this item is due to the increase in income from the Mechanical Catalog over the income for 1928–1929.

Inventory. This increase is due to a larger program of publications in process and in stock awaiting sale.

Deferred Charges. The change under this heading is due to the expenses for the Fiftieth Anniversary which are to be financed over several years and to the increase in the development costs of the Engineering Index.

Trust Funds. The Spirit of St. Louis Medal Fund of $3500 and the Worcester R. Warner Prize Fund of $23,250 account for part of this increase. The remainder of the increase is due to increases in existing funds.

Capital Account. This increase represents an investment of funds in the Capital Account.

Current Liabilities. The change in this item is best shown by the following table:

	Sept. 30, 1929	Sept. 30, 1930
Notes Payable	$ 80,000.00	$120,000.00
Liabilities for Unfilled Commitments	51,507.51	43,937.28
Historical Bibliography (Hollis Gift)	320.60	
Thurston Biography (Gleason Gift)	1,750.00	460.82
Accounts Payable		20,405.85
	$133,578.11	$184,803.95

Increase in the item of notes payable has been explained in the preceding paragraph. The new item of accounts payable is due to a large amount of printing bills for Transactions which came due at the close of the fiscal year.

Capital. Change in Capital Account is explained by the following table:

	Sept. 30, 1929	Sept. 30, 1930
Fixed Assets	$ 514,673.80	$ 515,682.34
Reserve for Retirement Allowance	20,608.00	26,232.32
Appropriated for Investment	322,137.62	317,148.93
Reserve for Engineering Index Development	20,000.00	25,000.00
Working Capital	183,231.13	221,280.61
	$1,060,650.55	$1,105,344.20

William J. Struss & Co., Certified Public Accountants, give the results of their examination of the books of the Society for the fiscal year ended September 30, 1930, in the accompanying statement of Assets and Liabilities.

Respectfully submitted,

F. A. SCHAFF, *Chairman*

MEETINGS AND PROGRAM

In the successful Semi-Centennial Anniversary Meeting several years' planning and activity by the Committee on Meetings and Program was brought to fruition. For more than five years the Committee on Meetings and Program had worked continuously on the plans for the celebration. The success of this event, therefore, is the result of the contributions of all of those who served on the Committee during that period and the members of the present Committee take great pleasure in thus acknowledging them.

The Anniversary meeting in Washington is the outstanding activity of the Committee on Meetings and Program during the fiscal year. It has been recorded fully in the publications of the Society and further detail is not necessary here. Suffice it to say that the objects of the Committee in the celebration were reached in that the celebration brought together representatives of the engineers of the world, focused the attention of the profession on its broader responsibilities, and was conducted in a manner befitting the standing of the Society.

Three other meetings were held during the year at Akron in October, 1929, the Annual Meeting in New York in December, 1929, and the Semi-Annual Meeting at Detroit in June, 1930.

AKRON MEETING

The Akron Meeting dealt with topics of interest to the industries in and about Akron. The dinner provided the platform for an address by W. E. Wickenden, President of the Case School of Applied Science, and for the first appearance before the Society of the President-Elect, Charles Piez. An exceedingly interesting program of inspection trips to the rubber plants of Akron attracted a goodly attendance.

ANNUAL MEETING

The Annual Meeting was the usual successful event, the registration being 2215. The presence of President Sperry at the World Engineering Congress in Japan required a slight change in the usual program and in place of the presidential address two addresses were given, one on "Economic Changes," by E. E. Hunt, and the second on "Engineers and American Life," by L. W. Wallace and J. E. Hannum. Dr. James Rowland Angell, President of Yale University, was the speaker at the dinner.

At the Knoxville and Akron meetings, the experiment was tried of eliminating the reporter from the sessions. These preliminary trials proved successful and this procedure was followed at this Annual Meeting. It also proved successful.

The Philadelphia Local Section cooperated by conducting the Open House on the opening evening of the meeting.

DETROIT MEETING

The Detroit Committee very wisely eliminated from their plans for the meeting the usual formal events and concentrated their efforts on making the meeting a success socially in an informal way. They provided an excellent program of visits to the interesting plants in Detroit as well as a boat trip for the entire party on the Detroit River and to Lake St. Clair.

A technical program of sixteen sessions provided a goodly amount of valuable material.

COMMITTEE REUNION

The Committee celebrated the completion of twenty-five years of its history by a reunion dinner on February 20, 1930. Thirty-seven members had served on the Committee since its inception in 1904 and seventeen of them were present at the dinner which was given over to reminiscences of Committee activities and suggestions as to forward-looking projects which the Society should undertake.

Respectfully submitted,

W. L. BATT, *Chairman*
G. M. EATON
F. M. FEIKER
J. W. PARKER
C. P. BLISS.

MEMBERSHIP

The Committee on Membership held eighteen meetings during the fiscal year 1929–1930.

The number of applications considered in the transaction of its work and a summary showing the action taken follows:

Applications pending, October 1, 1929	457
Applications received during fiscal year 1929-1930	1892
Total applications handled during year 1929-1930	2349
Recommended for membership	2018
Transfers denied	3
Deferred	1
Withdrawn	35
Applications pending, October 1, 1930	292
Total applications handled during year 1929-1930	2349

Those recommended for membership were divided into the following grades:

Members	442
Transfers to Member	140
Associates	51
Transfer to Associate	1
Associate-Members	338
Transfers to Associate-Member	82
Juniors	443
Juniors (R5 Rule 1)	521
Total recommended	2018
Transfers	223
Total new members recommended	1795

During the fiscal year 1929-1930 the Membership Committee made the following recommendations:

Elections declared void	149
Resignations accepted	330
Dropped from membership	692
Total loss	1171

Respectfully submitted,

L. K. COMSTOCK, *Chairman*
F. A. WALDRON
H. W. BUTLER
H. WEBSTER
O. E. GOLDSCHMIDT.

PUBLICATIONS

The outstanding event of the year ending September, 1930, was the celebration of the Fiftieth Anniversary of The American Society of Mechanical Engineers. To this successful celebration the Publications Committee contributed the special anniversary issue of *Mechanical Engineering* which was published in April. The issue featured the historical development of the Society, the engineers of the period who achieved prominence by reason of election to honorary membership, or to the presidency of the Society, and contemporaneous technological progress. The Society's Professional Divisions, by committees or through individuals, appointed to do so, prepared excellent historical surveys of progress in their fields, thus contributing notably to the history of engineering.

Mechanical Engineering has continued its program of publishing material of appeal to the widely varying interests of the diversified membership of the Society and of treating of matters of professional importance to all engineers. The summarizing leaflet, written in popular style, and intended to give a hasty survey of the papers of principal interest in *Mechanical Engineering*, has continued to be published as Section Two. Illustrations were introduced into most of this year's issues of this leaflet with good effect. The *Literary Digest* has been attracted to articles in the Society's Journal through the medium of Section Two and has commented on its articles in consequence.

The Transactions appeared bound in two volumes late in the spring of 1930. The rapidly increasing size of the Transactions has given the Committee some concern and is likely to result in a more careful scrutiny of papers offered for publication in the hopes of increasing quality and keeping publication costs within the budget.

Volume 3 of the Record and Index of the Society was published in September, 1930. After careful study of the problems the Publications Committee recommended to the Council that in the future the Record and Index be published as a section of the Transactions in pamphlet form similar to other sections issued by the Professional Divisions. The Council has approved this change, which is to take effect at once. There is thus restored to Transactions the Society Affairs material that it previously contained, and the Record and Index will cease to exist as a special publication in its present form.

The *A.S.M.E. News* has continued to give gratifying signs of filling the need for which it was intended. Interest in it is evident from the number of letters received on items published in its columns. The Committee has undertaken a study of a comprehensive plan for increasing the valuable service that the *News* renders.

As a result of the activities of the Applied Mechanics Division and its intense interest in subjects in its field that are highly specialized, the Publications Committee, with consent of Council, has been able to induce the McGraw-Hill Book Company to publish a book on "Plasticity," by A. Nadai. By means of the cooperative arrangements made, the publisher is assured of a favorable reception of the book and the engineering profession has an accession of great value to its literature on a little-known subject of rapidly growing importance. The Society expects to sponsor the publication of other books in a similar manner.

The sixteen eminent engineers of the world who were awarded the Fiftieth Anniversary Medal at the Society's Anniversary Celebration submitted monographs as to the technological and humanistic aspects of engineering progress in their respective countries. The Committee is pleased to report that Mr. Harrison W. Craver, librarian of the Engineering Societies Library, has consented to edit these monographs for publication. The work is now in progress and an early publication in book form of all of the monographs is expected.

As evidence of notable progress in the work of the Society's research committee on the thermal properties of steam, the Publications Committee reports the publication in the Spring of 1930 of "Steam Tables and Mollier Diagram," by Joseph H. Keenan. This important set of tables is published by the Society and has met with favorable notice; it is rapidly being adopted by the profession and by educational institutions.

In its reports of last year the Committee mentioned the proposed symposium by engineers edited by Dr. Charles A. Beard and published by Longmans, Green and Company. The symposium was published in April, 1930, under the title "Toward Civilization" and has been favorably reviewed and received. The Committee feels that its efforts in interesting Dr. Beard in the project have been well repaid by the opportunity which engineers have had of expressing their views in the present discussion of the mechanization of civilization.

Intense interest in the mechanical engineering problems involved in the petroleum industry has been a feature of the past year. The Publications Committee, wishing to further this interest, authorized, at the suggestion of the Petroleum Division, the publication of a special preprint known as *Petroleum Mechanical Engineering*, containing the papers to be presented at the National meeting of the Petroleum Division held in Tulsa, Okla., October 6 to 8, 1930. The expense of this unusual publication was met by special advertising solicited for printing as part of the pamphlet. Explanation of the objects and organization of the Society and the Petroleum Division were included, as were also an abstract of a historical article on the petroleum industry which appeared in the April issue of *Mechanical Engineering*, and a special selection of references to the contemporary technical literature of the oil industry supplied by The Engineering Index.

The Engineering Index Service

The marked progress made by The Engineering Index Service during the past year indicates that it may be no longer considered a speculative venture. The income for the fiscal year 1929-1930 has more than equaled the budget. The number of subscribers has increased more than fivefold, indicating that the value of the Service is being more widely recognized.

At the beginning of the fiscal year, the divisions of the Service were completely revised, to meet more adequately the needs of subscribers, which, together with some added features, have greatly broadened the effectiveness of the Service. At the same time, the subscription prices were reduced, many divisions now being priced as low as $7 per year, and the complete Service, $1500 per year.

The list of periodicals reviewed by the Service has been materially extended during the past year. Not only the regular, but also all irregular publications received by the Engineering Societies Library, except books, are now being reviewed. In addition, the reviews of new books, which are prepared regularly by the Library, are included in the Service.

Respectfully submitted,

W. A. Shoudy, *Chairman*
F. V. Larkin
W. H. Winterrowd
L. C. Morrow
S. F. Voorhees.

PROFESSIONAL DIVISIONS

During the last year the Professional Divisions have continued their splendid program of activities. Besides the usual activities of securing technical papers for Society and Divisional meetings, preparing their yearly progress reports, and developing research projects, there has been a noticeable increase of the activities of subcommittees functioning directly under the Divisions and doing some very constructive work. The table of Divisions' activities shows that 246 papers were secured and presented by the Divisions during the year. This does not include papers presented by them at usual Metropolitan Section meetings, or Division reports.

Petroleum Division

The most outstanding development of the year was the activity in the petroleum field. This was due to the splendid work of the Mid-Continent Section, aided by special financial assistance given the Petroleum Division by Council. As a result a number of active subcommittees were gotten under way and a large national meeting was held in Tulsa, October 6, 7, and 8, during the Petroleum Exposition.

The activities of this Division were divided into six subcommittee groups, three of which functioned primarily in the East and three at Tulsa. They have all given during the year splendid evidence of the valuable work they can do. One of them, on Lubrication Engineering, takes care of a long-expressed need, giving the practical lubrication engineer the opportunity of having a forum of his own. The Refining Committee, besides presenting an admirable program at the Tulsa meeting, has made a survey of possible research projects and is doing excellent work in developing support for A.S.M.E. research projects of value to petroleum refining. The utilization of petroleum as a fuel is under the direction of a committee which is providing a paper at Tulsa and a meeting in New York this winter.

The group in Tulsa initiated and sponsored the program there which included the forming of three subcommittees on Oil Transportation, Gas Transportation, and Production. The Tulsa group also have accomplished splendid committee work on problems of keen local interest, such as automatic pumping stations. The latter has culminated in the building of a demonstration automatic pumping station at the Petroleum Exposition which has received a good deal of favorable comment.

Other Divisions

Other Divisions have been functioning well during the past year. Special attention might be called to some outstanding activities. The Iron and Steel Division and the Machine Shop Practice Division cooperated in the Metal Congress in Chicago during the week of September 22. Our Society was one of four Societies holding simultaneous meetings during the week, and more than fourteen hundred members of the Society attended the Congress, attracted by the splendid program presented by the various groups.

Other interesting joint activities during the year were the national meetings of the Materials Handling and Management Divisions held at the time of a Management Congress in Chicago last March. A

[1] Includes Akron, Detroit, and Annual Meetings.
[2] Includes more than one meeting of the Division: [2a] National Meeting, Dayton, May, 1930; Pittsburgh Meeting, Feb., 1930; Seattle Meeting, May, 1930; Chicago Meeting, Aug., 1930; [2b] and [2c] National Meetings were held with Management Congress; [2d] National Meeting, Pittsburgh, Nov., 1929; New York Meeting, April, 1930.
[3] Fuels National Meeting transferred from October to February so as to hold it during Midwest Power Conference in Chicago.
* All members are registered in National Defense Division.
Note: Table does not include any meetings held after October 8, 1930.

similar cooperative program is being arranged for Cleveland next April with other societies interested in management. These two Divisions also have done excellent work in some of their subcommittees. The Waste Elimination Committee of the Management Division has attracted considerable attention, both in this country and abroad, and its work promises to be of increasing value. The Materials Handling Division, during the past year, formed a subcommittee of representatives of materials-handling equipment manufacturers to get concerted action on a number of vital problems in the field. The response of industry has been splendid, and a constructive program has been outlined for the coming year.

The Applied Mechanics Division is the youngest and one of the best organized. It is handling its highly technical field in an admirable fashion. During the past year it has cooperated actively in the International Congress of Applied Mechanics in Stockholm, and with the consent of Council has invited and urged that the next International Congress of Applied Mechanics be held in this country in 1938.

The Aeronautics Division, besides holding its National meeting at Dayton, Ohio, held several meetings jointly with Local Sections. One of these was held at the University of Washington under the auspices of the Western Washington Section late in May, and enabled a fine technical meeting to be held on the Pacific Coast due to the close cooperation between the Division and the Western Washington Section. Other similar joint meetings were held in Pittsburgh in March, and Chicago in August.

In cooperation with Pennsylvania State College, the Oil and Gas Power Division held another strikingly successful meeting on the college campus last June.

Attention might be called again to the splendid work that is being done by the smaller Divisions of the Society which have a large and fertile field for future growth. The following Divisions have been actively covering their fields and are gradually winning support and attention from the industries in their fields: Railroad Division, Wood Industries Division, Textile Division, and Printing Industries Division.

The Fuels, Power, and Hydraulic Divisions have been equally alert in bringing out the developments in their fields. The Fuels Division plans a National Meeting next February at the time of the Midwest Power Conference and Exposition. The Hydraulic Division is securing support for translation of important foreign hydraulic papers. Its Survey Committee prepared and issued a digest of foreign hydraulic literature particularly relating to research which is believed to be of considerable value and importance. Its Subcommittee on Standardization of Shaft Couplings has completed a set of standard dimensions for the standardization of this feature of hydroelectric units. This subcommittee had the benefit of conferences with turbine and generator manufacturers which brought about an early agreement leading to the actual use of the proposed standard dimensions by the industry.

Future Development

From the preceding brief review of the Divisions' activities for the year and the accompanying tabulation it is evident that the Divisions are functioning satisfactorily. However, the Divisions cannot have their fullest possible development without increased financial support to take care of their further growth. Each of the Divisions functions now with volunteer committeemen, who give a great deal of their own personal time and attention to Division work. They have to pay their own expenses to the national meetings of the Divisions, there being no funds to care for traveling expenses. Each Division has anywhere from five to twelve trade organizations and societies with which it must keep in touch, and in time this can be properly done only by having a part-time paid secretary for each Division.

Also, some of our Divisions (Iron and Steel, Materials Handling, Aeronautics, Printing Industries, Textile, Wood Industries, etc.), have found that they must have more of the technical men in their field as members of the Society or at least have them kept informed of what the Society is doing. To accomplish this, many of the Divisions have been extensively inviting non-members to attend their meetings in order to bring them in touch with what we are doing and to increase our usefulness to industry.

To take care of these growing Divisional needs it would seem that some method could be devised whereby the Divisions may bring into the Society greater revenue and in turn have more for their own growth. Such a method could possibly be devised as part of our publication policy. Our Divisions are responsible for the most of the technical material that is published, so that if they can increase its use and sale they should be allowed to profit more directly by the increased revenue. The Standing Committee on Professional Divisions is now discussing the matter with the Publications Committee in expectation of developing some plan.

Respectfully submitted,

J. W. Roe, *Chairman*
H. W. Brooks
W. F. Dixon
P. T. Sowden
C. B. Peck
R. T. Kent
Archibald Black, *Ex-Officio.*

LOCAL SECTIONS

A total of seventy-one Local Sections of the Society has now been authorized and are functioning in thirty-eight States of the Union. The territories of these Sections vary in size from a minimum radius of thirty miles from the City Hall of the headquarters city to that of the Mid-Continent Section embracing several states and parts of states. To the majority of members living in these respective communities or groups of communities the Society is encompassed in the activities of the Local Sections—aside from the receipt of its literature the Section is the Society.

It cannot be questioned that the present large membership of the Society is due principally to its geographical development through the Local Sections. The upward trend of the membership is chronologically coincident with the first meetings of the Society in geographical districts in 1909. When these geographical groups began in 1915 really to function to a degree that warranted the Council in appointing a Standing Committee to administer their activities, an even greater rate of increase of membership development occurred. The membership increase in the territory of the last authorized Section, St. Joseph Valley, shows that whereas there were 39 members at the time of organization on December first, there were on April first, fifty-one members, an increase of 31 per cent within a period of only four months.

Prospective Norwich Section

For some months active interest has been taken in the development of proper conditions under which a Section may be authorized in Eastern Connecticut with headquarters at Norwich, Conn. Mr. William Buck, of Jewett City, Conn., planned an organization meeting on October 29. A number of applications for membership are pending from this district. The territory will include Bradford and Westerly, R. I.

Meetings

The meetings of the Local Sections have a wide range in character. In addition to those held locally there are included meetings of national character where the Local Section provides all of the social portion of the programs for Semi-Annual Meetings, Regional Meetings, and also for meetings of the Professional Divisions. A large part of the success of the latter group has been dependent upon the organization of the Local Sections to provide necessary meeting places and personnel to handle local arrangements and to produce attendance. Continued cooperation with Professional Divisions is evident by the National Divisional Meetings which were held as listed herewith, the Local Section assisting in each case.

Cleveland	Machine Shop Practice	October 1–2, 1929
Philadelphia	Fuels	October 7–10, 1929
Rock River Valley	Wood Industries	October 16–18, 1929
Pittsburgh	Printing Industries	November 7–8, 1929
Chicago	Machine Shop Practice	March 3–5, 1930
Chicago	Materials Handling	March 5–7, 1930
Boston	Textile	May 2, 1930
Dayton	Aeronautic	May 19–22, 1930
Central Pennsylvania	Oil and Gas Power	June 12–14, 1930
Chicago	Machine Shop Practice	September 22–24, 1930
Chicago	Iron and Steel	September 24–26, 1930

While the main objective of the Local Sections meetings is not to produce papers of fundamental technical importance, nevertheless a considerable number of the papers appearing in the publications of the Society during the last fifteen years originated at Local Sections meetings.

Whereas attendance figures are not usually reported, and occasionally, for one reason or another, a Local Section meeting has not been reported to Headquarters, there is a record over the past five

years of 1815 meetings held by the existing Sections detailed by years as follows:

1925-1926	387
1926-1927	328
1927-1928	367
1928-1929	406
1929-1930	327
	1815

The number of meetings held by Sections during 1929-1930 is shown in the accompanying chart (Table 1). This chart also details the membership of the respective Sections on October 1, 1929, and October 1, 1930, the net increase, the percentage of membership increase, and the fact that ninety per cent of the entire membership is now residing within the territory of established Local Sections.

Scope of Service

The service of the Local Sections covers a very wide variety of activities. The most recent call made upon them has been to assist in the study of the Economic Status of the Engineer, and the response by the membership to a questionnaire relative thereto. Last fall they were asked in a number of instances to entertain prominent foreign engineers traveling through the United States en route to the World Engineering Congress in Japan. Frequently, they are called upon individually to provide details regarding the records and availability of a certain local engineer who is being considered for service on a governmental or Society committee or perhaps for employment or consultation service. They frequently serve in a wide variety of civic engineering developments either for their municipality or State or for the nation. They have contributed on several occasions to the entertainment of groups of members traveling to meetings at distant points. They have cooperated in furthering the activities of the Standardization and Research Committees, such as the adoption of the standard on fire-hose couplings. They have participated in campaigns on "Smoke Abatement." They have reviewed tentative reports issued by various committees which are disseminated through the Local Sections with the request that they be referred to a committee of experts in the local groups for study and report back to the National Committee. Also, they have made a study of local conditions pertinent to the laws or desirability for laws on Licensing and Registration of Engineers.

Transportation and Tours

Because of its geographical associations, the Committee on Local Sections was selected as the logical committee to administer the handling of the transportation of the Society, including the arrangement and conduct of the special tours in connection with the Fiftieth Anniversary Meeting of the Society. Two such tours were planned, tentatively arranged for, and given wide publicity, but there was not sufficient response to warrant going ahead with them. Arrangements were completed and carried out for special trains between New York and Washington. The handling of these travel arrangements obviously has developed a quantity of reliable data and connections which is available at all times not only to the officers of the Society, but to the individual members, many of whom have availed themselves thereof.

Reduced fares to Annual, Semi-Annual, and other national meetings are arranged under the supervision of the Committee and result in the saving annually of thousands of dollars on the part of members attending these meetings.

Elimination of Waste

Fourteen Local Sections arranged meetings this year on the matter of "Elimination of Waste," and a number of them also encouraged the organization of individual plant programs to accomplish this purpose. A total of 439 companies were sent literature.

Foreign Relations

The Committee on Local Sections has been responsible during the last few years for the development of an activity which has been carried on for several years by the Secretary, and which has been called recently by the term, Foreign Relations. Because so many of the contacts of the Society are developed through Local Sections, and because so many of the services rendered to foreign engineers are accomplished through the medium of the Local Sections, it has seemed logical for this Committee to undertake to cooperate with the Secretary in this highly important function of the Society.

In order better to serve the large number of engineers from other countries who visit the United States, either individually or in groups, a number of the larger industrial concerns have been negotiated with as to their willingness to entertain foreign visitors, or even American engineers, who might be interested in being shown through the respective plants. A very encouraging response has been received and relatively few concerns have been unwilling to cooperate. As a result, a system has been developed which simplifies the procedure in making the necessary arrangements, and also in giving adequate travel directions to those making the visits. In the matter of tours of any extent, it has been found that the Local Sections have been most willing to receive the visitors and frequently arrange to entertain them.

Another phase of Foreign Relations work which has been carried on over a period of several summers and was continued during the past year, has been making arrangements whereby recent graduates of engineering colleges who come to this country from England, and occasionally from other countries, are given the opportunity to visit

TABLE 1 MEMBERSHIP IN LOCAL SECTIONS, OCTOBER 1, 1930

[1] Loss in membership.
[2] New Section, Dec. 2, 1929.

Total membership in Society, Oct. 1, 1929, 19,421; Oct. 1, 1930, 20,016; 2.9 per cent gain. 90.1 per cent of membership in Local Sections. Total number of Student Branches, 105.

plants in the vicinity of New York during the few days when the vessels upon which they were sailing are in port.

Again, in a number of instances there are engineers of foreign countries, particularly of Germany, who come here regularly for a two-year period, during which they become familiar with American industrial conditions either through special courses in American technical colleges or through practical application in the various industries. Approximately one hundred German students visit the United States annually, and our Society has been instrumental in arranging their placements. A system has been devised whereby the Society keeps a record of the credentials of all persons introduced so that responsibility has been avoided for interlopers of any sort.

As a result, the Society's good-will in foreign countries has been broadened so that when American engineers desire to visit these countries, the Society is able to have opened to them certain plants and opportunities which were closed but a few years ago. Incidentally, there are increasing calls from foreign concerns for the services of American engineers, and this has helped to develop another interest of the Committee on Local Sections, namely, the Employment Service.

Employment

It has been deemed advisable to place under the supervision of the Committee on Local Sections the general direction of the Employment Service because of its geographical development. Offices have been established in Chicago and San Francisco to supplement the services rendered for some years past from New York. Other sections of the country are inquiring as to the wisdom of having additional offices opened in their territories. Inasmuch as the type of organization developed by the National Board of the Employment Service has provided that in each of the cities where offices are conducted, the local Advisory Committee be made up of one member representing each of the four Societies, and as the Local Sections in Chicago and San Francisco have selected the A.S.M.E. representatives, the activity has, to a certain extent, been under the direction of Local Sections.

The Employment Service is one which should promptly be made one of the outstanding features of the Society's activities. To a degree this has already been recognized by the Council in its having provided a committee to study the economic status of the engineer. The work of that Committee will be affected to a considerable extent by the employment or non-employment of the engineering professions as represented by the members of our own Society. The Employment Service, in order to take advantage of that phase of the developments of the Committee on the Economic Status of the Engineer, has made it possible for one of its staff to give part time to serve the Committee on the Economic Status in carrying on its investigation.

The employment activity has but recently come into the category of the responsibilities of the Local Sections Committee and it will be the aim of the Committee to develop the Service and extend its usefulness.

Mid-Western Field Office

The increasing and constantly widening scope of Society activities in the mid-western area have added to the expense and difficulty from year to year to contact properly with Sections and Student Branches of the Middle West, and therefore, upon the recommendation of the Committee on Local Sections, the Council authorized last year the development of mid-western headquarters at Chicago and the appointment of a mid-western field secretary. Several Sections in recent years have recommended that more attention be paid by the headquarters staff to their individual needs. In the sixteen mid-western states, twenty-six Local Sections and thirty Student Branches are active, and since the mid-western office was established at Chicago in October, 1929, another Section has been formed, designated the "St. Joseph Valley Section," with headquarters at South Bend, Ind.

Inasmuch as the Society already had a lease on an office in the Engineering Building in Chicago, only partially used by the Advertising Department, the Committee decided upon joint occupancy of the office with a stenographic assistant at that point in lieu of an assistant in the New York office. Therefore it was possible to add to the efficiency of the Chicago Advertising Office as well as to provide better and more prompt service to the Mid-Western Sections and Student Branches. In order to conduct this work without impairing the efficiency of the existing organization in the East, Mr. R. R. Leonard was promoted from the Publications Department to serve as Mid-West Field Secretary.

A large part of the efforts during the first year in the building up of this mid-western office has had to do with educational methods as far as the officers of the Local Sections and Student Branches were concerned so that they would learn to communicate with Chicago instead of New York, and they have been highly pleased with the results. The new system is effecting economies, helping in emergencies, and providing the kind of service which warrants increased devotion on the part of the many members of the Society who give unselfishly of their services to the many Committees administering the work of the Local Sections and Student Branches of this great mid-western industrial area.

Statement of Petroleum Activities in the Mid-Continent Section

On November 2, 1929, a telegram was sent to the Society headquarters by the Secretary of the Mid-Continent Section, requesting an immediate visit by an officer of the Society to discuss necessary procedure to obtain adequate activity by the Society on matters pertinent to the promotion of petroleum progress from the mechanical engineer's viewpoint. In response thereto, a conference was held on November 5 at Tulsa, and as a result thereof it was arranged to have representatives of the Mid-Continent Section and Petroleum Division present their proposed projects to Council and the interested Standing Committees of the Society during the course of the 1929 Annual Meeting. As a result it was decided to have Assistant Secretary Ernest Hartford visit Tulsa in January, 1930, for the purpose of assisting in the further development of the proposition and to arrange a program of activities to transpire in March, 1930, when members of Council and the Committee on Local Sections would meet at Tulsa for further consideration of the matter. During the month of January a number of technical committees were organized in the Mid-Continent area to work on various mechanical engineering problems concerned with the petroleum industry. More than one hundred and twenty men were appointed on these various committees, which undertook activities concerned with production of petroleum and its transportation, and also the very important matter of unfired-pressure vessels, of which such a large number are used in the petroleum industry. The Committee on Production decided that the most important problem needing development was prime movers for rotary drilling. Subcommittees were organized to handle the four phases of this problem—electricity, gas engines, oil engines, and steam. A Committee on Gas Transportation to study the various projects of mechanical engineering character which require development decided the first activity to engage its attention would be a study of compressors. The phase of transportation having to do with crude oil concerned itself with the development of an automatic pipe line pumping station which was designed by the Committee and constructed on the grounds of the International Petroleum Exposition. A second committee concerned itself with a study of the fixed and operating charges for motor-driven oil-pipe-line pumping stations. A Committee on Unfired Pressure Vessels undertook the study of the Unfired Pressure Vessel Section of the A.S.M.E. Boiler Construction Code, and is cooperating with the special committee of the Society engaged in the study of that problem so that it will provide adequately for the construction of vessels of this type which are used so extensively in petroleum practice.

March 9 to 12 brought to Tulsa seven members of Council and Secretary Rice, and five members of the Committee on Local Sections. This group was taken one day to visit several plants showing current practice in pumping stations both for natural gas and oil. Another day was devoted to a visit to the Oklahoma City field where the officers of the Society were accorded every facility to become familiar with intricacies of oil-field practice. They had opportunity to witness deep-well drilling with different types of prime movers by the rotary process. They saw large quantities of steam exhausting into the air, wasteful methods of using water, and inefficient use of gas and oil in the production of heat. They saw various phases of refining and in this way got some conception of the mechanical engineering problems of the petroleum industry with its investments of upward of twelve billions of dollars and engaging over one million and a quarter of people. They met with a number of leaders of the industry—both executives and technicians. These included such outstanding characters in the industry as Wm. G. Skelly, President of The Skelly Oil Company, and President of the International Petroleum Exposition; R. S. Knappen, Vice-President of the Gypsy Oil Company; Dr. John D. Finlayson, Chancellor of the University of Tulsa; Wm. B. Holden, Executive Vice-President of Tulsa Chamber of Commerce; Thomas R. Weymouth, Chairman of the Board of the Oklahoma National Gas Company; Wm. G. Heltzel, Chairman of the Petroleum Division of the A.S.M.E.; Mr. Pat. Murphy, Commissioner of Labor of the State of Oklahoma; David L. Trax, Consulting Engineer of Gypsy Oil Company; and Raymond Carr, Petroleum Engineer of the Sinclair Oil & Gas Co.; as well as the engineers of a number of manufactories of oil-country equipment of producing oil companies, and of public utilities serving the industry.

The result of the large amount of information derived by the officers

of the Society at this conference was the formulation of a program which was adopted at the Detroit meeting of Council, and which provided a special appropriation of $1500 to care for the necessary staff and traveling expenses between the 15th of June and 1st of October. The action taken by Council for the organization to handle the petroleum problem was as follows:

(*A*) That the responsibility for the professional activities of the A.S.M.E. in the petroleum field should be concentrated.

(*B*) That this responsibility should rest with the Petroleum Division.

(*C*) That the Petroleum Division, with the Mid-Continent Section through its representatives as provided below, shall recommend to the President an Advisory Committee, to be appointed by Council, or its Executive Committee, which shall have direct access to Council, for recommendations. This Advisory Committee may contain representatives of other Standing Committees of the Society, technical and industrial leaders of the petroleum industry, and other organizations and industries interested. This Advisory Committee shall be appointed annually so long as the need exists.

The Advisory Committee should:

(1) Advise the Petroleum Division Executive Committee in the formulation and execution of its program of activities

(2) Aid in securing cooperation of other bodies, and

(3) Help in coordinating the program with those of other agencies of the Society and outside.

(*D*) That the Chairman of the Mid-Continent Section shall be an ex-officio member of the Petroleum Division Executive Committee with vote. A working majority of the Petroleum Division Executive Committee shall for the present be from the Mid-Continent Section.

(*E*) That in endorsing this report, the above action does not supplant the existing organization of the Mid-Continent Local Section. The Chairman of the Mid-Continent Section continues to be the executive in charge of its activities in that territory.

(*F*) *Personnel of Petroleum Division*

It was agreed that the Petroleum Division Executive Committee be asked to canvass its personnel and make suitable recommendations to cover "*D*" above.

(*G*) *Staff and Financing*

(1) Staff support as to persons and times shall be in the hands of Calvin W. Rice, Secretary

(2) In view of the emergency which exists, expenses and clerical help needed in Tulsa and by the Petroleum Division up to October 1, 1930, be carried by a special contingency appropriation not to exceed $1500.00, as authorized at this time

(3) The recognized Petroleum Division is to outline a program and submit a budget for its activity October 1, 1930–1931, for consideration by Council at its October meeting.

As a result of this action, Assistant Secretary Hartford returned to the Mid-Continent Area and after developing certain committee work, negotiated with Professor Wm. H. Carson, Head of the Department of Engineering at the University of Oklahoma, to devote his full time during summer vacation season to maintain committee activities and particularly to direct a field test on a steam rotary-drill rig. This being the first time any such test had ever been undertaken, it was necessary to assemble certain types of recording apparatus heretofore unused in the oil fields. Certain portions of the apparatus had to be designed and constructed for the proposition. After overcoming many obstacles, the necessary apparatus was assembled to the equipment of a contractor on an Indian Territory illuminating oil company's well which started drilling in the Oklahoma City field the last week of September. Specific data are being recorded on a twenty-four hour per day basis with regard to the fuel consumption, water consumption, steam generated and used, and efficiency of slush pumps and other mechanical apparatus so that upon completion of the drilling of the well there will be available for the first time a definite knowledge of these various phases of operation. It is the plan of the Committee that these data shall be studied sufficiently to make apparent any deficiencies which might exist. Incidentally, certain of the apparatus, such as the engines being used on the job, will be taken to the laboratory of the University of Oklahoma and subjected to a laboratory test, which in turn will give comparable data which can be utilized in connection with the figures obtained from the practical operating test. The Committee will then consider the wisdom of undertaking to design what might be termed a theoretical project, a steam drilling rig, and if the progress warrants so doing, will undertake to persuade a group of oil-producing companies to have such apparatus outlined, built, and used in drilling in the well, subject also to another test which will record actual operating conditions in the same way as is now being done with the standard steam drill rig. After the theoretical calculations thereof are justified, it is probable that the final result of the activities of this Committee will be to revolutionize the present rotary drilling methods.

At this point credit should be given for the very generous and complete cooperation of the Engineering School and particularly the Department of Mechanical Engineering of the University of Oklahoma.

While these several committees were carrying on the projects outlined in the foregoing paragraphs, another group was actively engaged in developing a program of technical papers for presentation at the First National Meeting of the Petroleum Division of the A.S.M.E., which was held in the auditorium on the grounds of the International Petroleum Exposition during the seventh renewal of that stupendous demonstration of apparatus used by the petroleum industry. Twenty-five papers of unusual value and interest were prepared and presented in the A.S.M.E. issue of a special publication designated as *Petroleum Mechanical Engineering*, which contained the preprints of these papers together with a large volume of advertising. The success of this publication was such that it has encouraged the expectation that it will be made a regular semi-annual publication of the Society.

The automatic pipe-line station proved to be an outstanding feature of the Petroleum Exposition, with its uncanny functioning, especially through its remote-control station and apparatus whereby it was operated theoretically at a distance of fifty miles over telephone wires. Such demonstrations were recorded as the shutting down of the plant due to a hot bearing, the reversal of the pumps due to a break in the line and the sucking back into the station's supply tanks of the oil in the pipes between the station and the point at which the break occurred; and the more than human functioning of the apparatus whereby when all valves were set diametrically opposite to their accustomed position and the current was turned on they automatically rectified themselves and proceeded to operate.

Program for Ensuing Year. In order to guard against any duplication of effort or overlapping of activities conducted by other organizations carrying on similar activities, it was deemed advisable to invite major executives of the various branches of the petroleum industry to serve on an Advisory Board of the Petroleum Division of the A.S.M.E. This Board, which has been officially appointed by the Council of the A.S.M.E., comprises the following personnel, and will be added to from time to time as conditions warrant and opportunities present themselves:

Oil Pipe Line Transportation

Burton E. Hull, Houston, President, Texas Pipe Line Company.
H. S. Austin, Tulsa, President, Ajax Pipe Line Company.
J. R. Manion, Tulsa, President, Sinclair Pipe Line Company.

Production

Kendall Winship, Tulsa, Vice-President, Gypsy Oil Company.
A. W. Peek, Chicago, Director, Standard Oil of Indiana.

Refineries

Walter Miller, Ponca City, Vice-President, Refineries, Continental Oil Company.

Gasoline

F. E. Rice, Bartlesville, Vice-President, Phillips Petroleum Company.
S. G. Sanderson, Tulsa, General Superintendent Gypsy Oil Company.

Gas Transportation

E. F. Schmidt, Dallas, General Superintendent, Lone Star Gas Company.
T. R. Weymouth, Tulsa, President, Oklahoma Natural Gas Company.

Schools and Colleges

J. H. Felgar, Norman, Dean, University of Oklahoma.
W. H. Gladson, Fayetteville, Dean, University of Arkansas.
P. S. Donnell, Stillwater, Dean, Oklahoma A. & M. College.
R. L. Langenheim, Tulsa, Dean, University of Tulsa.
N. A. C. Smith, Bartlesville, U. S. Bureau of Mines.

This group met in Tulsa on Friday, October 3, and elected J. R. Manion as the permanent chairman. At that meeting it also endorsed the following:

Projects for Petroleum Division, A.S.M.E., 1930–1931. Through the new Tulsa Secretary, it is planned to assemble all available me-

chanical engineering data pertaining to the oil and gas industry and to prepare a bibliography of this to eliminate duplication by our own or other organizations.

(A) Boiler Code and Fluid Meters Committees

(1) Cooperation with A.S.M.E. Main Boiler Code Committee to assist them in keeping in touch with oil-field conditions and requirements.

(2) Continuation of Subcommittee on Unfired Pressure Vessels for use in field practice in riveted construction, welded construction, and combinations of riveted and welded construction.

(3) A.S.M.E. formed a National Fluid Meters Committee in 1916 to develop the theory of fluid meters of all kinds and to report on the best methods of their application. Reports have been issued which do not include the theory or practice of equipment generally used in oil and gas work. Progress was made last year when this Committee met with the Southwestern Meter School at Norman, Oklahoma. It is recommended that the Petroleum Division negotiate with the Fluid Meters Committee to appoint a subcommittee to care for the problems of the oil and gas industry.

(B) Oil Pipe Line Transportation

(1) Continuation of Automatic Pumping Station as a "proving ground" for equipment and apparatus as developed by various manufacturers. Development of "Uniform Code for Economic Analysis of Different Types of Oil Pipe Line Pumping Stations."

(2) Experiments on temperature loss in pipe lines, carrying hot oil of high viscosity.

(3) Assembling data to be incorporated in hand-book containing all useful information for oil-pipe-line men.

(C) Production

(1) Prime Movers for Rotary Drilling—(*a*) Steam: Running of test in Oklahoma City field and correlating and compiling data resulting therefrom, with report; (*b*) Electricity: Preparation of report from available data; (*c*) Gas Engine: Preparation of report from available data; (*d*) Oil Engine: Preparation of report from available data.

(2) Study of various reports and comparison thereof, with possible recommendation of theoretically ideal set-up of apparatus to improve the efficiencies and economies of rotary drilling under given conditions. This possibly to be followed by the actual assembling of an ideal "steam" or other prime mover rig, and the drilling of a practical well with another test run under practically same conditions as to set-up of test apparatus as is being followed now, thereby getting a result which will definitely prove the practical value of the theoretically ideal rig.

(D) Refineries

(1) Proposed Research Program on Heat Transfer Apparatus—(*a*) Vapor to Liquid Exchanger Problem: To determine factors influencing heat exchange values in condensing hydrocarbon vapors (such as mixtures of hydrocarbon vapors and steam, mixtures of hydrocarbon vapors and non-condensible gases) in vapor to liquid heat exchangers including pressure drops; (*b*) Liquid to Liquid Exchanger Problem: To determine factors influencing heat exchange values of the liquid flowing outside the tube bundle, including effect of non-condensible gases on liquid to liquid exchangers, including pressure drops.

(2) Fractionation and bubble-tower efficiencies.

(3) The termination of convection coefficients in furnaces.

(4) The effect of non-condensible gas on heat-transfer coefficients with pure hydrocarbon vapors or approximating a composition of naphtha and refined oils.

(5) An accurate pressure-drop formula for hydrocarbon mixtures flowing through tubes as in furnaces and determining accurately proper correction where a variable amount of vaporization takes place.

(6) Improving efficiencies of high-pressure hot-oil pumps.

(E) Gas Transportation

(1) Economic design of pipe line company stations—(*a*) Proper method of measuring volume of gas discharges by compressors; (*b*) Proper ratings and capacities of compressors.

(2) Economic design of drips from main lines.

(3) Complete investigation of gate valves with the plan of making suitable code.

Projects for Future Consideration. (1) Correct design of mud slush pumps. (In many cases drillers run at such high rates of speed that they do not get the full efficiency of the pump.)

(2) Transmission: The method of pumping wells is practically the same today as it was ten years ago, i.e., by the use of the walking beam and belt connections to the bull wheel. The A.S.M.E. could organize groups of engineers in an effort to develop improved methods for pumping deep wells.

(3) Specifications of gate valves (with a safety factor sufficient but not too high to be accepted by the petroleum industry).

(4) Development of hypothetical rotary hook-up for Diesel and other internal-combustion engines to prove the feasibility of these in future drilling activities due to the low cost of power developed. (Several Diesel engine manufacturers' representatives of Tulsa have stated their willingness to cooperate with the A.S.M.E. in developing suitable hook-ups for Diesel engines and rotary equipment.)

Personnel Identified With Petroleum Activities. Subsequently, at its meeting at French Lick, the A.S.M.E. Council approved of the foregoing recommendations and also voted an appropriation of funds necessary to employ a regular secretary to care for the petroleum activities of the Society in the Mid-Continent territory. With the consent of the Dean of Engineering of the University of Tulsa, Professor Edward Anderson, a full member of the A.S.M.E. for several years and now Associate Professor of Petroleum Engineering at the University of Tulsa, has consented to serve in this secretarial capacity and arrangements have been completed whereby he will have his office in the Tulsa Building, where he will have the assistance and cooperation of the Tulsa Chamber of Commerce. Present plans predict the actual opening of this office on November 15, after which date meetings of the various committees will be held regularly in this office and interested executives and engineers of the industry will be encouraged to call for any assistance that it may be possible for the A.S.M.E. to render.

TABLE 2 LOCAL SECTIONS VISITED BY MEMBERS OF THE COMMITTEE ON LOCAL SECTIONS, 1929–1930

Section	T. L. Wilkinson, Chairman	H. R. Westcott	C. W. Bennett	J. M. Todd	J. W. Haney	E. Hartford, Secretary

Washington, D. C.	Apr. 1930	Apr. 1930	.....	.....	.....	Apr. 1930

The Executive Committee of the Petroleum Division in general charge of all activities of the Division is comprised of the following:

W. G. Heltzel, *Chairman*
H. J. Masson, *Secretary*
W. H. Carson, *Western Secretary*
H. R. Pierce
J. W. Hays
Walter Samans
E. H. Barlow.

The Executive Committee of the Mid-Continent Section of the A.S.M.E. which is closely identified with this whole program has the following personnel:

A. J. Kerr, *Chairman*
H. W. Manley, *Secretary-Treasurer*
B. P. Sibole, *Vice-Chairman*
M. H. Kotzebue
F. S. Kelly
R. W. Curran.

Student Branches and Local Sections

Members of Student Branches have been encouraged during the past year to attend Local Section Meetings and the following Sections arranged meetings which would be of special interest to bring about cooperation.

Student Branch	Section	Date of Meeting
California Institute of Technology	Los Angeles	Feb. 19
Clemson College	Greenville	May 13
Drexel Institute	Philadelphia	Feb. 25
University of Florida	Florida	Nov. 18
State University of Iowa	Tri-Cities	Nov. 13
University of Kansas	Kansas City	Nov. 20
Northeastern University	Boston	Mar. 21
Lowell Textile Institute	Boston	Mar. 21
University of Minnesota	St. Paul	Nov. 26
University of Minnesota	St. Paul	Dec. 4
University of Nebraska	Nebraska	Apr. 8
North Carolina State College	Raleigh	Feb. 25
University of North Carolina	Raleigh	Feb. 25
Oregon State Agricultural College	Oregon	May 10
Rice Institute	Houston	Mar. 22
Syracuse University	Syracuse	Mar. 20
Villanova College	Philadelphia	Oct. 7
Washington State College	Inland Empire	Nov. 2
Washington State College	Inland Empire	Jan. 24
University of Washington	Western Washington	Nov. 22
University of Washington	Western Washington	Jan. 17
University of Washington	Western Washington	Apr. 18

The Committee on Local Sections visited a number of the Sections throughout the year en route to meetings of the Society, as will be noted from the accompanying report (Table 2).

Respectfully submitted,

Thomas L. Wilkinson, *Chairman*
Harry R. Westcott
Charles W. Bennett
James M. Todd
Jiles W. Haney.

AWARDS

The Committee on Awards held a number of meetings during the year to make plans for the awards of the Fiftieth Anniversary celebration of the Society, April 5 to 9, 1930, and in connection with other awards of the Society.

The Committee assumed the responsibility of selecting the artist for the Fiftieth Anniversary Medal and of securing acceptances by ambassadors and ministers to invitations to take part in the Fiftieth Anniversary celebration.

Through the splendid cooperation of the American Engineering Council, L. W. Wallace, Executive Secretary, the Committee was able to secure acceptances and participation in the ceremonies of ambassadors and ministers representing the various countries participating who presented the engineers selected by the engineering fraternities of their particular countries for the reception of the Fiftieth Anniversary Medal.

The Committee considered a number of artists for the preparation of the Fiftieth Anniversary Medal and finally selected Julio Kilenyi of New York, N. Y.

At the request of the Gantt Medal Board and the Daniel Guggenheim Medal Board your Committee on Awards presented their medalists during the same session at which the Committee presented the recipients of the A.S.M.E. Fiftieth Anniversary Medal.

Upon the recommendation of the Committee on Awards the Council reports the following awards for 1930:

The Melville Award to H. Diederichs and W. D. Pomeroy for their paper on "The Occurrence and Elimination of Surge or Oscillating Pressures in Discharge Lines From Reciprocating Pumps."

Junior Award to Ed Sinclair Smith, Jr., of Providence, Rhode Island, for his paper on "Quantity-Rate Fluid Meters."

Student Award to Gerard Eden Claussen, of the Polytechnic Institute of Brooklyn, for his paper on "High-Temperature Oxidation of Steel," and to Harold L. Adams and Richard L. Stith, of the University of Washington, for their paper on "A Wind Tunnel for Undergraduate Laboratory Experiments."

The Charles T. Main Award to Jules Podnossoff of the Polytechnic Institute of Brooklyn for his paper on "The Value of the Safety Movement in the Industries."

During the year the Committee has recommended six loans from the Toltz Fund, amounting to $1175 leaving a balance in the Toltz Fund of $1051.82.

In Memoriam—Dr. Ira N. Hollis

"The Committee on Awards of The American Society of Mechanical Engineers records with deepest sorrow the death of its Past-Chairman, Dr. Ira Nelson Hollis. Since its inception Dr. Hollis was a member of this Committee on Awards and as chairman for much of this time he brought many valuable suggestions to the committee for action. In directing the work of the Committee in the selection of papers for awards he was helpful and effective in obtaining prompt and fair decisions. His study of the interpretation of the meaning of engineering history gave him the ability to suggest most valuable subjects of the papers submitted for the Charles T. Main Award.

"His criticism of papers submitted to the Committee for Awards was most keen and by his guidance the Committee has usually been unanimous in its decisions.

"The present method of committee procedure has been developed during his chairmanship.

"The Committee extends to the daughters and son of Dr. Hollis its sincerest sympathy during this sad period of bereavement."

Respectfully submitted,

Arthur M. Greene, Jr., *Chairman*
H. L. Seward
Roy V. Wright
K. H. Condit.

CONSTITUTION AND BY-LAWS

During the past year the Committee on Constitution and By-Laws, upon suggestion of Council, has recommended change in the wording of Article B8, Paragraph 5 of the By-Laws, to place the meetings of the Executive Committee at the call of the President and to limit the selection of members of the Executive Committee to definite officers, placing the membership at nine, five only of whom may vote.

Another important change is the proposed revision of Article C5 of the Constitution, "Fees and Dues," as recommended in the report of the Special Council Committee on Society Revenue. The report on the amendment ballot is given in the report of the Council.

This Committee has also in hand a thorough study of the By-Laws and the Rules with the object in view of eliminating repetitions and inconsistencies, and bringing into better classification the statements of the various duties of officers and committees. This is a matter of considerable weight and each Standing Committee of Council is working on it with the idea of suggestions for the final complete survey which will be made by the Committee on Constitution and By-Laws before it reports to the Council within the next year.

Respectfully submitted,

George E. Pfisterer, *Chairman*
A. D. Blake
Thomas C. McBride
R. S. Neal
H. H. Snelling.

RELATIONS WITH COLLEGES

Nine new Student Branches have been established during the year, making a total of 105 Branches—almost ten per cent more than last year. The new Branches are located at Clarkson College of Technology at Potsdam, New York; University of Detroit, Detroit,

Michigan; Michigan College of Mining and Technology, Houghton, Michigan; Missouri School of Mines and Metallurgy, Rolla, Missouri; University of North Carolina, Chapel Hill, North Carolina; North Dakota State Agricultural College, Fargo, North Dakota; University of Notre Dame, Notre Dame, Indiana; Rhode Island State College, Kingston, Rhode Island; and Texas Technological College, Lubbock, Texas.

There were 637 meetings reported, an increase of 39 meetings over last year. Greater cooperation between the Local Sections and the Student Branches is shown by the fact that there were twenty-one meetings in which both the Student Branch and the Local Section in the vicinity cooperated, while last year there were only nine. Prizes for best papers were awarded to students by the Atlanta, Louisville, New Orleans, Philadelphia, San Francisco, and Tri-Cities Sections. Both the Indianapolis and the Tri-Cities Sections have sponsored debates between two or more Student Branches.

Student Branch Conferences have been held at the Annual Meeting, the Spring Meeting, and the French Lick Regional Meeting of the Society. President Piez spoke at the most successful luncheon the Student Branches have ever held during the Annual Meeting, and the afternoon program proved very interesting and constructive.

The Committee has issued the Student Branch Bulletin monthly during the school year. This Bulletin spreads the news of the Branches and contains special articles for Student Branch officers.

Visits were made during the year by Mr. Abbott, Professor Church, Mr. Libby, Dean Prentice, Mr. Rice, Mr. Hartford, and Mr. Meyer to the following institutions: University of Arkansas, University of California, Cornell University, North Carolina State College, Ohio State University, Oklahoma A. & M. College, University of Oklahoma, Purdue University, Rensselaer Polytechnic Institute, Washington University, and Yale University.

The Committee is pleased to report that, for the first time in a number of years, every Student Branch has been active and has given us complete cooperation. Cooperation with the National Safety Council has continued and many of the Student Branches have held meetings with their liaison safety representatives as speakers.

Membership in the Student Branches has increased by almost five hundred members in the past year. The Committee calls attention to the fact that the Student Branches are the least expensive as well as one of the greatest feeders to membership in the Society, and urges that the Committee not be forced by lack of appropriation to curtail its activities to purely routine office matters.

Respectfully submitted,

S. H. Libby, *Chairman*
M. C. Maxwell
D. B. Prentice
E. F. Church, Jr.
W. L. Abbott.

EDUCATION AND TRAINING FOR THE INDUSTRIES

The Committee met frequently during the Annual Meeting in December, 1929, to discuss its program for 1930. Another meeting was held in Washington at the Fiftieth Anniversary. Careful consideration was given to a possible survey of one or more industrial districts in which Sections of The American Society of Mechanical Engineers were active. After considerable discussion it was decided that we were not prepared to undertake a larger program at that time.

The Committee prepared a program for the Detroit meeting of the Society which consisted of:

(1) "Training Aeronautical and Automotive Service Mechanics," by A. D. Althouse, Head of Auto and Aero Department, Cass Technical High School.

(2) "Training and Recruitment of Auto Mechanics Through Factory Sources," by William F. Rasche, Principal, Milwaukee Vocational School.

Mr. W. S. Conant, member of the Committee, presided at this meeting.

The Committee also sponsored a meeting in Milwaukee which was organized by Mr. Falk, of the Committee. The subject was "Apprentice Training" and the program was as follows:

(1) "Why Trade Apprenticeship Concerns the Engineer," by Charles Schoen, Works Manager, Kearney and Trecker Corporation.

(2) "Some Aspects of the Local Movement for Apprentice Training," by Harold S. Falk, Vice-President and Works Manager, The Falk Corporation.

(3) Discussion.

(4) Display of work done by apprentices in Milwaukee plants, particularly drawings made by drafting apprentices which would be of greatest interest to the engineer.

A meeting was also held at Richmond, Virginia, on "Apprentice Training" for which Mr. Bailey, Advisory Member of the Committee, was responsible.

Information has been supplied to inquirers interested in setting up training courses.

A program for one session at the Annual Meeting in December has been prepared as follows:

(1) "Apprentice Training in Virginia," by C. F. Bailey, Newport News Shipbuilding and Dry Dock Company.

(2) "The Apprentice Training Movement in Wisconsin Industry," by Harold S. Falk, Vice-President and Works Manager, The Falk Corporation.

(3) Discussion.

(4) "Opportunities for Aviation Training in the Aeronautical Industry," by J. S. Marriott, Chief Inspection Service, Aeronautics Branch, U. S. Department of Commerce.

Mr. Charles H. Colvin, President, The Pioneer Instrument Company, will preside at this meeting.

The main effort of the Committee has been to promote and sustain interest in organized training to improve industrial efficiency. The need for such education has increased since we must largely depend on our national skill rather than on imported artisans.

Respectfully submitted,

R. L. Sackett, *Chairman*
W. S. Conant
J. T. Faig
H. S. Falk
D. C. Jackson
C. F. Bailey } *Advisory*
S. S. Edmands } *Members*

LIBRARY

The Library Committee represents the A.S.M.E. on the Joint Board of the Engineering Societies Library. The report of the Director for 1929 as approved for publication by the Library Board discloses increasing activity and service to the members of the Society.

A notable gift by James H. McGraw makes possible the indexing of past periodical publications, a gap not taken care of by the current indexing done by our Society, and this work will be valuable in research work and will benefit every member who consults the Library. Gifts of money by Mr. William S. Barstow and the late Dr. Ira N. Hollis should be noted, the latter enabling the listing of material in the Library on the history of engineering.

About 38,800 members of the Founder Societies were served during the year, an increase of 5 per cent over 1928. The rental collection continues to serve a specific need of our members.

As indicating the wide interest in the Library, material of value was received from more than 1000 donors during the year. A total of 1329 current periodicals, 50 more than available during the previous year, are on our shelves. Nearly 8000 items of value were added to the main collection during the year and the duplicate collection available for lending has been materially increased. The main collection now numbers more than 135,000 items, and the catalog contains nearly 400,000 cards under 122,238 classifications.

The Library continues to be operated within the budget approved by the Library Board.

Respectfully submitted,

Henry A. Lardner, *Chairman*
Alten S. Miller
George F. Bateman
Ely C. Hutchinson
Calvin W. Rice, *Secretary.*

RESEARCH

Twenty-seven committees were actively at work at the close of the year on a corresponding number of cooperative research projects in most of the important specialized fields of mechanical engineering. Two projects were terminated during the year, Fuels and Spark Arresters, while two new ones were added, Automatic Pumping Stations and Sound Measurement, by action of the Council on the recommendation of the A.S.M.E. Research Committee which administers the Society's research activities. The personnel of the special research committees, which includes both engineering executives and technologists, now totals 409 men, 43 per cent of whom are non-members of the Society.

Financing

Each year's summing-up reveals an increase in industrial support for the experimental programs of the committees. During the past year expenditures from cash contributions made by industry have totaled approximately $50,000, or more than three times the Society's research budget for the same period. In other words, the Society is giving and receiving a technical service, through the published committee reports, worth at least four times its investment. This does not take into account, of course, the expenditure of time and the cost of travel of committee members in this voluntary committee work, an item which probably exceeds to a considerable extent the industrial contributions. It should be recorded also that Engineering Foundation has responded generously to requests for aid to these committees during the first years of their work.

Accomplishments

One of the most tangible results of research committee work is published reports, treatises, and related papers. These have filled sixty-three (63) pages of *Mechanical Engineering*, 237 pages of Transactions, and an unknown number of pages in other technical publications. This material will be available in book form at the time of the 1930 Annual Meeting. Notices of current committee progress and future plans of general news interest have appeared from time to time in the *A.S.M.E. News*.

Two additions have been made this year to the A.S.M.E. Research Publication Series: (1) The third edition of Fluid Meters, Their Theory and Application, Part 1, by the A.S.M.E. Special Research Committee on Fluid Meters, and (2) a bibliography of 800 annotated and indexed references on the Cutting of Metals, by O. W. Boston. The first instalment of an extensive bibliography on Riveted Joints by R. A. deJonge has also been issued in printer's proof form to those concerns which contributed toward the expense involved. It will be generally available in published form when completed. Material has been collected by S. Timoshenko and W. M. Coates for a bibliography and monograph on the Stress Analysis of Pressure Vessels, which may be expected in published form during the coming year.

Committee Progress

A brief review of progress by the various Special and Joint Research Committees follows:

Lubrication. A. E. Flowers, Chairman. Dr. Flowers succeeded M. D. Hersey as Chairman in December, 1929. At that time also Prof. Earle Buckingham was elected Secretary.

The Committee has been successful in raising funds sufficient for the first year of its enlarged experimental program at the Bureau of Standards and work was begun in January, 1930. This work is being directed by Mr. Hersey and includes studies of (1) viscosity at high pressure, (2) factors affecting journal-bearing design, and (3) the phenomena of oiliness. A progress report will be made at the Society's 1930 Annual Meeting. Albert Kingsbury will also present at that time an experimental method for determining pressure distribution in oil films in various types of bearings, with results. This paper is based on a study he has carried on for some time in cooperation with the Committee.

The translations of a number of important foreign papers on lubrication have been completed and it is planned to publish them in a volume together with the most valuable papers that have been presented before the Society on the subject in the past.

Fluid Meters. R. J. S. Pigott, Chairman. During the Society's Annual Meeting, December, 1929, this Committee held a Symposium on Fluid Flow, at which were presented progress reports of the subcommittees and papers by several of their members.

At the invitation of the University of Oklahoma, this Committee held a meeting in Norman, Oklahoma, at the time of the seventh annual Southwestern Gas Measurement Course held by the College of Engineering in April, 1930. The members who were able to attend made a few helpful suggestions on the problems of gas metering and bespoke the cooperation of those present in assisting the Committee to make the fluid-meter reports of maximum benefit to the natural-gas industry.

The Committee was represented during a preliminary discussion of the possibilities of standardization in fluid-flow measurement at the meeting of the International Standards Association in Paris this summer.

The third revision of Part 1 of Fluid Meters, Their Theory and Application, has been completed and published by the Society. Part 2, dealing with the Description of Meters, has been submitted to the A.S.M.E. Research Committee in manuscript form for publication. The manuscript of Part 3, Influence of Installation, will be submitted soon to the members of the Special Research Committee on Fluid Meters for review prior to a meeting in December.

Thermal Properties of Steam. Alex Dow, Chairman. Industry has contributed some $24,000 during the past year to the continuation of the Committee's research program at the Bureau of Standards and Massachusetts Institute of Technology.

Six technical representatives of the Committee attended the Second International Steam Table Conference in Berlin this summer with the German, British, and Czechoslovakian experimenters. Excellent progress was made in the revision of the points and the tolerances of the skeleton table formulated at the First International Conference last year in London. At the close of the three-day conference considerably more experimental data had been included within the scope of the Table. The next conference will be held in the United States in 1932.

The Committee held the usual open conference for the public discussion of its technical progress at the December, 1929, Annual Meeting. Three comprehensive papers written by N. S. Osborne, E. F. Fiock, and N. S. Osborne, H. F. Stimson, and E. F. Fiock, which review the past nine years' work for the Committee at the Bureau of Standards, have been published by the Society and the Bureau. The Society has also published a book containing tentative steam tables and the Mollier diagram formulated by Prof. J. H. Keenan, a member of the Committee, which embodies the most up-to-date data available.

Strength of Gear Teeth. Earle Buckingham, Acting Chairman. In December, 1929, the Committee and the engineering profession in general suffered a great loss through the death of Wilfred Lewis, organizer and chairman of the Committee since its inception.

During the year Professor Buckingham has given a large amount of time to the preparation of an exhaustive report on the results of the Committee's experimental program which he has directed at Massachusetts Institute of Technology during the past four and a half years.

Cutting of Metals. W. W. Nichols, Chairman. The activity in this Committee has centered largely in the Subcommittee on Tungsten Carbide Cutting Materials, F. C. Spencer, Chairman. At the Society's Detroit meeting in June he reported the experiences of some fifty users of these cutting tools, the purpose being to reveal their possibilities and limitations. The committee will conduct a symposium at the December, 1930, Annual Meeting to bring out the relative merits of high-speed tool steel, stellite, and tungsten-carbide cutting tools.

In July the Subcommittee on Cutting Fluids inaugurated an experimental program at the University of Michigan under Prof. O. W. Boston for the purpose of establishing relations between the physical and chemical characteristics of cutting fluids and their performance. This work is being financed by contributions from industry and Engineering Foundation.

In September the Bibliography on Cutting of Metals came off the press. This had been prepared by Professor Boston and presented to the Committee and the Society for publication. It contains some 800 annotated and indexed references.

Mechanical Springs. J. K. Wood, Chairman. The work of Dr. D. J. McAdam on fatigue of helical springs at the U. S. Naval Experiment Station, which had been partially financed for a year by the Committee, was terminated when Dr. McAdam left the station in July. He is now preparing a report on this study. The research of Prof. M. F. Sayre on the elasticity of spring materials at Union College has been continued throughout the year. This work will be reported on at the 1930 Annual Meeting of the Society, as will that of Prof. J. B. Reynolds, who has been cooperating with the Committee on studies of conical spring design at Lehigh University. The Westinghouse Electric and Manufacturing Company reported on its spring research work at the technical sessions sponsored by the Committee and held during the Society's 1929 Annual and 1930 Semi-Annual Meetings. During the year the Committee has continued its policy of distributing quarterly a bibliography of current springs literature to its members and financial contributors.

Messrs. J. R. Townsend, Bell Telephone Laboratories, and C. T. Edgerton, Crucible Steel Company, were elected in June to succeed Messrs. Wood and Rockefeller as Chairman and Secretary, respectively. They take office in December, 1930.

Effect of Temperature on Properties of Metals. H. J. French, Chairman. The experimental program has been continued by the various industrial laboratories cooperating with the Committee in an effort to develop data on which to base test codes for high-temperature tensile and creep tests. Fatigue tests of metals at high temperatures are being carried on at the University of Illinois under the direction of Dr. H. F. Moore and financed by the Committee.

An up-to-date supplement to the Bibliography on the Effect of Temperature on the Properties of Metals, published by the A.S.M.E. in 1928, has been turned over to the Society for publication. Papers

by individuals on the high-temperature properties of metals have been obtained and sponsored by the Committee at meetings of both the A.S.M.E. and the A.S.T.M. during the year. In order to bring out the present high-temperature needs for metals in industry and reveal the possibilities and limitations of present-day metals the Committee is arranging a comprehensive symposium to be held at the A.S.T.M. Annual Meeting in June, 1931.

Prompted by the rapidly growing industrial demand for information on this subject the Committee is now undertaking to raise $20,000 for a three-year research program at some suitable laboratory.

Condenser Tubes. A. E. White, Chairman. During the year the Brooklyn Edison Company has made a preliminary study for the Committee of the effect of air and turbulence on condenser-tube deterioration. The results of this investigation indicate that the present investigation should be widened to include representative operating conditions throughout the power industry. The N.E.L.A. Prime Movers Committee has endorsed the proposal and funds are now being raised to carry it out. The Committee's third progress report was published by the Society during the year.

Boiler Feedwater Studies. S. T. Powell, Chairman. Joint Committee of the A.B.M.A., A.R.E.A., A.W.W.A., N.E.L.A., A.S.T.M., and A.S.M.E. The Committee continued its policy of giving publicity at the Annual and Semi-Annual Meetings of the Society to the great need for a study of boiler-feedwater problems and to progress being made in their solution. Abstracts of the technical literature of the world pertaining to the subject have been regularly supplied the members of the Committee from Chemical Abstracts and the Engineering Index Service.

Boiler Furnace Refractories. W. A. Carter, Chairman. Upon the resignation this year of Dr. C. F. Hirshfeld, who organized and has been chairman of the Committee since its inception, he was succeeded by W. A. Carter as chairman.

At the University of Illinois a satisfactory laboratory method has been developed for testing the resistance of refractories to slag action and thus predicting their service value. Extensive experimental work is now being carried on at the Ceramic Station of the Bureau of Standards and at Battelle Memorial Institute to determine the reactions and equilibria that underlie refractory failures in boiler-furnace operation.

A symposium on slag testing of boiler-furnace refractories has been arranged by the Committee for the Society's 1930 Annual Meeting for the purpose of interesting various industrial concerns in testing their own particular products on the lines laid down by the Committee, thus checking its work and adding to the general data now available. Industry continues to respond generously in financial support to the Committee's program, some $33,000 having been contributed to date.

Elevator Safeties. M. H. Christopherson, Chairman. The Committee has vigorously prosecuted its program of research and code interpretation in connection with the revision of the present American Standard Code for Elevators.

The buffer tests that have been in progress for the past two years on the Committee's experimental elevator at the Bureau of Standards are now completed. Twelve different types of buffers were exhaustively tested under impact by the elevator at various loads and speeds. The data obtained are being used by the elevator industry to improve these devices. A similar examination of undercar safeties is now under way. Some $58,000 has been spent to date by the Committee on this program. Meetings have been held every two months throughout the year to review the results accomplished and to confer with the research associate concerning the experimental program.

Worm Gears. Earle Buckingham, Chairman. The analysis of certain phases of the problem published last year called attention to the values of certain design factors and to the inadequacy of the conventional method for producing worm gears. As a direct result, several concerns are developing new types of production facilities so as to be able to take full advantage of certain neglected design factors. Tests are being carried on also to give quantitative data on the value of these design factors as well as to reveal other information on the action of worm drives.

Welding of Unfired Pressure Vessels. E. H. Ewertz, Chairman. Joint Committee with the American Welding Society. During the year the A.S.M.E. Boiler Code Committee requested this Committee to advise whether a certain type of light-gage welded tank came within the requirements of the Code. Tests were accordingly made at Lehigh University on tanks supplied by the manufacturers. A report is now being prepared.

Spark Arresters. Since the publication and wide distribution last year of the report pointing out that existing types of spark-arresting equipment used on steam-generating apparatus in forest areas seem to be satisfactory if properly applied and maintained, the A.S.M.E. Research Committee has decided that there is nothing further it can do at the present time to foster this cause.

Saws and Knives. A. S. Kurkjian, Chairman. Mr. Kurkjian succeeded Carle M. Bigelow as Chairman in December, 1929. The Committee held a conference of tool and machinery manufacturers and users at the time of the April meeting of the Woodworking Machinery Manufacturers Association in St. Louis, in an effort to initiate a program of cooperative research and standardization. Negotiations are still continuing. The Engineering Foundation has made a grant of $1000 to such a program, contingent on substantial support by industry.

Existing Supplies of Hardwoods. No activity during the year. The Committee is awaiting results of tests being made at the University of Michigan on samples of woods which have been collected in tropical America. These tests are designed to reveal the applicability of tropical woods to the requirements of the American woodworking industries.

Strength of Vessels Under External Pressure. W. D. Halsey, Chairman. Considerable data have been collected both in the United States and abroad from manufacturers and users of this type of vessel concerning their design practice and performance records. This material is being studied with the purpose of evolving reliable design formulas which may be incorporated in the A.S.M.E. Boiler Code.

Absorption of Radiant Heat in Boiler Furnaces. W. J. Wohlenberg, Chairman. Little accomplishment has been reported by this Committee during the past year. It is undertaking, however, to correlate and analyze data submitted from time to time by the power industry on the transfer of heat in boiler furnaces, with the intention of developing practical design formulas.

Fuels. F. R. Wadleigh, Chairman. This Committee was discharged by the Council in May, 1930, because the time did not seem to be right for the functioning of a correlating committee such as this one was intended to be.

Velocity Measurement of Fluid Flow. W. F. Durand, Chairman. Prof. H. E. Hartig and Prof. H. B. Wilcox have continued their experimental work at the University of Minnesota leading to the development of a method of measuring fluid velocities by means of the location of nodal points in wave systems. Engineering Foundation is financing this investigation.

Physical Constants of Refrigerants. Joint sponsorship with the American Society of Refrigerating Engineers to encourage the continuation of research at the National Bureau of Standards on the determination of the physical constants of certain refrigerants. During the past year further efforts have been made to bring about the appropriation of funds by the Federal Government for this project. As a result of these efforts, the Department of Commerce has agreed finally to include such an item in its budget for the fiscal year 1932 and there is a very good expectation that it will be granted. In the interim an attempt is being made to collect $5000 from industry to provide the Bureau of Standards with added facilities until the Governmental funds are available two years hence.

Management Formulas. W. E. Freeland, Chairman. With the aid of this Committee Prof. F. E. Raymond, Massachusetts Institute of Technology, has been making a study of economic production quantities and uneconomical minimum cost production in manufacturing. The results have been reported during the year in two papers read before the Society by Professor Raymond. The Committee is at present engaged in obtaining financial support for a study of the selection and replacement of manufacturing equipment.

Diesel Fuel-Oil Specifications. L. H. Morrison, Chairman. Work has been confined this year to the initiation of field tests throughout the country on the committee's two model fuel-oil specifications for heavy and light Diesel engines suggested last year. The results of these tests indicate that the specifications are not, as yet, complete enough for practical purposes. Accordingly, an experimental investigation of combustion in a Diesel cylinder is being formulated, which it is hoped will furnish the information needed to develop more satisfactory specifications. Two progress reports were published during the year.

Wire Rope. The extensive investigation of the performance of wire rope under various conditions of use which has been conducted during the past two years by the A.S.M.E. Research Committee has resulted in the organization of a special research committee. The first activity of this Committee is in the direction of securing

authentic information and data on the life of wire rope in service. Companies and associations in the various fields of application are being asked to cooperate. Close contact has also been established with the wire-rope investigations being carried on in England and Germany.

Airplane Vibration With Special Reference to Instruments. A. Klemin, Chairman. The Committee has collected considerable information from manufacturers of airplanes, airline operators, and manufacturers of aircraft instruments on their difficulties with the vibration of these instruments. A report will be made at the December, 1930, Annual Meeting of the Society, giving a review of the situation, suggesting practical remedies, and outlining further research that is needed.

Heavy-Duty Anti-Friction Bearings. W. Trinks, Chairman. Contributions from industry of some $4500 early in the year made it possible for the Committee to put a research engineer at work full time on its program of determining the possibilities and limitations of this type of bearing in the operation of rolling mills. Carnegie Institute of Technology has provided office facilities for the research engineer. Considerable data also have been obtained both in the United States and abroad from mill and bearing manufacturers and users relative to the forces acting between rolls and the materials being rolled. A progress report entitled "Forces Acting on Roll-Neck Bearings" has been published by the Society.

Removal of Ash as Molten Slag From Powdered-Coal Furnaces. P. B. Rice, Chairman. Tests have been run throughout the year in the laboratory furnaces set up at the Bureau of Mines in Pittsburgh to study the possibilities of removing ash from powdered-coal furnaces in the form of molten slag. The Bureau is contributing the research facilities and personnel for the investigation, while the Committee is providing materials and special equipment. The work is not yet considered far enough advanced for the publication of a progress report.

Automatic Oil-Pipe-Line Pumping Stations. W. G. Heltzel, Chairman. The organization of this Committee in March, 1930, grew out of the activities of the Society's Mid-Continent Section. Its personnel consists of engineers selected from the pipe-line companies, the power and electrical industries, and the manufacturers of pipe-line equipment in and around Tulsa, Oklahoma. Meeting once a week over a period of more than four months the Committee developed a workable scheme of automatic control and erected an experimental pumping station. This station represents an investment of some $45,000 in donated equipment. A series of tests are now being carried on to determine what changes and refinements are necessary to make the station entirely satisfactory for practical use. The Committee presented a report on its work at the National meeting of the A.S.M.E. Petroleum Division in Tulsa in October of this year.

Methods and Apparatus for Noise Measurement. W. B. White, Chairman. Organized in March, 1930, to conduct an investigation of the instruments and methods for sound measurement now available with a view to the development and establishment of an objective scale for comparison and record. A study of preventable noises in machinery and an investigation of the transmission, absorption, and reflection of sound within buildings from an engineering standpoint are also among its objectives. The Committee is at present attempting the difficult job of formulating the specifications on which to base sound-measurement formulas. Its personnel includes most of the leading technical men in this country familiar with the subject.

Respectfully submitted,

ROBERT L. STREETER, *Chairman*
WILLIAM R. WEBSTER
WALTER H. FULWEILER
ALEX D. BAILEY
ANDREY A. POTTER.

STANDARDIZATION

The annual report of the A.S.M.E. Standardization Committee for the year October 1, 1929, to October 1, 1930, shows considerable progress in the organization of new committees and in the work of the committees previously organized.

ORGANIZATION

The Society in the past year accepted one new sponsorship, that on the Standardization of Pressure and Vacuum Gages, July, 1930, and in the same month proposed jointly with the American Foundrymen's Association the Standardization of Foundry Equipment to the American Standards Association. In addition to these, twenty-seven (27) sectional committees are now sponsored or jointly sponsored by the Society under the procedure of the American Standards Association. Two-hundred and twenty-one (221) subcommittees and subgroups have been formed by these sectional committees in order that the work assigned to them might be carried forward with greater facility. During the current year these subcommittees and subgroups were increased from 186 to 221. The total number of members of these committees is now 1008, of which 384 are members of the A.S.M.E.

At the suggestion of the American Standards Association the A.S.M.E. Standardization Committee at its December, 1929, meeting reviewed the organization and plans of the Sectional Committee on the Standardization of Elevators. It was informed that the proposed standardization could not be undertaken at the present time, owing to the necessity of extensive research. The Committee accordingly voted to approve the discharge of this Sectional Committee.

This year organization meetings of the following committees were held: Sectional Committee on the Standardization of Stock Sizes, Shapes and Lengths for Hot and Cold Finished Iron and Steel Bars, June 3, 1930; Three Technical Committees of the Sectional Committee on Small Tools and Machine Tool Elements—Splines and Splined Shafts, June 9, 1930, Electric Welding Dies and Electrode Holders, June 9, 1930, and Milling Machine Tables, June 19, 1930; and Subcommittee No. 4 on Plumbers' Threads of the Sectional Committee on Standardization of Pipe Threads, October 15, 1929.

During the spring and summer months the personnels of the following committees were developed: Sectional Committee on Pressure and Vacuum Gages; Subcommittee No. 7 on Copper Water-Tube Fittings, Subcommittee No. 8 on Cast Iron Soil Pipe and Fittings, and the Subgroup on Cast Iron Traps of the Sectional Committee on the Standardization of Plumbing Equipment; and Subcommittee No. 6 on Lag Screws and Subcommittee No. 7 on Survey of Present Practice of the Sectional Committee on Standardization and Unification of Screw Threads.

STANDARDS APPROVED

The standards of dimensions and letter symbols completed under the A.S.A. procedure and published in pamphlet form this past year number seven (7). These are the Standards for Slotted Head Proportions (Machine Screws, Cap Screws, and Wood Screws); Ball and Roller Bearings; Cut and Ground Thread Taps; Milling Cutters; Roller Chains, Sprockets, and Cutters; Symbols for Photometry and Illumination; and Navigational and Topographical Symbols. The following six (6) additional standards were completed and placed before the sponsor organizations for approval: 25 Lb. Cast Iron Pipe Flanges and Flanged Fittings; 800 Lb. Hydraulic Cast Iron Pipe Flanges and Flanged Fittings; Symbols for Heat and Thermodynamics; Graphical Symbols for Radio Communication; Woodruff Keys and Keyslots and Cutters; and Track Bolts.

PUBLICITY

During the year thirty-five (35) pages of text pertaining to the work of Standardization were published in *Mechanical Engineering*. Current items of interest were also published in the *A.S.M.E. News*. Publicity has been given also to the standards developed by the sectional committees both in *Mechanical Engineering* and in the technical press by the reproduction of preliminary proposals issued from time to time by the committees. Twenty-five hundred copies of tentative draft standards in printer's proof form were distributed to both the consumer and producer interests during the year.

MECHANICAL STANDARDS ADVISORY COUNCIL

After four years of planning and conferring the Mechanical Standards Advisory Council reported on March 13, 1930, that it was ready to take its place with those groups which have been organized to give advice to their respective industries and to the American Standards Association on questions relative to progress in the standardization of dimensions, codes, and specifications of special interest to the mechanical industries.

Responding to the call of the A.S.M.E. Standardization Committee, a preliminary conference was held in April, 1926, to which fifty organizations known to be interested in standardization were invited. This first conference recommended the organization of an advisory council to the mechanical industries and appointed a Special Committee on Policy, Plan, and Scope.

The report of this Committee was presented at a second conference held in June, 1928, at which a temporary Executive Committee was

elected. The Constitution of the Mechanical Standards Advisory Council was completed in October, 1928, by the temporary Executive Committee and in December, 1928, the Council was called together for permanent organization. A permanent Executive Committee was then appointed and it held its first meeting in New York in December, 1929. At the present time twenty-five organizations have accepted membership in the Council.

A call for a general meeting of the Council has been issued for December 4, 1930, at which a proposed program of activity will be discussed and acted upon.

The A.S.M.E. Standardization Committee has acted as host at these several conferences and has made every effort to bring about the satisfactory organization of this important body.

Sectional and Subcommittee Reports

Shafting. C. M. Chapman, Chairman. During the past year the Sectional Committee has held under advisement the several recommendations previously made for revision of the American Standards for Cold Finished Shafting (1924), Square and Flat Stock Keys (1925), Plane Taper Stock Keys (1927), and Gib Head Taper Stock Keys (1927). Two different recommendations, dealing with the proposed extension of the existing series of flat keys to include keys for shafts larger than six (6) inches in diameter, have been submitted to the members of the Sectional Committee. The first of these was not considered altogether satisfactory, so a second was developed with a view to eliminating the objectionable feature of the first. This proposal will be discussed and acted upon at the next meeting of the Sectional Committee.

Subcommittee on Woodruff Keys. L. C. Morrow, Chairman. After the revisions, prompted by the general distribution of the proposed American Standard for Woodruff Keys, Keyslots, and Cutters, were approved by the Sectional Committee in April, 1930, it was held pending the addition of introductory notes. These were developed during the summer months and approved by the Sectional Committee for inclusion in this proposal. The proposed standard was then submitted to the A.S.M.E. Council for approval. This is expected in October, at which time it will be transmitted to the A.S.A. for its approval and designation as an American Standard.

Plain Limit Gages. The Tentative American Standard for Tolerances, Allowances and Gages for Metal Fits developed by this Sectional Committee was approved by the American Standards Association in December, 1925. Since then approximately 4000 copies have been distributed. In order that this Standard might be reviewed and revised, it was decided to reorganize the Sectional Committee and on September 23, 1930, forty letters of invitation to appoint representatives were sent to interested organizations. The reorganization meeting will probably be held early in December.

Ball and Roller Bearings. F. W. Gurney, Chairman. This Sectional Committee has completed the American Standard on Single Row Sizes and the Recommended Practice on Wide Type of Ball and Roller Bearings. These standards were approved by the American Standards Association in April, 1930.

The standardization of Metric Thrust Bearings and Metric Roller Bearings will be begun upon the receipt of recommendations from the S.A.E. Ball and Roller Bearings Division. The second of these parts of the project is to be interchangeable with the corresponding annual-type ball bearing having the same series numbers. The Committee has continued to review and check the tolerances and allowances of the various types of bearings and the fit of these bearings on the shaft and in the housings.

Gears. B. F. Waterman, Chairman. While no proposals for American Standards have been completed during the year and presented to the A.S.A. for approval and recognition, considerable real progress has been made toward that end by certain of the ten subcommittees.

Subcommittee on Nomenclature. E. W. Miller, Chairman. Through the activities of the Committee of the American Gear Manufacturers Association on this subject a decision has been reached in the controversy covering single and multiple letter symbols. The former are to be designated as "symbols" and the latter as "abbreviations." The manufacturers' committee has developed a list of abbreviations, definitions, formulas, and illustrations of gear terms employed in correspondence concerning Spur, Helical, Herringbone, Bevel, and Worm Gearing. By mutual consent, therefore, the Subcommittee is undertaking to supply a list of corresponding single-letter symbols.

Subcommittee on Spur Gear Tooth Form. H. J. Eberhardt, Chairman. The Committee held a meeting in Cleveland in May, 1929, for the consideration of the criticisms and comments which had been received as a direct result of the distribution of printer's proof copies of 14½-Degree and 20-Degree Full Depth Involute Gear Tooth Forms. This revision is now completed and the proposal will soon go to the Sectional Committee for approval by letter ballot. Messrs. F. W. England and J. P. Breuer have been added to this Subcommittee.

Subcommittee on Materials. T. D. Lynch, Chairman. During the year the Committee has reviewed the large number of replies which were received as a direct result of the distribution of printer's proof copies of the proposed American Standard for Gear Materials and Blanks. Within a month or so this proposal should go to the Sectional Committee for approval by letter ballot.

Subcommittee on Inspection. G. L. Markland, Jr., Chairman. At the two meetings which this Subcommittee held during the year the large volume of comment received by mail was carefully reviewed. This work is still in progress. At the last meeting a considerable increase in the personnel of the Committee was made.

A. A. Ross has been made Chairman of the Subcommittee on Helical Gears and the Committee has drafted a proposal on Herringbone Gears. No definite progress has been made this year by the Subcommittees on Worm Gears, Bevel Gears, and Horsepower Rating.

Pipe Flanges and Fittings. C. P. Bliss, Chairman. This year the Sectional Committee completed and approved two proposed American Standards, namely, those for the 800 Lb. Hydraulic Cast Iron Pipe Flanges and Flanged Fittings and the 25 Lb. Cast Iron Pipe Flanges and Flanged Fittings. The Chairman reports satisfactory progress by the several subcommittees.

Subcommittee No. 1 on Cast Iron Flanges and Flanged Fittings. A. M. Houser, Chairman. This Committee completed during the year the proposed 800 Lb. Hydraulic Standard which in November, 1929, was approved by the Sectional Committee and subsequently submitted to the three Sponsors. The Heating and Piping Contractors National Association and the A.S.M.E. gave their respective approvals in January. The approval of the Manufacturers Standardization Society of the Valve and Fittings Industry, however, was given conditionally pending changes in the section pertaining to Markings and Materials.

The Standard for 25 Lb. Cast Iron Pipe Flanges and Flanged Fittings as proposed by this Subcommittee was approved by the Sectional Committee and the Sponsors. In September it was submitted to the A.S.A. for approval and designation as an American Standard.

The proposed standard for Ammonia Fittings was completed by the manufacturers' subgroup of this Subcommittee in May. It will be discussed at a meeting of the Refrigerating Machinery Association to be held at St. Louis in October.

Subcommittee No. 2 on Screwed Fittings. S. G. Flagg, Jr., Chairman. This Committee has approved for general distribution to industry for review and comment a proposed standard for Pipe Plugs of Cast Iron, Malleable Iron, Cast Steel, and Forged Steel. This canvass of industry will be completed early in October.

Subcommittee No. 3 on Steel Flanges and Flanged Fittings. C. P. Bliss, Chairman. In December, 1929, this Subcommittee sent out a questionnaire concerning the performance of companion flanges and flanged equipment made to the dimensions of the American Tentative Standard for Steel Pipe Flanges and Flanged Fittings. Based on the replies received certain revisions were made in the Committee's original proposal for companion flanges. This revised draft, now in proof form, will be discussed at the October meeting of the Subcommittee. In addition a proposed Standard for Steel Base-Fittings for 250, 400, 600, and 900 Lb. per Sq. In. has been completed by the Subcommittee and is to be distributed immediately to industry for comment.

The Subcommittee's new proposals for 120, 150, and 1500 Lb. Steel Pipe Flanges and Flanged Fittings are to be discussed at the October meeting.

Subcommittee No. 5 on Face to Face Dimensions of Ferrous Flanged Valves. F. H. Morehead, Chairman. The work of this Subcommittee is progressing slowly. The M.S.S.V.F.I. recently requested that the Committee exclude from its scope for the present the standardization of face-to-face dimensions of valves rated at 150 lb. and 400 lb. W.S.P.

Subcommittee No. 6 on Malleable Iron or Steel Brass Seat Unions. C. P. Bliss, Temporary Chairman. The manufacturers' subgroup of this Subcommittee has held three meetings during the past year and considerable progress has been made in collaboration with the A.R.A. Subcommittee on Locomotive Design and Construction, toward formulating a proposed American Standard for 300 Lb. Ground Joint Unions and Combination Union Fittings. This

proposal will soon be released by the Subgroup, at which time it will be set in type for consideration by the Subcommittee and industry in general.

Subcommittee No. 8 on Marking of Pipe Fittings. W. S. Morrison, Chairman. This Subcommittee sent out a questionnaire in December, 1929, in order to obtain an expression from industry as to whether or not markings were necessary, could be put on the fittings, and how they should be applied. To this a very fair response was received representing a great diversity of opinion. One of the sponsors of this project, the M.S.S.V.F.I., is making a similar study.

The following two Subcommittees did not meet during the year: Subcommittee No. 4 on Materials and Stresses, A. M. Houser, Chairman, and Subcommittee No. 7 on Rating of Pipe Fittings, H. C. Heaton, Chairman. No specific progress has been reported.

Bolt, Nut, and Rivet Proportions. A. E. Norton, Chairman. Since its organization this Sectional Committee has presented six standards for approval as an American Standard and publication. The latest standard to receive this designation is that on "Slotted Head Proportions," April, 1930.

Subcommittee No. 1 on Large and Small Rivets. J. E. J. Kiernan, Chairman. Since the distribution in March, 1928, of the proposal for Large Rivets by the Subcommittee it has been working on proposed tolerances. When the replies to its April, 1930, letters on proposed tolerances have been completely reviewed, it is expected that the Subcommittee will release its revised proposal to the Sectional Committee. Two standards developed by this Subcommittee have been approved as American Standards, Small Rivets (1927), and Tinners', Coopers', and Belt Rivets (1928).

Subcommittee No. 2 on Wrench Head Bolts and Nuts. H. A. Spanagel, Chairman. During the year this Subcommittee has been at work revising the American Tentative Standard which was approved by the A.S.A. in February, 1927. A meeting was held in Detroit in June, 1930, to discuss in detail the proposed revisions. The members of the Committee had previously agreed to certain changes in nut sizes on the recommendations of the Bolt, Nut, and Rivet Manufacturers Association.

Subcommittee No. 3 on Slotted Head Proportions. E. Winsor Reed, Chairman. The American Standard for Slotted Head Proportions was approved by the American Standards Association in April, 1930, and was published in pamphlet form by the A.S.M.E.

Subcommittee No. 4 on Track Bolts. C. W. Squier, Chairman. The sponsors approved the proposed standard for Track Bolts within these twelve months and presented it to the American Standards Association in September, 1930, for approval and designation as an American Standard.

Subcommittee No. 9 on Socket Head Cap and Set Screws. H. Koester, Chairman. The Subcommittee held meetings in October, 1929, and in September, 1930, to discuss its preliminary proposal, which will be set in type very shortly for general distribution for criticism and comment.

Identification of Piping Systems. A. S. Hebble, Chairman. This Committee prepared the present American Recommended Practice entitled "Scheme for the Identification of Piping Systems," which was approved by the A.S.A. in November, 1928. There was no need for activity this year.

Small Tools and Machine Tool Elements. C. W. Spicer, Chairman. This Sectional Committee met in December, 1929, to review and plan the work of the various technical committees under its supervision. At this meeting the organization of three new technical committees was approved: (1) Electric Welding Dies and Electrode Holders; (2) Splines and Splined Shafts; and (3) Milling Machine Tables.

Four of this Sectional Committee's Standards have been approved by the A.S.A. so far: T-Slots, Their Bolts, Nuts, Tongues, and Cutters, March, 1927; Tool Holder Shanks and Tool Post Openings, April, 1929; Milling Cutters, April, 1930; and Cut and Ground Thread Taps, April, 1930.

Technical Committee No. 3 on Machine Tapers. E. F. DuBrul, Chairman. A meeting of this Committee was held in December, 1929, at which the results of the questionnaire sent to 650 companies were discussed. At this meeting a Subgroup on Dimensions, Tolerances, and Gages was appointed. The Technical Committee plans to meet on October 20 to receive the report of the Subgroup.

Technical Committee No. 4 on Spindle Noses and Collets for Machine Tools. E. F. DuBrul, Chairman. Technical Committee No. 4 met jointly with Technical Committee No. 11 on Chucks and Chuck Jaws on June 10 to discuss the replies received as a result of the distribution of copies of the joint proposal made by these two Technical Committees and distributed in May, 1930, for general criticism and comment. At this meeting a Subgroup was appointed, with J. E. Lovely as Chairman, to study and correlate the spindle nose proposals submitted with the comments and to develop a new proposal. As a part of the activity of this Subgroup sample chucks of the several proposed standard designs are being made and sent to a machine-tool manufacturer in Cincinnati, where comparative tests will be made for the committee. The Committee will hold its next meeting on October 21.

Technical Committee No. 5 on Milling Cutters. C. W. Machon, Chairman. The final recommendations of four of the subgroups of this Technical Committee, namely, Sections of Profile Cutters, Keyways, Nomenclature, and Formed Cutters, were completed during the year, edited, and approved by the Sectional Committee, the sponsors, and the A.S.A. Combined in one pamphlet they were published as an American Standard for Milling Cutters, April, 1930.

Technical Committee No. 6 on Designations and Working Ranges of Machine Tools. E. F. DuBrull, Chairman. This Technical Committee since its organization meeting in December, 1928, has been gathering data for its first report. It now plans to meet on October 20 to review these data.

Technical Committee No. 7 on Twist Drill Sizes. C. J. Oxford, Chairman; and Technical Committee No. 8 on Drill Bushings, C. E. Rundorff, Chairman. These two committees have held three joint meetings during the past year in Cleveland, Detroit, and New York. At one of these meetings subgroups were appointed to study Lengths and Diameters of Drills, and Liner Outer Diameters and Tolerances of Bushings. At the June meeting in Detroit the comments received as the result of the distribution of the 450 copies of Proposal "C" on Twist Drill Sizes and Lengths (Straight Shanks) were discussed. This proposal included a supplementary table comparing the proposed sizes with the present ones. These Committees have called their next joint meeting for the first week in December in New York.

Technical Committee No. 9 on Punch and Die Holders. S. Diamant, Chairman. At the December, 1929, meeting the committee found it desirable to increase its personnel by adding four new members. It decided to combine Subgroups 1 and 2, Styles and Materials, as it had been found that their work overlapped. The work of collecting and correlating data on Styles and Sizes with a view to eliminating certain sizes, authorized at the last meeting, has progressed satisfactorily so that a meeting of the Committee is planned for the first week in December.

Technical Committee No. 10 on Circular Forming Tools and Holders. This project was approved by the Executive Committee in 1928. However, in attempting to organize the Committee very little interest in the subject was found. The work will probably be dropped for the present.

Technical Committee No. 11 on Chucks and Chuck Jaws. J. E. Lovely, Chairman. The first proposal of this Committee, combined with that on Spindle Noses, was broadly distributed in May, 1930. At a joint meeting of the two Committees held in Detroit in June it was decided to separate the section on Chucks and Chuck Jaws from that on Spindle Noses. This was done and the committee has scheduled a meeting for October for the purpose of reviewing the progress made during the summer months preliminary to a restatement of its proposal in tabular form.

Technical Committee No. 12 on Cut and Ground Thread Taps. C. M. Pond, Chairman. The American Standard for Cut and Ground Thread Taps was approved by the American Standards Association in April, 1930, and is now in pamphlet form.

Technical Committee No. 13 on Splines and Splined Shafts. C. W. Spicer, Chairman. The organization of this Committee was authorized at the meeting of the Sectional Committee held in December, 1929. At the first meeting, which took place in Detroit in June, 1930, the members of the committee were requested to collect all the data available on this subject in the files of their companies and to forward copies to the Chairman so that such data might be distributed with the minutes of the meeting for study and correlation by the members of the Committee.

Technical Committee No. 14 on Electric Welding Dies and Electrode Holders. J. A. Weiger, Chairman. At its organization meeting held in Detroit in June the Committee decided to direct its attention first to the standardization of arms, holders, and tips of electric-resistance spot-welding machines. A second meeting of the Committee was held in Chicago in September, 1930, at which plans were made for the distribution of a questionnaire to the manufacturers and users of this equipment covering the above items.

Technical Committee No. 15 on Milling Machine Tables. G. A. Bouvier, Chairman. The organization of this Committee was

authorized at the December, 1929, meeting of the Sectional Committee and its first meeting was held in June, 1930, at Detroit. At this time a subgroup was appointed to draft a proposal covering the tee-slot spacing for the several present sizes of tables. Data which deal with the cross-sections of the various types of milling-machine tables are now being collected by the Committee for study at its next meeting.

Scientific and Engineering Symbols and Abbreviations. J. F. Meyer, Chairman. The Committee's ambition to complete the standards on its present list during 1930 has been practically realized. Since its organization in 1926 seven (7) standards developed by the Committee have been approved by the American Standards Association and published in pamphlet form. In addition, two (2) proposed standards are now before the A.S.A. A more detailed statement of the work of the Committee follows.

Subcommittee on Symbols for Mechanics, Structural Engineering, and Testing Materials. J. T. Faig, Chairman. The criticisms and comments received from the general distribution of the preliminary report of the Committee are now in the hands of the Chairman. A revision of the proposed standard will be accordingly ready in a short time for transmission to the Sectional Committee for study and approval.

Subcommittee on Symbols for Heat and Thermodynamics. S. A. Moss, Chairman. This proposal has been approved by the Sectional Committee and the approval of the five sponsor bodies was completed in September. The standard is accordingly before the A.S.A. for final approval and recognition as an American Standard.

Subcommittee on Symbols for Photometry and Illumination. E. C. Crittenden, Chairman. The proposal of this Committee was finally approved and published in August, 1930. The standard consists of a revision of the symbols contained in "Illuminating Engineering Nomenclature and Photometric Standards" which was formulated under the sponsorship of the Illuminating Engineering Society and adopted as an American Standard in 1925.

Subcommittee on Electrotechnical Symbols Including Radio. J. F. Meyer, Chairman. The proposed standard on Graphical Symbols for Radio Communication is now before the A.S.A. for approval. Two other standards prepared by this Subcommittee have been finally approved, Letter Symbols for Electrical Quantities, approved in February, 1929, and Graphical Symbols for Telephone and Telegraph Use, approved in July, 1929. The Subcommittee is now engaged in the development of Symbols for Electric Power including Interior Wiring, Traction and Railway Signaling.

Subcommittee on Navigational and Topographical Symbols. G. L. Hosmer, Chairman. The first proposed standard to come from this Subcommittee was approved by the A.S.A. in July, 1930. It will be published shortly.

Subcommittee on Abbreviations for Engineering and Scientific Terms. G. A. Stetson, Chairman. The members of the Subcommittee have spent the year in refining the proposal made last year. A committee of the A.I.E.E. has cooperated with it relative to the abbreviations of certain electrical terms.

Plain and Lock Washers. C. W. Squier, Chairman. The Chairman of Subcommittee No. 1 on Plain Washers, F. Doepke, reports that this Subcommittee has not its proposal in shape for submittal to industry for comment. Subcommittee No. 2 on Lock Washers, of which C. H. Loutrel is Chairman, met in December, 1929, at which time it was decided to include methods of testing in this standard. The Committee plans to develop these methods of test and, together with a table of dimensions, to release the proposed standard to industry shortly for general criticism and comment.

Machine Pins. M. E. Steczynski, Chairman. This Sectional Committee in September, 1930, distributed a proposal on Taper and Cylindrical Machine Pins to industry for criticism and comment. A considerable number of helpful criticisms have been received, so it is very likely that a meeting of the Committee will be held in December.

Code for Pressure Piping. E. B. Ricketts, Chairman. The Sectional Committee has held two meetings during the past year, one at New York in December, 1929, the other at Detroit in June, 1930. At both of these meetings the progress reports of the several Subcommittees were submitted and discussed at length.

Subcommittee on Power Piping. J. H. Lawrence, Chairman. The Subcommittee has been actively engaged in the revision of the previous draft of the Power Piping section of the Code and the redrafted portions were discussed at two meetings, one held at New York in December, 1929, and the other at Detroit in June, 1930. While considerable progress has been made, this section is not, as yet, in final form.

Subcommittee on Gas and Air Piping. A. Iddles, Chairman. The work of this Subcommittee has progressed to a point where its section of the Code is in final form except for possible changes which may be made necessary as a result of requests from the natural-gas industry. It is expected that a final draft will be completed before the meeting of the Sectional Committee in December, 1930.

Subcommittee on Refrigerating Piping. A. H. Baer, Chairman. The Subcommittee has experienced considerable difficulty in drafting the section on refrigerating piping, but has recently reported that it expects to release its first proposal for general distribution in the near future.

Subcommittee on Oil Piping. A. D. Sanderson, Chairman. Some slight modifications have been made during the past year in this section of the Code and these, including a section for higher temperature and pressures and some modifications in the cast-iron-pipe requirements, were discussed at a meeting held at Detroit in June, 1930.

Subcommittee on Piping Materials. F. H. Morehead, Chairman. The first meeting of this Subcommittee since its organization was held at Detroit in June, 1930. It was decided there that the Committee should abandon the plan of abstracting specifications and should report in their entirety all specifications for materials applicable to pressure piping. Progress in gathering these data has been reported since the meeting.

Subcommittee on Fabrication Details. C. G. Spencer, Chairman. A meeting of this Subcommittee was held in June at Detroit and the progress made by the various Subgroups was discussed, considerable time being given to welding and the qualifications of welders. In June, after the Detroit meeting, a draft proposal on Fabrication of Hangers, Supports, Anchors, Sway Bracing, and Vibration Dampeners was sent to all members of the Subcommittee and Sectional Committee for consideration and criticism. The Subgroup on Joints Other Than Welded distributed a questionnaire to industry during the summer and replies will be discussed at the next meeting.

Drawings and Drafting Room Practice. F. DeR. Furman, Chairman. During the Annual Meeting of the Society in December, 1929, this Sectional Committee held a meeting at which time a Subcommittee on Editing was appointed, consisting of the Chairman of each of the six Subcommittees. Professor T. E. French was appointed Chairman of this new Subcommittee.

Three of the Subcommittees, those on Method of Indicating Dimensions, Lettering, and Line Work, distributed proposals for criticism and comment the latter part of 1929. These proposals attracted considerable attention on the part of industry and the extensive comments received are now being studied by the members of these Subcommittees, preparatory to redrafting and review by the members of the Sectional Committee.

Subcommittee on Layout. D. Baker, Chairman. F. G. Wolff, who has been acting as Chairman of this Subcommittee, found it necessary to resign, and D. Baker was appointed to carry on its work. A first report in the form of a definite proposal was presented to the Sectional Committee in January, 1928.

Subcommittee on Graphical Symbols for Drawings. T. E. French, Chairman. This Committee has had during the year a similar experience to that of the Subcommittee on Layout. G. H. Drake, who has been acting as Chairman since its organization, was unable to continue, so Prof. T. E. French was appointed to carry on the work. A set of proposed standard symbols for plumbing fixtures was distributed for criticism and comment to a selected list of architects in the United States and members of the American Institute of Architects. The replies received were then duplicated and distributed to the members of the Sectional Committee.

Graphic Presentation. E. F. DuBrul, Chairman. The Sectional Committee on Graphical Presentation was organized in November, 1926, since which time its various Subcommittees have been developing the individual sections of the proposed standard.

Subcommittee on Terminology. R. J. McFall, Chairman. For the past two years this Committee has been working on the enlargement of the section on terminology originally distributed in November, 1928. At the time of this distribution the replies indicated the necessity of extending its scope.

Subcommittee on Survey of Current Practice. A. H. Richardson, Chairman. Current practice in graphical presentation has been studied intensively by this Subcommittee with the result that it has collected a very large amount of information. It has invited the Subcommittees on Time Series Charts and Non-Time Series Charts to meet with it in a joint meeting early in October for the purpose of studying this material which Chairman Richardson has carefully analyzed and coordinated.

Subcommittee on Engineering and Scientific Graphs. W. A. Shewhart, Chairman. Through the activities of the Subcommittee a Round Table Conference on the Analysis and Presentation of Data was held during the Annual Meeting of the A.S.M.E. in December, 1929. The attendance at this Conference numbered more than 80 and one of the resolutions passed recommended the appointment of a Joint Committee for the Development of Statistical Applications in Engineering and Manufacturing, the personnel of which is to consist of representatives of the American Statistical Association, the American Mathematical Society, the American Society for Testing Materials, and the A.S.M.E. This Committee has since been appointed and is now functioning. At the present time the Subcommittee is making arrangements for an open meeting to be held during the 1930 Annual Meeting of the Society.

Transmission Chains and Sprockets. F. V. Hetzel, Chairman. The first of this Sectional Committee's standards for Roller Chains, Sprockets, and Cutters was approved by the American Standards Association in July, 1930. This standard is now available in pamphlet form as an S.A.E. publication. The committee is now at work on a proposal for Silent Chains.

Wire and Sheet Metal Gaging Systems. W. W. Hutchins, Chairman. This Sectional Committee's three Subcommittees on Flat Stocks, Wires and Rods, and Tubing, Piping, Conduit and Casing have not reported any progress during the past year.

Electric Motor Frame Dimensions. W. F. Dixon, Chairman. In December, 1929, this Sectional Committee approved the proposed standard for Mounting Dimensions of Low-Voltage 60-Cycle Squirrel-Cage Induction Motors. The joint sponsors, the N.E.M.A. and A.S.M.E., gave their approval in November, 1929, and January, 1930, respectively. In April, 1930, it was submitted to the A.S.A. for approval and designation as an American Standard. Since that date the N.E.M.A. has requested the A.S.A. to withhold approval of this standard.

Pipe Threads. E. M. Herr, Chairman. Within the twelve months of the past year two of the Subcommittees of the Sectional Committee on Pipe Threads held meetings. The progress made at these meetings is recorded in the following paragraphs.

Subcommittee on Taper Pipe Threads. S. B. Terry, Chairman. In April, 1930, this Subcommittee held its first meeting. The relation between the A.P.I. Standard Line Pipe Thread and the American Standard was thoroughly discussed and a Subgroup was appointed to confer with the A.P.I. Committee in Chicago next November. Consideration was then given to the content and form of the American Standard pamphlet (B2–1919) and it was decided to make no change in the form of thread, taper, pitch, and terminology.

Subcommittee on Plumbers' Threads. L. A. Cornelius, Chairman. At its organization meeting in October, 1929, the Committee discussed at length the specifications for (1) Plumbers' Fine Threads and (2) Corporation and Cutoff Cocks. Subgroups were then appointed to develop the details of proposed standards for these two applications.

The Subcommittees on Straight Pipe Threads, Screw Threads for Rigid Conduit, and Threads for Thin Tubes have held meetings previously, and are awaiting the recommendations of the Subcommittee on Taper Pipe Threads before completing their proposals.

Wrought Iron and Wrought Steel Pipe and Tubing. H. H. Morgan, Chairman. In June, 1930, the Sectional Committee met in Detroit to consider the formula for calculating nominal pipe-wall thickness as developed by the Subgroup on Basic Formulas and proposed jointly by Subcommittees Nos. 2 and 3. The formula, which had been evolved is a modification of the Barlow Formula and favored by the A.S.M.E. Boiler Code Committee, seemed to meet the requirements of pipe-wall thickness calculations, so was approved at this meeting subject to vote by letter ballot. It was recommended that, as the next step, tentative wall-thickness schedules based on this formula should be prepared and referred to Subcommittees Nos. 2 and 3.

Subcommittee on Plan, Scope, and Editing. H. H. Morgan, Chairman. This Subcommittee met in Detroit in March and in June, 1930, for an advance discussion of the problems before the Sectional Committee and to plan for the development of this project.

Subcommittee on Pipe and Tubing for Low Temperature Service. J. J. Shuman, Chairman, and Subcommittee on Pipe and Tubing for High Temperature Service, H. H. Murray, Chairman. A joint meeting of these two Subcommittees was held on June 10 prior to the Sectional Committee meeting. The two Subcommittees approved the formula for pipe-wall thickness and recommended its submission to the Sectional Committee for approval. Upon the approval of this formula by the Sectional Committee the two Subcommittees began the preparation of schedules of pipe and tubing sizes and weights covering the ranges needed by industry.

Speeds of Machinery. A. E. Hall, Chairman. The Sectional Committee on Speeds of Machinery was organized in October, 1928. The Subcommittee on Plan and Scope met last December and appointed a subcommittee on Questionnaire and Canvass of Industry. Mr. English, Temporary Chairman of this newly appointed committee, plans to call the first meeting at the time of the A.S.M.E. Annual Meeting in December.

Fire-Hose Couplings. Since the approval in May, 1925, of the American Standard for Fire-Hose Couplings Threads, there has been a steady increase in its acceptance by cities and towns of the United States. The National Board of Fire Underwriters, the Chamber of Commerce of the United States, and the A.S.M.E. Local Sections have assisted in the promulgation of this standard and in increasing the use of gages by municipal authorities in accepting equipment. The conversion of existing equipment to this standard also is progressing satisfactorily. The N.B. of F.U. makes an annual canvass of the cities on this subject.

Screw Threads for Hose Couplings. H. W. Bearce, Chairman. The Sectional Committee met in July, 1930, to review and discuss the draft of the proposed standard for Small Hose Coupling Screw Threads for All Connections having Nominal Inside Diameters of 1/2, 3/4, 1, 1 1/4, 1 1/2 and 2 Inches, which had been drafted by a Subcommittee. Based on the discussion at this meeting a revised draft of the proposal was prepared. This is being set in type for distribution for criticism and comment prior to further action by the Sectional Committee.

Plumbing Equipment. W. C. Groeniger, Chairman. At the time of the organization of the Sectional Committee on Standardization of Plumbing Equipment in August, 1928, six Subcommittees were appointed. This spring it was found desirable to appoint two more Subcommittees to develop the sections on Copper Water Tube Fittings (No. 7) and Cast Iron Soil Pipe and Fittings (No. 8). The work of organizing these two Committees and the Subgroup on Cast Iron Traps has been carried on during the spring and summer with the result that meetings of all three will be held very shortly.

Subcommittees: No. 1 on Plumbing Code, No. 2 on Staple Vitreous China Plumbing Fixtures, No. 3 on Staple Porcelain (All Clay) Plumbing Fixtures, and No. 4 on Enameled Sanitary Ware have the same personnel as the Standing Committees on the same subjects organized by the U. S. Department of Commerce.

Subcommittee No. 5 on Traps. A. R. McGonegal, Chairman. The organization meeting of the Subcommittee on Traps was held in January, 1930. At that meeting the necessity for the appointment of Subgroups to develop the proposals for traps in the following seven classes was made evident: Brass lavatories and sinks; brass; cast iron; lead; vitreous china; miscellaneous traps; interceptors and catch basins. The Subgroup on Brass Lavatories and Sink Traps met in New York on March 18. The other Subgroups, while not completing their proposals, have reported progress.

Subcommittee No. 6 on Brass Plumbing Products. J. L. Murphy, Chairman. The Subgroup on Compression Cocks, Washer Screws, Faucets, and Tail Piece Parts has sent copies of its recommendations, based on the replies to its questionnaire to manufacturers, to the members of the Subcommittee for comment.

Subcommittee No. 7 on Copper Water Tube Fittings. The proposal on Brass Fittings for Flared Copper Tubes is the first of the Sectional Committee's proposals to be set in type. Copies will shortly be distributed for general criticism and comment.

Standardization and Unification of Screw Threads. R. E. Flanders, Chairman. Through the activities of its Subcommittees this Sectional Committee has made very substantial progress toward the completion of its task during the past year. A meeting is scheduled for October 16 to receive and review the reports of these Subcommittees.

Subcommittee on Scope, Arrangement, and Editing. R. E. Flanders, Chairman. Two meetings of this Committee were held, one in October, 1929, and the other in April, 1930. The first meeting was devoted to a careful review of the 1928 report of the National Screw Thread Commission and the assignment of its several sections to the Subcommittees for further study and report. At this meeting the Committee considered also certain special screw-thread applications not definitely covered by the N.S.T.C. report.

At the second meeting, on the recommendation of the wood-screw manufacturers, it was decided that there was no consistent demand for the standardization of the thread form of wood screws. A similar action was taken concerning screw threads for valve stems.

Plans for the survey of current screw-thread practice proposed and approved at the May, 1929, meeting of the Sectional Committee were discussed and developed at these two meetings.

Subcommittee on Terminology and Thread Specifications, Except Gages. C. W. Bettcher, Chairman. At its April 7, 1930, meeting this Subcommittee made a detailed study of the pamphlet describing the present American Standard (B 1a–1924) and the corresponding sections and paragraphs of the N.S.T.C. reports of 1924 and 1928. Its recommendations will be discussed by the Sectional Committee when it meets.

Subcommittee on Special Threads and Twelve Pitch Series, Except Gages. The organization meeting of this Subcommittee was held on April 10, 1930. Three of its actions are of special interest: (1) Approval of the twelve (12) pitch series as published in the 1928 report of the N.S.T.C., (2) naming of Subgroups to develop dimensions and tolerances for a new eight (8) pitch series, and (3) the appointment of a Subgroup to study the possibilities of establishing a standard screw thread for track bolts.

Subcommittee on Screw Thread Gages and Inspection. G. S. Case, Temporary Chairman. At its meeting in April, 1930, the Subcommittee on Screw Thread Gages and Inspection discussed the scope of its work with the result that it was decided to limit the present activities to (*a*) classification of gages, (*b*) gage tolerances, and (*c*) gages appearing in the 1928 report of the N.S.T.C. A Subgroup of three was appointed to draft recommendations.

Subcommittee on Survey of Present Practice. R. E. Flanders, Chairman. Through discussion at the various meetings of the Sectional Committee and the several Subcommittees certain features of the Survey of Present Practice have been determined. They are as follows:

(1) The samples will be gathered by an official representative of the Committee;
(2) These samples will be mailed to the Gage Division of the Bureau of Standards where they will be gaged;
(3) Approximately 100 concerns, both manufacturers and users, will be visited and certain information concerning the manufacture or use of the product will be recorded at that time; and,
(4) The list of firms has been prepared so as to cover adequately the major screw-thread manufacturing and using industries located in the eastern and the east-central sections of the United States.

Subcommittee on Acme and other Similar Threads, except Gages, and Subcommittee on Lag Screws did not hold meetings during the year but have made some progress by correspondence.

Rolled Threads for Screw Shells of Electric Sockets and Lamp Bases. R. E. Myers, Chairman. The Sectional Committee on the Standardization of Rolled Threads for Screw Shells of Electric Sockets and Lamp Bases was organized in March, 1929. After several meetings Subcommittee No. 1 released its proposed standard for general criticism. The replies are to be discussed at a meeting on October 2, after which the proposal will be submitted to letter ballot of the Sectional Committee.

Stock Sizes, Shapes, and Lengths for Hot and Cold Finished Iron and Steel Bars. F. H. Frankland, Temporary Chairman. The organization meeting of the Sectional Committee was held on June 4, 1930. The appointment of three Subcommittees was authorized, No. 1 on Hot Rolled Steels, No. 2 on Cold Finished Steels, and No. 3 on Hot Rolled Iron. The personnels of these three Subcommittees are now being completed.

Pressure and Vacuum Gages. Sponsorship for this project was assigned to the Society in June, 1930, by the American Standards Association. Accordingly, early in July letters of invitation were mailed to fifty-five (55) associations and societies requesting them to appoint official representatives on the Committee. As soon as a sufficient number of appointments have been made the Committee will be called together for organization. It is expected that this meeting will be held before January 1.

Respectfully submitted,

EDWARD J. KEARNEY, *Chairman*
H. BIRCHARD TAYLOR
LEWIS K. SILLCOX
WILLIAM S. MONROE
EARLE BUCKINGHAM.

SAFETY

The Standing Committee on Safety reports the following progress in the safety activities of the Society.

PUBLICITY

Throughout the year the Committee has continued its efforts to keep the importance of industrial safety before the technical sessions of the Society. In April, 1930, Chairman Mowery addressed letters to the members of the Executive Committees of the A.S.M.E. Professional Divisions in charge of papers and meetings suggesting that provision be made for five-minute talks on safety at their sessions on subjects closely relating to that of the session. At the Detroit Meeting in June a brief talk on safety was given at the Management Session.

During the summer months a considerable amount of work has been done in preparation for the safety features of the 1930 Annual Meeting. At this date it can be reported that a Symposium on Safety will be held on Monday, December 1, and a joint session on Safety and the Wood Industries has been arranged for Wednesday of Annual Meeting Week.

During the year a number of articles totaling two pages of text has been published in *Mechanical Engineering* and items of general and timely interest have been run in issues of the *A.S.M.E. News*.

NEW YORK BUILDING CODE COMMITTEES

On March 13, 1930, the Committee called an informal conference of its members and the seventeen A.S.M.E. members serving on Committees which are formulating the new Building Code of the City of New York. The conference was held for the purpose of discussing ways and means whereby the Society as an organization might help in this important work. The meeting recommended that a joint committee of the American Institute of Architects and the A.S.M.E. be appointed to review the proposed revised Building Code when it is nearly completed and to make recommendations, if necessary, to the Advisory Committee of the Building Code Committee.

SAFETY CODES

Five of the fifty safety-code committees now functioning under the procedure of the American Standards Association are sponsored solely or jointly by the A.S.M.E. These are:

Sectional Committee on a Safety Code for Mechanical Power Transmission Apparatus
Sectional Committee on a Safety Code for Elevators
Sectional Committee on a Safety Code for Machinery for Compressing Air
Sectional Committee on a Safety Code for Conveyors and Conveying Machinery
Sectional Committee on a Safety Code for Cranes, Derricks, and Hoists.

In addition to these Committees the Society has representation on 23 other Sectional Committees drafting safety codes.

PERSONNEL

The Sectional Committees on Safety Codes sponsored by the A.S.M.E. now have a membership of 218. Of this number 91 are members of the Society. These five Committees have subdivided their work among 22 subcommittees and subgroups, making a total of 27 committees at work on the Society's safety program.

ACTIVITIES OF SECTIONAL COMMITTEES

The Subcommittee on Research, Interpretations, and Recommendations formed in 1926 to develop reliable data on certain auxiliary apparatus for the revision of the Safety Code for Elevators, approved and published in 1925, continued its monthly meetings during the year. Its work was advanced to a stage where a revision of the Code was possible and in July, 1930, a revised draft was submitted to the members of the Sectional Committee on a Safety Code for Elevators for approval by letter ballot. This ballot is not yet complete.

The Subcommittee on Elevator Inspectors' Handbook held several meetings during the past year and its preliminary report is now being set in type prior to submission to the Sectional Committee for review and approval by letter ballot.

The Sectional Committee on a Safety Code for Mechanical Power Transmission Apparatus completed its original code in 1923. In 1927 it was slightly revised and given the status of an "American Standard" by the American Standards Association. On October 8, 1929, the Sectional Committee met to discuss a further revision of this Code in line with the work of its new Subcommittee on Mechanical Power Control, appointed in February, 1929.

No meetings of the Sectional Committee on a Safety Code for Conveyors and Conveying Machinery have been held since October

1, 1929. The work of the Committee has been carried on by correspondence but little progress has been made in further developing the four sections of the Code which are in preliminary form.

A meeting of the Sectional Committee on a Safety Code for Cranes, Derricks, and Hoists was held on January 21, 1930. The following three of its Subcommittees also met: Subcommittee No. 1 on Overhead and Gantry Cranes, January 20 and 21, 1930, Subcommittee No. 3 on Derricks and Hoists, March 24, 1930, and Subcommittee No. 5 on Jacks on November 6, 1929, and April 8, 1930. The Editing Committee is now correlating and editing the reports of Subcommittee No. 1 on Overhead and Gantry Cranes and Subcommittee No. 2 on Locomotive and Tractor Cranes.

The Safety Committees on which the Society has representation are as follows:

Safety Code Correlating Committee
Sectional Committee on Safety Code for Abrasive Wheels
Sectional Committee on Safety Code for Floor Wall Openings, Railings, and Toe Boards
Sectional Committee on Safety Code for Industrial Sanitation
Sectional Committee on Safety Code for Lighting Factories, Mills, and Other Work Places
Sectional Committee on Safety Code for Forging and Hot Metal Stamping
Sectional Committee on Safety Code for Ladders
Sectional Committee on Safety Code for Laundry Machinery and Operation
Sectional Committee on Safety Code for Logging and Sawmill Machinery
Sectional Committee on Safety Code for Aeronautics
Sectional Committee on Safety Code for Textiles
Sectional Committee on Underground Power Transmission and Power Equipment for Metal Mines
Sectional Committee on Safety Code for Machine Tools
Sectional Committee on Safety Code for Paper and Pulp Mills
Sectional Committee on Safety Code for Power Presses, and Foot and Hand Presses
Sectional Committee on Safety Code for Rubber Machinery
Sectional Committee on Safety Code for Walkway Surfaces
Sectional Committee on Safety Code for Amusement Parks
Sectional Committee on Safety Code for Window Washing
Sectional Committee on Safety Code for Color for the Identification of Gas Mask Canisters
Sectional Committee on Safety Code on Ventilation for Metal Mines
Sectional Committee on Safety Code on Ventilation in Coal Mines
Sectional Committee on Safety Code for Ventilation
Sectional Committee on Safety Code for Mechanical Refrigeration
Special A.S.A. Committee on Low Voltage Electrical Hazard.

Respectfully submitted,

HAROLD W. MOWERY, *Chairman*
JOHN PRICE JACKSON — ARTHUR M. TODE
LEW R. PALMER — THOMAS A. WALSH.

POWER TEST CODES

The Committee on Power Test Codes presents the following report for the year ending September 30, 1930.

TEST CODES COMPLETED

During the year three of the original Codes in the series of twenty-four test and supplementary codes were completely revised in the light of current practice and reprinted in pamphlet form. These were the Code on General Instructions and the Test Codes for Stationary Steam-Generating Units and Internal-Combustion Engines.

Twenty of the twenty-four test and supplementary codes and four of the thirty-seven sections of Instruments and Apparatus have been completed and published during the period 1922–1930 as follows:

Code on General Instructions
Code on Definitions and Values
Test Code for Solid Fuels
Test Code for Liquid Fuels
Test Code for Stationary Steam-Generating Units
Test Code for Reciprocating Steam Engines
Test Code for Steam Turbines
Test Code for Reciprocating Steam-Driven Displacement Pumps
Test Code for Centrifugal and Rotary Pumps
Test Code for Displacement Compressors and Blowers
Test Code for Feedwater Heaters
Test Code for Condensing Apparatus
Test Code for Atmospheric Water-Cooling Equipment
Test Code for Refrigerating Systems
Test Code for Evaporating Apparatus
Test Code for Steam Locomotives
Test Code for Gas Producers
Test Code for Internal-Combustion Engines
Test Code for Hydraulic Power Plants and Their Equipment
Test Code for Speed-Responsive Governors
Instruments and Apparatus:
Part 1, General Considerations
Part 2, Pressure Measurement
Chapter 1, Barometers
Chapter 6, Tables, Multipliers, and Standards for Barometers, Mercury Columns, and Pressure Measurements
Part 21, Leakage Measurement
Chapter 1, Condenser Leakage Tests

Two new test codes were completed within the year, namely, the Test Codes for Liquid Fuels and Atmospheric Water-Cooling Equipment. Both of these Codes were approved and adopted by Council as the standard practice of the Society in August and September, 1930, respectively. The Test Code for Liquid Fuels appeared in the December, 1929, issue of *Mechanical Engineering* and in December, 1929, at the Annual Meeting of the Society it was presented for discussion at a Public Hearing. The final revision of the proposed Code was based on the criticisms and comments received at this hearing.

In the January, 1930, issue of *Mechanical Engineering* the Test Code for Complete Steam-Electric Power Plants was published. This Code was then presented for discussion at a Public Hearing held in Detroit in June, 1930, and is now receiving its final revision by Individual Committee No. 11 on Complete Steam Power Plants.

Due to the extensive revision of the Test Code for Stationary Steam-Generating Units to cover certain important changes made necessary by present boiler practice, an abstract of the revised draft was published in the November, 1929, issue of *Mechanical Engineering*. The criticisms and suggestions received were of considerable assistance to the Individual Committee in bringing the Code up to date before re-publication.

Considerable progress has been made in the development of the Test Code for Centrifugal and Turbo-Compressors and Blowers. In the preparation of this Code, Individual Committee No. 10 learned that the Prime Movers Committee of the National Electric Light Association planned to cooperate with the Fan Manufacturers Association in the preparation of a Code for the testing of fans after installation. The services of Individual Committee No. 10 were offered to this group in an attempt to bring about complete cooperation in the development of this proposed test code.

A résumé of the progress which has been made during the past year in the preparation of the various parts and chapters of Instruments and Apparatus is as follows: Part 3, Temperature Measurement, Chapter 5 on Pyrometric Cones, appeared in the August, 1930, issue of *Mechanical Engineering;* Part 11, Measurement of Quality of Steam, appeared in abstract form in the June, 1930, issue of *Mechanical Engineering;* Part 17, Determination of the Viscosity of Liquids, was published in the March, 1930, issue of *Mechanical Engineering;* the development of the following parts and chapters has progressed appreciably within the past year: Part 2, Pressure Measurement, Chapter 2 on Static and Total Pressure, Static Holes and Tubes, Impact Tubes; Part 3, Temperature Measurement, Chapter 5 on Pyrometric Cones, Chapter 6 on Liquid-in-Glass Thermometers, and Chapter 7 on Bourdon Tube Thermometers; Part 5 on Measurement of Quantity of Material; Part 6 on Electrical Measurements; Part 8 on Measurement of Indicated Horsepower; Part 9 on Heat of Combustion; Part 13 on Speed Measurement; Part 16 on Density Determinations; and Part 20 on Smoke-Density Determinations.

The publication of preliminary drafts of the Power Test Codes and other related material in *Mechanical Engineering* for the year has filled sixteen (16) pages.

PERSONNEL CHANGES

The Committee records with deep regret the deaths during the year of four of its members who have been active in the work of the Individual Committees: W. J. A. London, who was a member of Individual Committee No. 6 on Steam Turbines; R. D. Pratt, who served on Individual Committee No. 4 on Stationary Steam-Generating Units; and Messrs. Thomas Shipley and Peter

Neff, both of whom were members of Individual Committee No. 13 on Refrigerating Systems.

Several additions have been made by appointment to the Individual Committees: C. U. Savoye on Committee No. 4 on Stationary Steam-Generating Units, H. D. Kelsey on Committee No. 10 on Centrifugal and Turbo-Compressors and Blowers, and E. L. Lindseth on Committee No. 19 on Instruments and Apparatus. Following the resignation of N. A. Carle as Chairman of Committee No. 11 on Complete Steam Power Plants, R. J. S. Pigott, who has had an important part in the development of the proposed test code, was unanimously elected to succeed Carle as Chairman.

National Contacts

The Committee this year has corresponded with the American Gas Associations, the American Standards Association, and the Pacific Coast Gas Association relative to the setting up of a standard temperature and pressure of reference for gas measurement under varying conditions of service and test.

International Contacts

Within the year the Main Committee, with the assistance of Individual Committee No. 4 on Stationary Steam-Generating Units, reviewed the Italian Standard Specifications for the Thermal Tests of Boilers (1929) which had been submitted by the Italian National Standardizing body. The Committee's comments on the Code were appreciated by the Italian Committee.

A preliminary draft of the V.D.I. Test Code for Testing Oil and Gas Engines, Gas Generator, and Waste Heat Using Apparatus was referred to Individual Committee No. 17 on Internal-Combustion Engines for study and review.

International Electrotechnical Commission

The Society and the Main Committee on Power Test Codes, through membership on the U. S. National Committee of the International Electrotechnical Commission, have been actively engaged in assisting to bring about international agreements on acceptance tests for hydraulic and steam turbines and internal-combustion engines during the past five years. The U. S. National Committee of the I.E.C. holds the Secretariat for the Advisory Committees on these types of prime movers. The Society was represented this year on the U. S. National Committee by Fred R. Low, William F. Durand, Francis Hodgkinson, C. Harold Berry, and H. Birchard Taylor.

The fifth meeting of I.E.C. Advisory Committee No. 5 on Steam Turbines was held in Stockholm, Sweden, June 30–July 4, 1930, and by intensive work the following parts of the proposed I.E.C. Publication on Steam Turbines were completed and approved:

Part I Specifications

- Appendix A Information to be supplied with inquiry or order for steam turbines
- Appendix B Suggested standard ratings of steam turbines
- Appendix C Suggested standard boiler steam pressures
- Appendix D Graphical symbols for heat power systems.

Part II Rules for Acceptance Tests

- Section 1 Object and scope
- Section 2 Enumeration and description of terms
- Section 3 Guiding principles
- Section 4 Instruments and methods of measurement
- Section 5 Computation of results
- Section 6 Report of tests carried out in accordance with I.E.C. Rules for Acceptance Tests.

This material was transmitted to the Plenary Meeting of the Commission held in Oslo, Norway, on July 9, 1930, and received the final approval of this governing body of the International Electrotechnical Commission.

During the eight months prior to the meeting the Secretariat was engaged in preparing and editing the material which had been developed at the previous meetings, the original bases of which are the specifications or codes previously formulated by the interested engineering and industrial groups of certain of the ten member countries. At this 1930 meeting of Advisory Committee No. 5, Messrs. Francis Hodgkinson, Irving E. Moultrop, William L. Abbott, Geo. A. Orrok, Harvey N. Davis, Joseph H. Keenan, and Ely C. Hutchinson represented the U. S. National Committee, while C. B. LePage attended on behalf of the Secretariat.

The International Electrotechnical Commission, through the resolution of its Committee of Action, appointed Advisory Committee No. 19 on Internal-Combustion Engines in November, 1929. An invitation was extended to the U. S. National Committee to accept the responsibilities of the Secretariat. After due consideration this invitation was accepted in December, 1929, and Francis Hodgkinson was appointed Director of the Secretariat and C. B. LePage, Assistant Director.

Capitalizing the experience in this field gained by the A.S.M.E. Committee on Power Test Codes and by the I.E.C. Advisory Committee No. 5 on Steam Turbines, the U. S. National Committee in preparing for an organization meeting of Advisory Committee No. 19, drafted a proposal for Part II, Rules for Acceptance Tests of Internal-Combustion Engines. An additional document was also prepared by the Secretariat which consisted of the U. S. National Committee's comments on the proposal of the British National Committee for Part I, Specifications.

Two sessions of Advisory Committee No. 19 were held at Stockholm on Saturday, July 5, at which the six documents placed before it by the National Committees of Great Britain, Switzerland, and the United States were reviewed in a general way. Since this was the first meeting of the Committee, the discussion was of a preliminary nature. When the meeting adjourned, a general agreement had been reached as to the subjects to which the Committee would give its first attention in preparing for its next meeting. The U. S. National Committee was represented by Messrs. Francis Hodgkinson, H. C. Dickinson, Harvey N. Davis, Ely C. Hutchinson, and H. S. Osborne, while the Secretariat was represented by C. B. LePage.

The twenty Individual Committees and the Main Committee on Power Test Codes now include in their personnel 119 members of the Society and 12 non-members.

Respectfully submitted,

Fred R. Low, *Chairman*

C. Harold Berry	David S. Jacobus
Lester P. Breckenridge	Charles E. Lucke
Edwin H. Brown	Lionel S. Marks
Alexander G. Christie	Lewis F. Moody
Harte Cooke	Irving B. Moultrop
Paul Diserens	Henry B. Oatley
Robert H. Fernald	Geo. A. Orrok
Edwards R. Fish	Reginald J. S. Pigott
C. F. Hirshfeld	Edwin B. Ricketts
Francis Hodgkinson	Edward N. Trump
Ozni P. Hood	William M. White
George A. Horne	Walter J. Wohlenberg.

BOILER CODE

The Boiler Code Committee submits the following report for the fiscal year ending September 30, 1930:

During this period the Committee held nine regular meetings devoted to interpretations and to the consideration of revisions and addenda to the various sections of the Code. The meetings continue to be of marked importance to the states, municipalities, and the boiler- and pressure-vessel industry. With the recent developments in this field, many questions of vital nature are submitted. The service rendered to the public in this manner is of incalculable value in providing for new developments and practice along various lines of advance.

Cooperation with the American Society for Testing Materials is still carried on to the advantage of the industry. During the year new Specifications have been adopted by the A.S.T.M., covering Arbitration Test Bar and Tension Test Specimen for Cast Iron, and have been accepted by the Boiler Code Committee for incorporation in the Code. In addition, in order to make the Material Specifications Section of the Code conform more closely with the A.S.T.M. Specifications, the style and general arrangement of the Specifications as they appeared in the 1927 edition of the Code have been rearranged so that they are identical with that of the A.S.T.M. This will prove of assistance in comparing the Specifications with those of the A.S.T.M.

The Committee has made numerous revisions of the various sections of its Code as a result of requests from manufacturers, inspectors, users, and others. These revisions include rules to cover any series of holes that may be placed longitudinally in a drum without reinforcement, rules for the reinforcement of manholes and other openings, and rules for riveted and welded nozzles. They also include rules for the more extensive use of fusion welding on power boilers and the extension of the pressure and diameter limitations for fusion-welded unfired-pressure vessels, provided that the Recommended Procedure is followed. These revisions were formally adopted by the Council and distributed in pink-colored addenda sheets on August 12, 1930. It is the Committee's understanding

that these revisions, while now acceptable in the various states and cities in which the Boiler Code has been adopted as their Standard and is operative, will not become mandatory until January 1, 1931, thereby allowing a reasonable period of grace after they are announced.

The Sub-Committee on Welding has actively cooperated with the Conference Committee of the American Welding Society. Proposed Specifications for the Fusion Welding of Drums or Shells of Power Boilers were published in the March, 1930, issue of *Mechanical Engineering*. The large amount of discussion received on these Proposed Specifications is an evidence of the great interest shown in the subject of fusion welding by engineers at large. Symposiums for the presentation and discussion of these specifications were held during the year by the American Welding Society and the National Board of Boiler and Pressure Vessel Inspectors. As a result it was brought out that there was an urgent need for similar specifications for the Code for Unfired Pressure Vessels to allow vessels covered by the Code to be fusion welded without limit as to dimensions or working pressures. The Committee therefore drafted such a set of specifications, which will soon appear in *Mechanical Engineering* for public comment. In addition to the latter specifications it is intended to further extend the scope of the rules covering unfired pressure vessels which may be fusion welded without being stress relieved.

The need has been shown for a list of official Interpretations of the Committee which can be considered inactive or obsolete as a result of revisions of Code rules that incorporate the basic ideas thereof. The number of interpretations is steadily increasing, and manufacturers have been put to considerable inconvenience in keeping track of the Cases which may still be considered active. This matter is being considered by the Committee, and as soon as this investigation has been completed, the list will be generally distributed.

Tests are being carried on by the Taylor Forge and Pipe Company, Chicago, Ill., with a view to presenting data to permit of amplifying the rules for nozzle and dome reinforcements that now appear in Pars. P-268 and U-59 of the Code.

The question of the use of fusion welding on calking edges of riveted joints is one which has been before the Committee for some time. The matter had been referred to the Conference Committee of the American Welding Society, but when the report was received, it was found that sufficient information concerning penetration of the weld was not presented. The matter is being given further consideration by the Subcommittee on Welding with a view to presenting a recommendation for incorporating a rule in the Code.

The Committee has been and is still actively cooperating with local groups in Oklahoma regarding the status of the Code for Unfired Pressure Vessels and its application to the conditions encountered in the petroleum field. Reports have been received from time to time to the effect that the petroleum interests, tank manufacturers, and others interested in the Mid-Continent oil fields, had under consideration the formulation of a Code to suit their particular needs, and as a result the Committee has actively endeavored to obtain the consideration of these interests of the Society's Code. Conferences between some of the members of the Committee and those interested have helped considerably toward the realization of the advantages to be gained in using our Code, and the facts at the present time warrant the statement that this matter will eventually be settled satisfactorily.

The Committee wishes to report cooperation with the Canadian Provincial boiler inspectors. As a result of the attendance of the Honorary Secretary of the Boiler Code Committee at the conference held at Calgary, Canada, in May, it was learned that these inspectors were much interested in the A.S.M.E. Code. The Heating Boiler and Unfired Pressure Vessel Sections of the A.S.M.E. Code were adopted at the conference almost in their entirety for use in Canada.

Messrs. W. A. Nevin and J. W. Turner have been appointed members of the Subcommittee on Heating Boilers. In recognition of the service of Charles S. Blake who has resigned as member and Chairman of the Sub-Committee on Rules for Inspection, he was appointed as Honorary Chairman and John A. Collins was appointed as member and Chairman in his place. V. M. Frost was appointed a member of the Executive Committee. H. B. Oatley was appointed a member of the Boiler Code Committee. Honorary membership on the Boiler Code Committee was conferred on Charles L. Huston upon severing his active connection after many years' service.

The Committee reports with deep regret the deaths of its Honorary Chairman, John A. Stevens, on November 18, 1929, of Messrs. S. F. Jeter, a member of the Committee, on December 31, 1929, and W. P. Eales, a member of the Subcommittee on Rules for Inspection, and Pennsylvania representative on the Conference Committee, on January 25, 1930.

Respectfully submitted,

F. R. Low, *Chairman*
D. S. Jacobus, *Vice-Chairman*
C. W. Obert, *Honorary Secretary*
H. E. Aldrich
W. H. Boehm
F. S. Clark
F. W. Dean
W. F. Durand
E. R. Fish
V. M. Frost
C. E. Gorton

J. O. Leech
LeRoy Mikels
E. F. Miller
M. F. Moore
I. E. Moultrop
C. O. Myers
H. B. Oatley
James Partington
C. L. Warwick
H. LeRoy Whitney.

PROFESSIONAL CONDUCT

During the fiscal year 1929-1930, the Society received one complaint of unprofessional conduct on the part of two members of the Society. This was referred to the Committee on Professional Conduct which decided that no official action should be taken.

The Secretary of the Society took care of three requests for advice on professional ethics.

Respectfully submitted,

John Hunter, *Chairman*
D. R. Yarnall
W. B. Powell
A. G. Christie
H. S. Philbrick.

Fiftieth Anniversary Celebration

THE Fiftieth Anniversary Celebration of The American Society of Mechanical Engineers brought together from Europe, Asia, Africa, Australia, and North and South America, distinguished engineers who testified to the economic and social effects of engineering and science on the progress of civilization in the countries which they represented. The testimony was impressive and authoritative.

The anniversary was memorable on account of its international atmosphere and the dominance of a spirit of progress, and because of the historical significance of the exercises in New York and in Hoboken.

The celebration was officially opened on Saturday morning, April 5, with the unveiling in the lobby of the Engineering Societies Building of a memorial tablet commemorating the Fiftieth Anniversary of the Society. The tablet, a very beautiful piece of memorial art, conceived and modeled by Julio Kilenyi, shows the engineer symbolized by a man of powerful physique gazing past some typical measuring instruments, indicative of this fundamental function of his technique, into the future, the plans for which are shown as being already within his grasp. This design had been adapted from the Fiftieth Anniversary Medal, also designed by Julio Kilenyi.

THE FIFTIETH ANNIVERSARY MEDAL

The presiding officer upon the occasion of the unveiling was Charles E. Gorton, vice-president of the Society, and the presentation address was made by Charles T. Main, a past-president. Francis Lee Stuart made a very gracious and feeling speech of acceptance for the Engineering Foundation, Inc. The actual unveiling was done by John Sweet, a grand-nephew of John E. Sweet, a founder and past-president of the Society.

Registration had started on the preceding afternoon and delegates had presented their credentials. The anniversary badges were replicas in bronze of the Fiftieth Anniversary Medal, which in turn repeated in medal form the motif on the official tablet. These medals were hung on various combinations of blue and gold ribbon that identified their wearers respectively as delegates, medalists, guests, and members of the staff.

McGraw-Hill Commemorative Exercises

The first of the events of historical significance was conducted under the auspices of the McGraw-Hill Publishing Co., Inc., and commemorated the part played by the *American Machinist* in the founding of the A.S.M.E. Transported by buses from the Engineering Societies Building to the McGraw-Hill Building, at 36th Street and 10th Avenue, New York, the party was then conducted to the thirteenth floor, where the ceremonies took place.

Kenneth Condit, editor of the *American Machinist*, acted as chairman for the occasion and introduced Malcolm Muir, president of the McGraw-Hill Publishing Co., Inc., who delivered the address of welcome. William Elmer, vice-president of the A.S.M.E., made the acknowledgment for the Society.

On a stage which had been erected at one end of the room was enacted a one-act play, "Just Before an Interesting Event" or "What Might Have Happened in the Office of the *American Machinist* Three Days before the Preliminary Meeting."

The scene showed the interior of the office of the *American Machinist* at 96 Fulton Street, on the morning of February 13, 1880. As the curtain rose, the bookkeeper, played by A. J. McElhone, entered and started a fire in the Franklin stove. He was followed by Jackson Bailey, editor of the *American Machinist*, played by Ralph S. Foss, and later by Horace B. Miller, publisher, played by William Chevalier. A conversation between Bailey and Miller eventually developed into a discussion of how best to bring together some engineers to discuss in an amicable manner the desirability of forming an association of mechanical engineers. As an enterprising publisher of an engineering journal, Mr. Miller was eager to take a position of leadership, and the happy thought of giving a dinner at the Astor House to pave the way for a settlement of possible differences caused him to dispatch a copy boy, played by Harry Erickson, to the hotel with a letter making arrangements for the dinner. History has it that the dinner accomplished its purpose, for after it, on February 16, 1880, the decision was reached to call the historic meeting of April 7 at Stevens Institute, at which the A.S.M.E. was founded.

Following the presentation of this play, a telegram of greeting from James H. McGraw was read. Roy V. Wright, past-vice-president of the Society, offered a motion of thanks and acknowledgment, which was heartily applauded and adopted. A delightful luncheon was served and there was ample opportunity for visiting and exchanging greetings. Copies of the anniversary issue of the *American Machinist*, a beautiful book, well illustrated, depicting the history of the Society and the corresponding advances in the engineering profession since 1880, were distributed. Accompanying this issue there was also a

reprint of the *American Machinist* of fifty years ago which announced the preliminary meeting for the discussion of the formation of an association of mechanical engineers.

The Pageant at Stevens Institute

After luncheon the party was taken by buses across the river to Stevens Institute of Technology in Hoboken, N. J., where a pageant, called "Control," written and directed by George Pierce Baker, director of the department of drama of Yale University, assisted by Harold Burris-Meyer, of Stevens, was presented. The cast was composed of students of the Institute.

The pageant was held in the auditorium of Stevens Institute because it was there that the original meeting of the Society convened. Symbolic figures, motion pictures, and well-acted scenes were used to illustrate the development of mechanical engineering during the past fifty years.

The theme of the pageant was developed through five main scenes, dealing with Watt and Boulton and the steam engine; Stephenson, and his railroad from Liverpool to Manchester over Chat Moss bog; Faraday's experiment in magneto-electric induction; the organization meeting of the A.S.M.E. on April 7, 1880; and Edison's first demonstration of electric lights.

The complete text of the pageant has been published in book form by the Society.

The Welcoming Dinner

On Saturday evening at the Hotel Roosevelt was held the Welcoming Dinner under the auspices of the Metropolitan Section of the Society. The toastmaster was Charles M. Schwab, past-president of the Society. The address of welcome was given by Col. Paul Doty, vice-president of the Society. Other speakers of the program included Edward J. Mehren, vice-president of the McGraw-Hill Publishing Co., who spoke as a representative of the engineering press, and Robert I. Rees, president of the Society for the Promotion of Engineering Education, who brought a message from the engineering educators of the country. The attendance exceeded 800.

Commemorative Services

On Sunday commemorative services were held at the Cathedral of St. John the Divine. The official party upon this occasion was headed by Robert L. Daugherty, vice-president of the Society.

At 3.50 p.m. the A.S.M.E. special train left for Washington with the official party, arriving there at 8.30.

Welcoming Assembly

The headquarters in Washington was at the Mayflower Hotel, and as in New York, the first order of the day was registration, the presentation of credentials, and the distribution of badges.

At 10 a.m. the welcoming assembly was held in the flag-draped National Council Chamber of the U. S. Chamber of Commerce Building, a few blocks from headquarters. Ralph E. Flanders, vice-president of the Society, presided.

Mr. Piez, president of the Society, whose illness prevented his attendance, was represented by the six vice-presidents of the Society, Paul Doty, William Elmer, Conrad N. Lauer, Robert L. Daugherty, Charles E. Gorton, and Mr. Flanders.

Mr. Flanders spoke feelingly of the absence of President Piez. He then reminded his audience of the death of Chief Justice Taft, of his splendid and fearless life, and of the remembrance that the Society would always have of his address to them in 1917, and asked that all stand for a moment in honor of his memory.

In welcoming the delegates in the name of the Society, Mr. Flanders assured them of the appreciation with which their greetings were received. He then turned the meeting over to the Secretary of the Society, Calvin W. Rice, who introduced the delegates from engineering organizations both of other countries and of our own, who brought greetings and addresses from their fellow-engineers. A complete list of all delegates will be found at the end of this account. The countries and their representatives were as follows:

Australia, A. H. Chapman
Austria, Adolf Giesl-Gieslingen
Belgium, Albert de Smaele
Canada, Alexander J. Grant
Colombia, Julio Garzon Nieto
Denmark, A. C. Gronbeck
France, Georges Claude
Germany, Karl Maybach
Great Britain, William Henry Patchell
Japan, A. Ouchi
Mexico, Norberto Dominguez
Netherlands, Auguste Plate
Norway, Bjarne Johnsen
Union of South Africa, Wesley Ernest John
Sweden, Vilhelm Nordström
Switzerland, Henry A. Naville
Turkey, L. A. Scipio

Cuba's delegate was not present, but sent greetings by telegraph. Czechoslovakia's greetings were given by the Czechoslovakian minister. Senator Luiggi, who was to have brought Italy's greetings but unfortunately was taken ill upon his arrival, was unable to attend any of the sessions, at which universal regret was expressed.

Greetings from the engineering organizations in the United States were brought by Francis Lee Stuart, representing the American Society of Civil Engineers, by William H. Bassett, president of the American Institute of Mining and Metallurgical Engineers, and by Harold B. Smith, president of the American Institute of Electrical Engineers.

The engineering colleges in the United States were represented by Palmer C. Ricketts, president of Rensselaer Polytechnic Institute, while Admiral David W. Taylor presented the greetings from the scientific and professional societies in the United States. The business organizations of the United States had for their spokesman William Butterworth, president of the United States Chamber of Commerce.

The beautifully engrossed greetings and elaborately illuminated scrolls brought by the delegates and representatives were later put on display in the Chinese Room of the Mayflower Hotel, and were the object of much admiration throughout the meeting.

Humanistic Aspects of Engineering

Sixteen monographs had been prepared covering the social and economic effects of engineering upon the lives of the people represented by the distinguished engineers who had been chosen to receive the Fiftieth Anniversary Medal which had been struck in memory of the occasion.

Charles E. Gorton, vice-president of the A.S.M.E., acted as chairman at the first session for the presentation of the addresses summarizing the monographs.

These summarizing addresses were outlined in the account of the Fiftieth Anniversary celebration published in the May, 1930, issue of *Mechanical Engineering*. The complete monographs are to be published in book form. The names of those who prepared the monographs and presented the addresses are given in the following paragraphs.

The Austrian monograph was edited by Hofrat Ing. Ludwig Erhard, director, Technical Museum, Vienna, and president of the Oesterreichischer Verein deutscher Ingenieure. The co-editors were Prof. Ing. Josef Fugiewicz, mining, Prof. Dr. Ing. Othmar Keil-Eichenthurm, foundry, General Direktor Ing.

Friedrich Brock, power management, Sektionschef Ing. Bruno Enderes, communication, Oberbaurat Ing. Ernst Stelzer, technology, and Sektionschef Ing. Otto Kunze, technical institutions. Ing. Dr. Adolf Giesl-Gieslingen made the summarizing address.

The Belgian monograph was prepared by a group consisting of The Honorable Georges Theunis, Minister of State, Dr. Edouard Gosselin, professor of physics at the Military School of Belgium, Prof. Edouard W. Bogaert, University of Brussels, and Chief Engineer of the Marine, Prof. Gommaire Von Engelen, University of Ghent, Prof. Chas. Hanocq, University of Liége, Prof. Gustave Gillon, University of Louvain, and Prof. René J. Bradfer, School of Mines and Metallurgy at Mons. The summarizing address was presented by Dr. Albert de Smaele.

The Canadian monograph was presented in abstract by its author, Brigadier-General Charles H. Mitchell, Dean, Faculty of Applied Science and Engineering, University of Toronto, and Past-President, Engineering Institute of Canada.

Ing. Dr. h. c. Emil Zimmler, President, Masaryk Academy of Work, contributed the Czechoslovakian monograph, and Dr. Josef Z. Schneider presented the address summarizing it.

The address summarizing the French monograph was presented by Georges Claude, inventor and scientist. This memorial of engineering achievements in France was divided into chapters, each one of which had been edited by an outstanding specialist so that it might be as complete and as exact a document as possible. The authors were Maurice Michel-Schmidt, public works; Louis Breguet, aviation; Charles de Fréminville, the automobile; General Gustave Ferrié and Professor André Blondel, wireless telegraphy; Albert M. G. R. Portevin and M. Galibourg, metallurgy; Casimir Moteil, motors; Professor Denis Eydoux, hydraulics; Pierre Parent, mines; Professor Paul Boucherot, electrical engineering; Maxime Laubeuf, ships; Arsène d'Arsonval and M. Billardon, refrigeration; and Professor Camille Matignon and M. Montier, railways.

Dr. Ing. Conrad Matschoss, director of the Verein deutscher Ingenieure, author of the German monograph, delivered the address summarizing it.

The British monograph was summarized in an address by its author, Mr. Loughnan St. L. Pendred, president of the Institution of Mechanical Engineers and editor of *The Engineer* (London).

Prof. Dr. Ing. Luigi Luiggi, Senator, Kingdom of Italy, honorary member of the American Society of Civil Engineers, and member of the Institution of Civil Engineers, was the author of the Italian monograph. Although Senator Luiggi had come to this country especially to present the address summarizing his monograph, he was detained in New York on account of illness and his address was read Tuesday morning by C. E. Davies, assistant secretary, A.S.M.E.

Dr. Masawo Kamo, head of the department of mechanical engineering, Tokyo Imperial University, president of the Society of Mechanical Engineers of Japan, and honorary member of The American Society of Mechanical Engineers, was the author of the Japanese monograph and made the address summarizing it.

The presentation of the monographs covering the humanistic aspects of engineering was continued on Tuesday morning, with William Elmer, vice-president of the A.S.M.E., presiding.

Senor Ing. Norberto Dominguez presented the summarizing address of the Mexican monograph, of which he was the author.

The monograph devoted to engineering in The Netherlands was written by Prof. Ir. Daniel Dresden, president of the Jaffa Engine Works, who also presented the address summarizing it.

Vilhelm Nordström, manager of the De Laval Steam Turbine Company, Sweden, delivered the address summarizing the monograph from the Scandinavian countries. Mr. Nordström's collaborators in writing the monograph were Ing. Povl Vindig, past-president, Danish Engineering Society, Denmark; Ing. Prof. B. Wuolle, professor of industrial economy, Technical University of Helsingfors, Finland; and Ing. Reidar Lund, consulting engineer, Norway.

The Colombian monograph was written by Prof. Julio Garzon Nieto, chief engineer for the Ministry of Foreign affairs, who presented it in abstract.

The monograph on engineering in the southern countries of South America was written by Prof. Donato Gaminara, of Uruguay. The address summarizing it was delivered by Dr. L. S. Rowe, director-general of the Pan-American Union, Washington, D. C.

The chief editor of the Swiss monograph was Prof. Dr. Aurel Stodola, Grashof Medalist of the Verein deutscher Ingenieure. The collaborators in preparing the monograph were Prof. Dr. B. Bauer, electrotechnology; Prof. Dr. E. Böhler, political economy; Dr. h. c. E. Huber-Stockar, railways; Prof. E. Meyer-Peter, hydraulics; and Prof. Dr. W. Wyssling, power development. Henry A. Naville, of the Brown-Boveri, presented the summarizing address.

For the United States, Dr. Carl E. Grunsky, consulting engineer, president of the American Engineering Council and past-president of the American Society of Civil Engineers, delivered an address in which he summarized the monograph which he had written on the influences of engineering in this country. Following Dr. Grunsky, Dr. Fred R. Low, past-president of the A.S.M.E. and editor-emeritus of *Power*, presented "A Half-Century of Progress in Mechanical Engineering in the United States," a group of reports prepared by the Professional Divisions of the A.S.M.E. and their representatives.

The Founders' Luncheon

On Tuesday noon, at the Mayflower Hotel, a luncheon was served at which special medals were presented to the six living founder members of the Society; Ambrose Swasey, Robert F. Grimshaw, John S. Coon, Francis H. Richards, John W. Cloud, and Eugene H. Robbins. These medals were identical with the Fiftieth Anniversary Medal except that the inscription on the obverse had been changed to make the medal appropriate to the occasion. John R. Freeman, past-president of the Society, acted as chairman of the ceremonies of presentation, and Prof. Robert L. Daugherty, vice-president, presented the medals and the certificates which accompanied them. Of the six living founder members, Ambrose Swasey and Robert Grimshaw were the only ones at the luncheon. Mr. Swasey and Mr. Grimshaw made brief addresses in response to the applause that greeted them when the medals were awarded.

The medals awarded to the other four were received in their absence by well-known members of the Society, Edward N. Trump representing Mr. Coon, George Bond representing Mr. Richards, Prof. Wm. T. Magruder representing Mr. Cloud, and Dean R. L. Sackett representing Mr. Robbins.

The Conferring of Honors

The most impressive session of the Fiftieth Anniversary Celebration was the convocation for the conferring of honors held on Tuesday afternoon in the National Council Chamber of the United States Chamber of Commerce Building. These exercises were made memorable not only because of the distinguished engineers who were to receive the awards, but also because of the fact that the chief diplomatic officer of each country presented to the Society for the conferring of the Fiftieth Anniversary Medal the engineer selected for this honor by the engineering profession of his country.

The marshals for the occasion, appropriately robed, escorted the medalists and the ambassadors from the reception room at

the right of the stage to seats in the front of the room. The marshals were the members of the Society's committee on awards: Kenneth H. Condit, Arthur M. Greene, Jr., Herbert L. Seward, and Roy V. Wright. On the stage were Conrad N. Lauer, vice-president of the Society, who acted as chairman and presented the medals, Dr. Wm. F. Durand, president, Guggenheim Medal Board, L. P. Alford, chairman of the Gantt Medal Board, and C. E. Davies, assistant secretary of the Society.

The Fiftieth Anniversary medals were presented first. The ambassador or other diplomatic officer of the country represented by the medalist, and the medalist were escorted to the platform by the marshals, the ambassador approaching from the right of Mr. Lauer, and the medalist from his left. The ambassador was then presented to Mr. Lauer, and in turn presented the medalist. Mr. Lauer then delivered a brief address citing the distinguished achievements of the medalist and presented him with the Anniversary Medal in bronze. A gold replica of the medal was then pinned to the medalist's coat and the party left the stage. The same procedure was followed in presenting the Daniel Guggenheim Medal, the Gantt Gold Medal, the A.S.M.E. Medal, and the Melville Medal, with the exception that Dr. Durand presented the Guggenheim Medal and L. P. Alford the Gantt Medal. A list of the medalists follows.

A.S.M.E. Fiftieth Anniversary Medalists

Austria. Hofrat Ing. Ludwig Erhard. Represented by His Excellency Edgar L. Prochnik, Minister to the United States.

Ludwig Erhard is director of the Technical Museum in Vienna, honorary member of the Technical University of Vienna, and president of the Oesterreichischer Verein deutscher Ingenieure. He was born at Passau, Bavaria, in 1863, and attended the Technical University at Munich. He engaged in mechanical-engineering work for several years, was at the head of the Bavarian Museum for Industry and Craft in Vienna, and technical director of the Austrian Institute for the Promotion of Craft of the Chamber of Trade, Craft, and Industry in Vienna. The Technical Museum in Vienna, one of the world's great museums, owes its prominence to the work of Erhard, a most notable achievement.

Belgium. To the Fédération des Associations Belges d'Ingénieurs, under whose auspices the monograph for that country was prepared.

Bronze medals were presented to the authors. Baron Gaston S. P. de Bethune represented the Fédération at the Anniversary. He was presented by Vicomte de Lantsheere, Chargé d'Affaires, Belgian Embassy.

Canada. Brigadier-General Charles H. Mitchell. Presented by His Excellency Vincent Massey, Minister to the United States.

Charles Hamilton Mitchell, dean of the Faculty of Applied Science and Engineering of the University of Toronto since 1919, president of the Engineering Institute of Canada for 1929, and the recipient of many military honors, was born at Petrolia, Ontario, Canada, in 1872. He received the degrees of B.A.Sc., C.E., and honorary L.L.D. from the University of Toronto, served as city engineer of Niagara Falls, N. Y., as engineer for the Ontario Power Company of the same city, and conducted a consulting practice in Toronto for several years. He has had an outstanding military career and has received many honors including the D.S.O., C.M.G., and C.B. He is an officer of the Legion of Honor, France, Order of the Crown of Italy, and Order of Leopold, Belgium, and has been given the Croix de Guerre, Belgium, and the Croce di Guerra, Italy.

Colombia, S. A. Prof. Julio Garzon Nieto. Presented by The Honorable José M. Coronado, Chargé d'Affaires, Colombian Embassy.

Julio Garzon Nieto, civil engineer and since 1910 chief engineer of the Office of Longitudes of the Ministry of Foreign Affairs of Colombia, received diplomas from the Catholic University of Bogota in 1882 and from the National University of Colombia in 1887, and also a degree from Rensselaer Polytechnic Institute, Troy, N. Y., in 1894. He served for some time as professor in the Colegio Mayor de Nuestra Sonora del Rosario, in the National Lyceum, in the Artisans' Institute, and as a member of the faculty of Mathematics and Engineering in the National University of Colombia. He then went into engineering work and served first as chief engineer of public works of the Department of Cundinamarca and as engineer of the Girardot Railway. He has done notable work in connection with the adjustment and settlement of boundaries in South America. In 1900–1901 he was sub-chief engineer of the Colombian delegation engaged in the adjustment of the boundary between Colombia and Venezuela. In 1911 he was chief engineer for Colombia on the joint commission for determining the Colombian-Venezuelan boundary. He also was chief engineer of the Colombian delegation for the settlement of the boundary with Equador. Later, he was technical adviser of the Colombian Legations in Spain and in Switzerland during the arbitration with Venezuela from 1918 to 1922; and was chief engineer of the Colombian delegation for the settlement of the boundary with Venezuela during the work of the commission of Swiss experts who as arbitrators determined the definite delineation of the frontier with Venezuela in 1922–1923.

Czechoslovakia. Dr. Stan. Špaček. Represented by His Excellency Ferdinand Veverka, Minister to the United States.

Dr. Špaček, of Prague, civil engineer experienced in construction, railroad and highway engineering and reclamation service, and an authority on economics in relation to these phases of engineering, was born in Slepotice, Czechoslovakia, in 1876, and received his engineering training and degree at the Technical University in Prague. He was engaged from 1902 to 1920 in railroad service, on highway development, and on irrigation and land reclamation projects in connection with the improvement of agriculture in his country. He served in the technical attaché service in Prague, and became general secretary of the first International Congress for Scientific Management, in Prague. In 1929 Dr. Špaček was appointed chief of Section E for Technical Economics in the Ministry of Public Works in Prague. He is also Honorary Docent of Technical Economics on the faculty of the Technical University in Prague. He is an honorary member of the Society of Industrial Engineers, Chicago, and of the Association of Friends of the Masaryk Academy of Work, Prague.

France. M. Georges Claude. Presented by His Excellency Paul Claudel, Ambassador to the United States.

Georges Claude, scientist and inventor, was born in 1870. He devoted many years to research, invention, and new ways of producing materials for industrial application, especially the liquefaction of air and of oxygen and hydrogen, the production of nitrogen and ammonia, and the industrial use of the new rare gases, argon, neon, and helium. One of his earliest achievements was the invention of the process in which acetylene is dissolved and stored under pressure in acetone, and which has made acetylene available for many uses in other countries as well as in France.

He made possible the production of pure oxygen by fractional distillation and rectification, on a scale that permits its use in industry. In 1914 he developed the liquid-oxygen bomb. Through years of work (1900–1914) he developed a process of producing pure nitrogen, and later (1918–1925) another for the fixation of nitrogen by synthesis of ammonia under high pressure. In connection with this synthesis he accomplished the preparation of hydrogen by liquefaction and distillation. He has developed the transformation of ammonia with a view to its use as fertilizer, by starting with sylvinite, and this has been accomplished with a correlative production of carbonate of soda. The industrial separation of the gases, argon, helium, and neon from the air was the subject of research and investigation by Mr. Claude during the years 1907 to 1928. He conceived and developed the neon light. At the present time he is engaged in investigations relating to the industrial extraction of thermal energy from the sea, the successful achievement of which will be of great importance.

Germany. Prof. Dr. Ing. Conrad Matschoss. Presented by His Excellency Friedrich W. von Prittwitz und Gaffron, Ambassador to the United States.

Conrad Matschoss, Director of the Verein deutscher Ingenieure (Society of German Engineers), and promoter of engineering interests and technical education in Germany, was born in 1871 at Neutomischel (Posen). After attending high school he studied engineering at the Technical University of Hanover. From 1898 to 1906 he taught mechanical engineering in the State College of Engineering at Cologne. In 1906 he became associated with the Verein deutscher Ingenieure as a member of the editorial staff of the society's publications. During the next two years he also completed his work on the "Development of the Steam Engine," and in 1908 it was published in two-volume form under the auspices of the society. Under his editorship the society then initiated the series of annual publications entitled "Beitrage zur Geschichte der Technik und Industrie"

(Contributions to the History of Engineering and Industry), of which nineteen volumes have appeared. Another work was one on the German hydraulic laboratories. Dr. Matschoss has also edited a series of books on behalf of the German Museum. Since 1909 he has lectured on the history of engineering at the Technical University, Berlin, in addition to his other duties.

Great Britain. MR. LOUGHNAN ST. L. PENDRED. Presented by His Excellency Sir Ronald Lindsay, Ambassador to the United States.

Loughnan St. L. Pendred, editor of *The Engineer* (London) and President, 1930–1931, of the Institution of Mechanical Engineers, was born in 1870. He received his technical education at the City and Guilds of London Institute, South Kensington, and the Technical College, Pinsbury. Mr. Pendred then indentured himself as an apprentice to James N. Paxman, head of Davey, Paxman and Company, Ltd., of Colchester. Finishing his time there, he went to Ghent in Belgium, where he spent some months in the works of Van den Kerchove and then went to the Chemin de Fer de l'Ouest, now the French State Railways, where he worked both in the railway shops and the office. On his return from France he entered the Ordnance Department of Sir W. G. Armstrong, Whitworth and Company, Ltd. He joined the editorial staff of *The Engineer* in 1896.

Italy. PROF. DR. ING. LUIGI LUIGGI. Represented by His Excellency Giacomo de Martino, Ambassador to the United States.

Dr. Luiggi, Senator of the Kingdom of Italy, honorary president of the National Council of Public Works of Italy, consulting engineer for harbors, rivers, and canals, member of international commissions on navigation works, was born in Genoa in 1856. He attended the University of Genoa, took his degree in civil engineering at the Royal University of Turin in 1878, pursued a special course in harbor engineering in the principal English ports for a year, and at the present time is professor of harbor engineering at the University of Rome. In 1896 the Argentine Government invited Dr. Luiggi to take charge of harbor works at Bahia Blanca, where he carried out extensive constructions, including graving docks, piers, barracks, and other buildings, and batteries. Later he built a system of lighthouses and semaphoric and telegraph stations along the coast of Patagonia; he also served as consulting engineer for new harbor works at Buenos Aires, Rosario, and Montevideo, and on inland irrigation works. In Africa, Dr. Luiggi prepared plans for the improvement of two harbors on the Red Sea, and was entrusted by the Italian Government with projects and works in the harbors of Tripoli and other cities. Since 1913 he has been a member of the International Committee for the Suez Canal, and of the European Commission for the Navigation of the Danube. In 1923, for the Egyptian Government, he prepared plans for the improvement of the harbors of Suez and Alexandria, and in 1926 planned other Egyptian works. He has also been consulted by the Greek and the Albanian governments.

Japan. DR. MASAWO KAMO. Presented by His Excellency Katsuji Debuchi, Ambassador to the United States.

Dr. Kamo, head of the Department of Mechanical Engineering of Tokyo Imperial University, member of the engineering standards committee of the Japanese government, and president of the Society of Mechanical Engineers of Japan, was born in Tokyo in 1876. He was educated at the Tokyo Imperial University and Engineering College, receiving the degrees of M.E. and Doctor of Engineering. Later he studied thermodynamics and applied mechanics in England and Scotland, and for three years made a special study of steam turbines and refrigerating machinery in the United States. Dr. Kamo has been on the faculty of Tokyo Imperial University since 1898, and head of its department of mechanical engineering since 1912. As professor of mechanical engineering he has held the chair of thermodynamics and steam turbines; he has also been a lecturer on cold storage and refrigeration on the Faculty of Agriculture, and on outlines of engineering industry on the Faculty of Economics. In addition to his service in standardization work in Japan, Dr Kamo designed the machinery departments for the first turbine steamers in Japanese waters, and for the training ship of the Japanese Nautical College.

Mexico. SEÑOR ING. NORBERTO DOMINGUEZ. Presented by His Excellency Manuel C. Téllez, Ambassador to the United States.

Norberto Dominguez, Secretary of the Asociación de Ingenerios y Arquitectos de Mexico, lecturer, newspaperman, and author of articles on literary, political, and economic subjects, has also been active for many years in federal service in Mexico and as representative of his country elsewhere. He was born in Hidalgo del Parral, Chihuahua, Mexico, in 1867. Shortly after completing the mining engineering course at the Escuela Nacional de Ingenieros in the City of Mexico, he was appointed assayer and inspector at the Durango branch of the federal mint. Subsequently he was transferred to the post of chief of the federal assay office at Monterey, and in 1898 to that of director of the mint at Culiacan. In 1903 Señor Dominguez was appointed Postmaster-General of the Republic by President Diaz, who, eight years later, transferred him to his cabinet as Minister of the Department of Public Works. President Huerta appointed him to posts of responsibility in his government, including that of Chief of the Department of Commerce. In 1920, Señor Dominguez was elected to the House of Representatives from the District of Parral. Subsequently he served as mining engineer with different interests; as editor of the illustrated review, *Reconstruccion;* and as director of the newspaper, *El Comercio.* He is the author of several books.

Netherlands. PROF. DR. DANIEL DRESDEN. Presented by His Excellency J. H. van Royen, Minister to the United States.

Daniel Dresden, since 1928 president of the Jaffa Engine Works, Utrecht, Netherlands, was born in Amsterdam in 1886 and obtained his early technical training there. Later he attended the Technical Academy at Delft, from which he received a degree in mechanical engineering in 1910. After engaging for a short time in the design and manufacture of safes and locks at the Lips works, and in designing a power station and distributing system in Leeuwarden, Professor Dresden became associated with Stork Brothers, of Hengelo, Netherlands, as chief designing engineer in their steam-turbine and centrifugal-pump departments. In 1920 he was appointed professor of mechanical technology at the Technical Academy of Delft. Since that time he has also served as consulting engineer for municipal power stations and made study trips and steam-turbine tests in Switzerland, France, Scandinavia, Hungary, Czechoslovakia, Spain, and the United States.

Sweden. MR. VILHELM NORDSTRÖM. Presented by His Excellency W. Bostrom, Minister to the United States.

Vilhelm Fredrik André Nordström, technical manager of the De Laval Steam Turbine Company, Stockholm, was born at Gefle, Sweden, in 1883. He was graduated from the Royal Technical University of Stockholm in 1905, and until 1911 was associated with Prof. J. E. Cederblom's Mechanical Laboratory, devoting himself to aerodynamics and steam power. The following year he was graduated from the Commercial Institute of Stockholm and became connected with the De Laval Company. He was appointed to his present position in 1918. Mr. Nordström served as Swedish delegate to the conference of the International Electrotechnical Commission in New York in 1926, and to the meeting of the I.E.C. Advisory Committee No. 5 on Steam Turbines at The Hague in 1928. He contributed a paper on "High Steam Pressures" to the World Power Conference in London in 1924.

Switzerland. PROF. DR. AUREL STODOLA. Represented by His Excellency, Marc Peter, Minister to the United States.

Aurel Stodola, professor of mechanical engineering at the Swiss Federal Technical University, Zurich, from 1892 to 1929, and distinguished engineer and author in the field of heat engines, was born in Liptó-Szent Miklós, Hungary (now part of Czechoslovakia), in 1859. He was graduated from the Swiss Federal Technical University in 1881, and later studied in Berlin and Paris. Prior to his appointment as professor at the University of Zurich he was connected with Staatsmaschinenfabrik, of Budapest, and the Prager Maschinenfabrik, formerly Ruston & Co., of Prague. Dr. Stodola has published numerous scientific papers and treatises on heat engines, and his treatment of this subject in his book entitled "Dampf und Gasturbinen" won him the Grashof Medal of the Verein deutscher Ingenieure. The book has been translated into both English and French.

United States. DR. C. E. GRUNSKY. Presented by the Honorable Joseph P. Cotton, the Acting Secretary of State.

Carl Ewald Grunsky, consulting engineer, San Francisco, authority on municipal utility management, past city engineer of San Francisco and adviser on irrigation and reclamation, was born in 1855 near Stockton, San Joaquin County, California. After graduating from the Stockton high school in 1870 he went to Stuttgart, Germany, for his engineering education, and in 1877 was graduated from the Polytechnic Institute in that city. For the following ten years he worked in the California State Engineer's Department. During this service he had charge of irrigation investigations in the Great Central Valley of California and made special studies of the water resources of the state, giving attention to rainfall and streamflow and to methods of water utilization. The Governor of California appointed him a member of the Examining Board on Rivers and Har-

bors, and later he became consulting engineer on flood-control studies under the State Commissioner of Public Works. Mr. Grunsky established himself as consulting engineer first at Sacramento and then in San Francisco. He was engineer for a number of irrigation districts, notably the Modesto, and on water and sewerage projects for the city of San Francisco. From 1899 to 1903, under its new charter, Mr. Grunsky was city engineer of San Francisco; under his recommendation the development of a water supply from the Tuolumne River and the Hetch Hetchy project was started. In 1904 President Roosevelt appointed him a member of the Panama Canal Commission; the next year, when the Canal Commission was reorganized, Mr. Grunsky was appointed consulting engineer in the U. S. Reclamation Service and adviser to the Secretary of the Interior on reclamation problems. He resigned in 1907 to take up private practice.

Uruguay, S. A. PROF. DONATO GAMINARA. Represented by His Excellency J. Varela, Minister to the United States.

Donato Gaminara, civil engineer, was born in Montevideo, Uruguay, in 1886, and was graduated in civil engineering in 1906 from the university in that city. He became a professor in the university, and later was dean of its engineering faculty and professor of ports and lighthouses. He was engaged in engineering work for three years in Rio Grande do Sul, in New York for one year, and is now engaged in consulting engineering work in Uruguay. Señor Gaminara is a past-president of the Society of Civil Engineers of Uruguay and of the Society of Engineers of Montevideo, and a past governor of the Rotary International for the district covering Argentina, Brazil, and Uruguay. He was a member of the Pan-American Highway Commission to the United States in 1924.

THE DANIEL GUGGENHEIM MEDAL

First Award

Medalist for 1929, ORVILLE WRIGHT. Medal presented by Wm. F. Durand, President, Guggenheim Medal Board.

"To Orville Wright, for design and construction, with his brother, now deceased, of the first successful engine-propelled airplane." With such simplicity of citation the Board of Award bestowed the first Daniel Guggenheim Medal. But the achievement itself is one which had baffled scientists, technicians, practical men, and dreamers ever since the first inquiring mind watched a bird in flight.

Orville Wright was born in Dayton, Ohio, in 1871, and educated in the public schools. He and his brother Wilbur experimented with models of airplanes practically all their lives. They saw the problem of successful flight as two-fold: First, they figured they must produce some form of glider which would stay in the air long enough to give them actual experience in the air; and then they needed an engine light enough but powerful enough to supply adequate motive power. The story of their experiments with gliders, and of their development of an engine which would successfully raise and keep a plane aloft, is a familiar one. Their first successful flight with a heavier-than-air machine was made on December 17, 1903. They are the inventors, too, of the system of controls used in practically all flying machines today.

THE GANTT GOLD MEDAL

Medalist for 1930, FRED J. MILLER. Presented for the award by Dexter S. Kimball, Past-President of the A.S.M.E. Medal presented by L. P. Alford, Chairman, Gantt Medal Board.

When Fred J. Miller was factory manager for the Remington typewriter factories, he engaged Mr. Gantt as his consultant on management problems, and a friendship began between the two men which terminated only with Mr. Gantt's death. In recognition of the fact that Mr. Miller, in the Remington factories, made one of the first applications on a large scale of sound principles of scientific management, the Gantt Gold Medal for 1930 has been awarded to him.

Fred J. Miller was born at Yellow Springs, Ohio, in 1857. After a high-school education he entered industry to serve a four-year apprenticeship as a machinist. He became interested in shop-management problems early in life, and while acting as foreman of Warder, Bushnell, Glessner and Company he published accounts of the methods he was using there which attracted the attention of the *American Machinist*. The result was that he was called by the *American Machinist* to an editorial position, from which he rose to be editor-in-chief. After twenty years in journalism, Mr. Miller was for nine years general manager of the group of Remington typewriter factories. During the war he was commissioned Major of Ordnance in the United States Army, where he was engaged in organization and personnel work. He was president of the A.S.M.E. in 1920.

A.S.M.E. MEDAL

Medalist for 1929, WILLIAM LEROY EMMET. Presented for the award by Arthur M. Greene, Jr., Chairman, Committee on Awards of the Society. Medal presented by Conrad N. Lauer, Vice-President of the Society.

The award of the A.S.M.E. Medal for 1929 was made to Mr. William LeRoy Emmet for his "contributions in the development of the steam turbine, electric propulsion of ships, and other power-generating apparatus." He directed the development of the Curtis turbine by the General Electric Company, every detail of which was radically new; designed the machinery for the first ship driven by electric motors; was the first serious promoter of electric ship propulsion; and developed the mercury-vapor power process.

Mr. Emmet was born in 1859 at Pelham, N. Y., and was graduated from the U. S. Naval Academy. He left the Navy, however, to take up electrical engineering. His most important electrical work has been in the development of the general use of alternating currents and in the invention and design of machinery to further their practical application. In the mechanical-engineering field, his work in the development and introduction of the steam turbine has been outstanding. He is the inventor of the vertical-shaft steam turbine, of which a large number have been built, and many details of turbine design now in general use are to his credit. He is best known recently for the development on a commercial scale of the mercury-vapor process for the generation of power.

MELVILLE MEDAL

Medalist for 1929, JOSEPH WICKHAM ROE. Presented for the Award by Arthur M. Greene, Jr., Chairman, Committee on Awards of the Society. Medal presented by Conrad N. Lauer, Vice-President of the Society.

Professor Roe's paper, "Principles of Jig and Fixture Practice," presented at the Annual Meeting of The American Society of Mechanical Engineers in December, 1928, won for him the award of the Melville Medal for 1929. The Committee's decision to award the medal for this paper as "a thesis of exceptional merit" is based upon the fact that it presents for the first time in condensed form a résumé of the principles of design of jigs and fixtures, and adapts the formulas derived by the Society's Materials Handling Division to the economic problems involved in determining the investment justified in jigs and fixtures.

Joseph W. Roe was born in New York in 1871 and was graduated from Sheffield Scientific School in 1895. He became interested in machine tools, their problems in design and manufacture, early in life, and had years of practical experience with these problems, with various firms, before entering the profession of teaching. His book, "English and American Tool Builders," is an important historical contribution on the machine-tool industry. Professor Roe's interests, apart from engineering education, still lie in the machine-tool field and in the practical problems of industrial management. He has served as president of the Society of Industrial Engineers. In 1925 he directed a study of civil aviation for the Department of Commerce and the American Engineering Council. (He had been a major in the Air Service of the United States Army during the World War.) He accepted his present position as professor of industrial engineering and head of the department of industrial engineering at New York University in 1920, following more than a decade as a member of the engineering faculty at Yale.

THE ANNIVERSARY DINNER

The Fiftieth Anniversary Dinner was held at the Mayflower Hotel on Tuesday night. At seven o'clock, their excellencies, the ambassadors of the several countries whose engineers had been honored at the convocation for the conferring of awards, their wives, and guests having assembled with the members of the Society and their guests to the number of more than eight hundred, four flourishes of the trumpet announced the arrival of the President of the United States and his party, and as the Marine Band played "Hail to the Chief," the President crossed the room and took his place amid enthusiastic applause.

Following the dinner the toastmaster, Dr. William F. Durand, past-president of the Society, expressed the great regret which every one felt at the unavoidable absence of Charles Piez, president of the Society, and called upon Secretary Calvin W. Rice to read the greeting which Mr. Piez had written.

Dr. Robert A. Millikan, director of the Norman Bridge Labo-

ratory of Physics of the California Institute of Technology, Pasadena, Calif., Nobel prize winner in physics in 1923, A.S.M.E. medalist in 1926, Edison medalist of the A.I.E.E., Hughes medalist of the Royal Society of Great Britain, research physicist, author, interpreter of science to the layman, was the principal speaker. His address dealt with the bond between pure physics and engineering, and was divided into four parts, having to do with (1) the direction and shape of the curve of history itself, (2) the method that seems to have been used in drawing that upward curve, (3) the identification of its draftsmen, and (4) what seem to be our own opportunities and responsibilities as scientists and engineers in connection with it. The address was summarized in *Mechanical Engineering*, May, 1930, page 525.

The Hoover Gold Medal Award

The first award of the Hoover Gold Medal, commemorating the civic and humanitarian achievements of Herbert Hoover, was presented to the man for whom it was named.

The trust fund creating the award was the gift of Conrad N. Lauer, of Philadelphia. It is held by The American Society of Mechanical Engineers and is administered by a Board of Award consisting of representatives of the American Society of Civil Engineers, the American Institute of Mining and Metallurgical Engineers, The American Society of Mechanical Engineers, and the American Institute of Electrical Engineers. The medal is to be awarded by engineers to a fellow-engineer for distinguished public service.

J. V. W. Reynders, past-president of the American Institute of Mining and Metallurgical Engineers, delivered the address presenting the medalist, and following Mr. Reynders' address, Dean Dexter S. Kimball, president of the Board of Award and past-president of the A.S.M.E., presented the medal to the Honorable Herbert Hoover. His response was included in the report of the celebration in the May, 1930, issue of *Mechanical Engineering*.

Wednesday in Washington

Wednesday in Washington was devoted to excursions, sightseeing, and the reception at the White House. The first excursion of the morning was to the Navy Yard to see the naval gun factory, the experimental model basin, the wind tunnel, and the diving school. Sightseeing tours of Washington, Arlington, Georgetown, Fort Meyer, and Mount Vernon were arranged for those who did not visit the Navy Yard. In the afternoon the Bureau of Standards, where special arrangements had been made to inspect the laboratories where work was in progress, and other important government buildings were visited. At the White House Reception, President and Mrs. Hoover shook hands with more than one thousand guests.

Institutions Officially Represented at the Fiftieth Anniversary Celebration

Agricultural and Mechanical College of Texas
L. W. Wallace, Edgar C. Rack

Albany Society of Engineers
Ernest McN. Scarle

American Academy of Arts and Sciences
Lionel S. Marks, Edward Furber Miller

American Association for the Advancement of Science
Robert A. Millikan, Charles Russ Richards

American Association of Engineers
Harold Almert, D. B. Steinman

American Association of Petroleum Geologists
Arthur Knapp

American Association of State Highway Officials
Jacob L. Bauer, H. D. Williar

American Association of University Professors
George B. Pegram, William T. Magruder

American Astronomical Society
Raymond S. Dugan

American Automobile Association
George C. Diehl

American Boiler Manufacturers Association
George S. Barnum, E. R. Fish

American Bureau of Welding
C. A. McCune, H. L. Whittemore

American Ceramic Society
Ross C. Purdy

American Chemical Society
Elmer A. Sperry, W. M. Corse

American Concrete Institute
Maxwell M. Upson, P. H. Bates

American Economic Association
Horace B. Drury, Harlow S. Person

American Electric Railway Association
A. T. Clark, R. H. Dalgleish

American Electrochemical Society
Elmer A. Sperry

American Engineering Council
Carl E. Grunsky, A. W. Berresford

American Forestry Association
George H. Collingwood

American Foundrymen's Association
Guilliam H. Clamer, Fred Erb

American Gear Manufacturers Association
George L. Markland

American Gas Association
Conrad N. Lauer, John A. Clark, Jr.

American Geographical Society
Hamilton Fish Kean, Frederic C. Walcott

American Institute of Architects
Frederick L. Ackerman, William I. Deming, William L. Plack, Stephen F. Voorhees

American Institute of Chemical Engineers
H. C. Parmelee, Alfred H. White

American Institute of Consulting Engineers
Philip W. Henry, Frederic A. Molitor

American Institute of Electrical Engineers
Harold B. Smith, A. W. Berresford

American Institute of Mining and Metallurgical Engineers
W. H. Bassett, George D. Barron

American Institute of Refrigeration
Louis Baron, Wrisley Brown

American Institute of Steel Construction, Inc.
L. H. Miller

American Institute of Weights and Measures
C. R. Burt, Walter M. McFarland

American Library Association
George F. Bowerman, Albert F. Zahm

American Management Association
C. S. Ching, Thomas R. Jones

American Mathematical Society
George A. Campbell, E. V. Huntington

American Physical Society
George K. Burgess, Harvey N. Davis, Arthur L. Day, H. E. Ives

American Railway Association (Mechanical Division)
J. E. Ennis, G. W. Rink

American Railway Engineering Association
C. C. Cook, John R. Leighty

American Society for Municipal Improvements
Edward S. Rankin

American Society for Steel Treating
Francis F. Lucas, John A. Mathews

American Society for Testing Materials
T. D. Lynch, A. A. Stevenson

American Society of Agricultural Engineers
S. H. McCrory, R. W. Trullinger

American Society of Civil Engineers
WILLIAM BARCLAY PARSONS, FRANCIS LEE STUART

American Society of Heating and Ventilating Engineers
W. H. CARRIER, L. A. HARDING

American Society of Naval Engineers
R. W. PAINE, O. L. COX

American Society of Refrigerating Engineers
H. D. EDWARDS, DAVID L. FISKE

American Society of Swedish Engineers
ERIC A. LOF, ROBERT WERNER

American Standards Association
WILLIAM J. SERRILL, A. A. STEVENSON

American Welding Society
J. H. DEPPELER, J. C. LINCOLN

Army Ordnance Association
L. A. CODD, C. G. METTLER

Asociacion de Ingenieros y Arquitectos de Mexico
GUILLERMO B. PUGA, NORBERTO DOMINGUEZ

Association des Ingénieurs Conseils de la République Tchécoslovaque
J. NOVAK

Association of Czechoslovakian Engineers and Architects in Praha
JOSEF Z. SCHNEIDER

Association of Edison Illuminating Companies
W. L. ABBOTT

Association Technique Maritime et Aéronautique (France)
MASON SMITH CHACE, WILLIAM F. DURAND

Bergakademie Clausthal (Germany)
HERMANN MAIER-LEIBNITZ

Bergakademie Freiberg (Germany)
FREDERICK GLEASON CORNING, OTTO FRITZSCHE, HERMANN MAIER-LEIBNITZ

British Association for the Advancement of Science
P. J. COWAN

British Engineering Standards Association
WILLIAM HENRY PATCHELL, LOUGHNAN ST. L. PENDRED

Brooklyn Engineers Club
W. W. MACON

Brown University
JAMES ALEXANDER HALL, WILLIAM H. KENERSON

California Institute of Technology
R. L. DAUGHERTY, ROBERT A. MILLIKAN

Carnegie Institute of Technology
THOMAS S. BAKER, SUMNER B. ELY

Carnegie Institution of Washington
ARTHUR L. DAY, J. A. FLEMING

Case School of Applied Science
PAUL J. KIEFER

Catholic University of America
THOMAS J. MACKAVANAGH, GEORGE A. WESCHLER

Chalmers Tekniska Institut (Sweden)
ERIC A. LOF., ROBERT WERNER

Chemical Society (England)
MARCUS BENJAMIN, H. D. DAKIN

Chicago Technical College
CHARLES W. MOREY

Clarkson Memorial College of Technology
JOHN ALEXANDER ROSS, JR., JOSEPH EUGENE ROWE

Clemson Agricultural College
S. B. EARLE, B. E. FERNOW

Cleveland Engineering Society
WARNER SEELY

College of the City of New York
ARTHUR BRUCKNER, FREDERICK KUHLEN

Columbia University
CHARLES EDWARD LUCKE, WILLIAM A. SHOUDY

Cooper Union
GEORGE F. BATEMAN, F. M. HARTMANN

Cornell University
DEXTER S. KIMBALL

Dansk Ingeniörforening (Denmark)
HAROLD I. FEIIS, A. C. GRONBECK

Dartmouth College
HAROLD JOHN LOCKWOOD

Den Norske Ingeniörforening (Norway)
BJARNE JOHNSEN, C. B. THORNE

Den Polytekniske Forening
HELGE SCHIBSTED

Detroit Engineering Society

Semi-Annual Meeting, Detroit, Mich.

MORE than 600 members of the Society and their guests attended the Semi-Annual Meeting at Detroit, Mich., from June 9 to 12, 1930. Technical sessions and business and committee meetings were held at the Book-Cadillac Hotel.

Because of his continued illness, President Piez was unable to be present to preside at the meeting of the Council, held on Monday morning. Representing him was Colonel Paul Doty, Vice-President of the Society. Past-President Dow was on hand to welcome the Council to Detroit.

A meeting of the standing committee on Local Sections was held Sunday preceding the opening of the meeting; a conference of Local Sections' delegates took place Tuesday morning; and a luncheon of Council with the Local Sections' delegates Tuesday noon. The delegates of the Student Branches held a conference on Wednesday morning. Technical and executive committees were in session throughout the week. Two committee organization meetings were held, those of the technical committees on Splines and Splined Shafts and on Milling Machine Tables, both of which have been created to deal with sections of the work on the standardization of small tools and machine tool elements.

As a result of daily meetings of the Nominating Committee the following nominees for the offices of the Society for 1931 were presented:

President, Roy V. Wright
Vice-Presidents, William A. Hanley, Thomas R. Weymouth, Harvey N. Davis
Managers, W. L. Batt, H. L. Doolittle, H. L. Whittemore
American Engineering Council Delegates, W. R. Webster, Roy V. Wright, Joseph W. Roe, D. Robert Yarnall, E. N. Trump, B. E. Hull, E. O. Eastwood, W. Trinks, Warner Seely, William S. Conant.

For the purpose of receiving discussion of its test code for complete steam-electric power plants, a public hearing of the Power Test Codes Committee was held on Monday morning. Much valuable discussion was presented for consideration in the final revision of the code.

The technical sessions of Monday afternoon were preceded by a business meeting at which Colonel Doty presided. Calvin W. Rice, Secretary, presented for its first reading an amendment to the Constitution of the Society increasing initiation fees for Members and Associates from $25 to $35, establishing a fee of $10 for promotion from Associate Member to Member, and changing the fifteen-dollar fee for the promotion of a Junior to a higher grade to a fee of $15 for his promotion to Associate Member and $25 for promotion to Member. It was voted to submit the amendment to the membership for letter ballot.

Entertainment

The program of entertainment opened with an informal reception and dance on Monday evening. C. F. Hirshfeld, manager of the Society, gave an address of welcome to which a response was made by Colonel Doty.

On Tuesday night the men were entertained at a smoker. Vaudeville players from the Detroit theaters offered a variety of song and dance numbers.

A high point in entertainment was the boat ride on Wednesday, in which approximately 300 members and guests participated. The steamer *Eastern States*, which had been chartered for afternoon and evening, took the party up the Detroit River, past Belle Isle, through Lake St. Clair into the St. Clair River, as far as the Marysville plant of the Detroit Edison Company. The weather was delightful and the ride scenically interesting.

A quartette sang frequently through the afternoon and evening and the program included dancing, deck games, and cards, as well as an excellent dinner.

Inspection Trips

Detroit, with its many automobile manufacturing plants and other interesting industries, provided an ideal location for inspection trips. The general program had been laid out with this in mind, there being no conflicts between technical sessions and inspection trips. On Tuesday afternoon six simultaneous trips were scheduled. Some went to the River Rouge Plant

of the Ford Motor Company, where they saw the assembly line, the glass plant, and machine shop. From there they went to the Ford Airport and the airplane factory, where all-metal tri-motor airplanes were under construction, and where Byrd's plane, the *Josephine Ford*, and Schlee and Brock's *Pride of Detroit* were on exhibition. At Greenfield the party saw the Ford industrial museum, built as a reproduction of Independence Hall at Philadelphia, and the buildings of the Edison Institute of Technology which Ford had recently founded. It was also possible to get a general view of the early American village which is part of the same development, and of the original Menlo Park buildings in which Mr. Edison worked.

Another group chose to inspect the General Motors Research Laboratories, which act in a consulting capacity to all of the General Motors Divisions and which are equipped for a great variety of work. This group also visited the Bohn Aluminum & Brass Co. and the McCord Radiator Corporation.

The third group inspected the General Motors Proving Ground of more than 1000 acres, and the fourth visited the Chevrolet forge plant and the Murray body plant.

The Packard Motor Car Company and the Detroit-Michigan Stove Company were the objectives of the fifth group, while the sixth visited the Cadillac Motor Car Company and the Delray Station of the Detroit Edison Company.

On Thursday afternoon many of the members and their guests visited the Grosse Isle Airport. A buffet luncheon at the Chateau Voyageurs and a demonstration of Eastman air yachts and amphibions preceded an inspection of the airport, where many types of airplanes were to be seen and free demonstration flights were offered to any one who cared to go into the air. An interesting feature was the talk on gliders and the demonstration of the launching of gliders. After the inspection of the Curtiss Flying School, an opportunity was afforded of attending the commencement exercises of the school.

In addition to the trip to Grosse Isle, the program for Thursday included excursions to the Fisher Body plant, Pontiac, Mich.; to the Detroit Seamless Steel Tubes Company, American Brass Company, and Ambassador Bridge; and a general sightseeing trip including an inspection of Greenfield Village. Many special trips were individually arranged, and every courtesy was extended those who wished to stay over until Friday to visit such plants as the Yellow Coach and Truck Plant, the Oakland and Pontiac plants at Pontiac, Mich., and the dry-quenching coke plant of the Consumers' Power Company, at Flint, Mich.

Ladies' Program

In order to provide for the ladies who attended the meeting and who did not join in the excursions of Tuesday afternoon, special arrangements were made. An automobile trip that afforded an opportunity to see something of Detroit and its suburbs ended at the Detroit Golf Club, where tea was served. That evening, while the men were at the smoker, the ladies held a bridge tournament in the Crystal Ball Room. On Wednesday they joined the boat trip, and on Thursday some went to Grosse Isle, while others visited Greenfield Village.

Technical Program

The following summary of the technical program gives the various sessions, the papers presented, and their authors.

Monday Morning, June 9

Machine Shop Practice (I)

(Auspices of Machine Shop Practice Division)

Refinements in Finishing Cylindrical Bores, J. W. Hindes and James G. Young
What Happens When Metal Is Cut, O. W. Boston

Properties of Metals

(Auspices of Joint Research Committee on Effect of Temperature on Properties of Metals)

Flow Characteristics of Special Fe-Ni-Cr Alloys and Some Steels at Elevated Temperatures, H. J. French, Wm. Kahlbaum, and A. A. Peterson
Flow Characteristics of Some Lead Cable Sheath at Temperatures above Atmospheric, C. L. Clark and C. Upthegrove
An Apparatus for the Determination of Creep at Elevated Temperatures, A. E. White

Applied Mechanics (I)

(Auspices of Applied Mechanics Division)

Power Application to Oscillating Axles, Alain Madlé
Automatic Brakes with Servo-Action, F. Loewenberg

Monday Afternoon, June 9

Machine Shop Practice (II)

SYMPOSIUM ON TUNGSTEN CARBIDE

(Auspices of Machine Shop Practice Division)

Introductory Address, Ernest F. DuBrul
Cutting Tests with Cemented Tungsten-Carbide Lathe Tools, T. G. Digges
Application of Tungsten Carbide to Saws, C. M. Thompson
The Use of Tungsten Carbide as a Cutting Material on Heavy Machine Tools, Coleman Sellers, 3d
Report of Metal Cutting Committee on Tungsten Carbide (A.S.M.E. Research Sub-Committee), Frank C. Spencer

Boiler Feedwater Studies

(Auspices of Joint Research Committee on Boiler Feedwater Studies)

Electrical-Conductance Measurements of Water and Steam, and Applications in Steam Plants, Max Hecht and D. S. McKinney
Fractures in Boiler Metal, A. E. White

Applied Mechanics (II)

(Auspices of Applied Mechanics Division)

Steady Forced Vibration as Influenced by Damping, Lydik S. Jacobsen
Longitudinal Wave Transmission and Impact, L. H. Donnell

Tuesday Morning, June 10

Industrial Power

(Auspices of Power Division)

Tests of the Resistance to Repeated Pressure of Forged, Riveted, and Welded Boiler Shells, H. F. Moore
Boiler Settings for Burning Refuse Wood, Charles S. Gladden

Paper and Pulp Conference

(Auspices of Printing Industries Division)

Welcome to Detroit, John E. Coulter
Welcome from the Printing Industry, George R. Keller
Technical Specifications for Paper Users, B. L. Wemhoff
Permanence Standards for Printing and Writing Papers, B. W. Scribner

Wood Industries

(Auspices of Wood Industries Division)

Airplane Spruce, E. J. Fishbaugh
End-Matching, Edge-Jointed and Surface-Laminated Wood Parts for Auto-Body Building, Gilbert G. White
Training Men for the Wood-Using Industries, Samuel T. Dana

Applied Mechanics (III)

(Auspices of Applied Mechanics Division)

The Stresses in Rotating Disks, Thomas H. Frost and K. F. Whitcomb
Flow of Gases at a Rate Exceeding the Acoustic Velocity, O. G. Tietjens

Wednesday Morning, June 11

FUELS AND POWER

(Auspices of Fuels and Power Divisions)

The Dry Quenching of Coke, WILLIAM O. RENKIN
Recovery of Fly Ash From Pulverized-Fuel Stacks by Use of Stack Sprays, J. W. MACKENZIE

MANAGEMENT

(Auspices of Management Division with American Management Association Cooperating)

Five-Minute Talk on Safety—Is Management Responsible for Industrial Casualties? GEORGE OPP
Management of the Small Manufacturing Plant: Its Characteristics and Advantages, CROSBY FIELD
Management of the Large Manufacturing Plant: How to Retain the Advantages of the Small Plant, A. B. REYNDERS

MECHANICAL SPRINGS

(Auspices of A.S.M.E. Special Research Committee on Mechanical Springs)

Stresses and Deflections in Helical and Spiral Torsional Springs as Affected by Curvature. Progress Report No. 6 of Special Research Committee on Mechanical Springs, M. F. SAYRE
Further Research on Helical Springs of Round and Square Wire, ARTHUR M. WAHL

Thursday Morning, June 12

CENTRAL STATION POWER

(Auspices of Power Division)

Comparative Performance of a Large Boiler Using Oil and Natural-Gas Fuels, FRANK G. PHILO
Comparative Performance of a Pulverized-Coal-Fired Boiler Using Bin System and Unit System of Firing, ARTHUR E. GRUNERT

AERONAUTICS

(Auspices of Aeronautic Division)

Air Transportation, PAUL GOLDSBOROUGH
Automotive Methods and Practices Involved in Aircraft Engines, O. E. SZEKELY
Motorless Flight, DONALD F. WALKER

EDUCATION AND TRAINING

(Auspices of Committee on Education and Training for the Industries)

Five-Minute Talk on Safety—The Prevention of Industrial Casualties Through Instruction in Foremen's Schools, Rotative Safety Committees, etc., R. F. THALNER
Training Aeronautical and Automotive Service Mechanics, A. D. ALTHOUSE
The Training and Recruitment of Auto Mechanics Through Factory Sources, WM. F. RASCHE.

French Lick Springs Meeting

MILD October weather, a famous health and pleasure resort set in the colorful hills of Southern Indiana, combined with excellent technical sessions and a splendid entertainment program, made the meeting of the Society held at French Lick, Ind., October 13–15, 1930, a most delightful event. Except for a conference of the Committee on Local Sections on Sunday, no committee meetings were scheduled.

The Student Session arranged for Monday afternoon proved to be a most interesting technical event. Papers were presented by representatives of Armour Institute of Technology on "The Power Industry;" University of Cincinnati, "Cooperative Education;" University of Illinois, "Research in Mechanical Engineering;" University of Louisville, "Cooperative Education;" Purdue University, "Instruction in Flying to Engineering Students;" Rose Polytechnic Institute, "Mechanical Engineering in the Coal Industry;" and Washington University, "Heat Treatment of Nickel Steel Welds." A prize of $25 offered by William A. Hanley, Manager of the Society, for the best contribution to this Session, was awarded to Allen G. Stimson, representative of Rose Polytechnic Institute. Mr. Stimson gave a concise statement covering the reasons for mechanization in the coal industry and its results.

At a luncheon for students with Council members on Monday Dr. C. E. Grunsky, President of the American Engineering Council, delivered a most inspiring message.

TECHNICAL PROGRAM

The titles and authors of papers presented at the French Lick Meeting are given in the following summary of the technical program.

Monday Morning, October 13

AUTOMOTIVE

Engineering Problems of Modern Motor Cars, WM. G. WALL
The Diesel Engine for Automobiles, C. L. CUMMINS

Monday Afternoon, October 13

STUDENT SESSION

See paragraph above.

Tuesday Morning, October 14

MANUFACTURING

Developments in the Conveyor Field, HENRY R. GOTTHARDT
Psychometry and Some Common Effects of Air Conditioning on Materials, D. C. LINDSAY
Machine Tool Milestones, Past and Future, SOL EINSTEIN

Wednesday Morning, October 15

GLASS AND STONE INDUSTRY

High-Burned Kaolin Refractories, F. H. NORTON
Engineering Problems in the Stone Industry, H. S. BRIGHTLY
Limestone Research, H. C. PEFFER

ENTERTAINMENT

The Entertainment Committee provided a varied program, including a trip to the Marengo Caves, an inspection tour of the Bedford Limestone Quarries, a miniature-golf tournament for the ladies, tournaments on the regular golf courses for both ladies and men, a bridge tournament for the ladies, and a horseshoe pitching contest for the men.

An informal dinner on Monday evening and the banquet Tuesday evening brought very valuable contributions from outstanding engineers in the Middle West. William A. Hanley painted a graphic picture of industry today as compared with the old hit-and-miss methods of manufacturing and safety of a generation ago. Dr. Allen D. Albert, assistant to the president of the Chicago World's Fair Centennial Celebration, said that the progress of the past century is the clear product of science, therefore, the motif of Chicago's celebration in 1933 would be "Science."

Dr. Edward C. Elliott, President of Purdue University, addressed the banquet gathering on "The Sixth Estate," which he defined as those who recruit the leadership of our day. "Engineers must assume the responsibility of preparing these young men not for jobs, but for the joy of serving humanity," he declared. "They must be the masters of machines and must not allow machines to master them. Fitness for the job must be the creed of the craft."

Fifty-First Annual Meeting

HELD at a time when the business depression was perhaps being most keenly felt throughout the country, the 1930 Annual Meeting of the Society at New York, December 1–5, was surprisingly well attended, the registration being the largest ever recorded, 2562. Those who established this record must have found their time well spent. The program was not only unusually varied and worth while, but it was in many respects peculiarly suited to the current conditions in industry. The stabilization of employment and the engineer's relation to this and kindred problems were the subjects of several conferences and addresses. Technical sessions and committee meetings stressed the subjects of research, standardization, accident prevention, and industrial management. Conferences of the Council and Local Section and Student Branch delegates studied ways in which the Society might bring aid to the solution of these problems.

Conferences on Unemployment

At a meeting of the Council on Monday morning, December 1, L. W. Wallace, executive secretary of the American Engineering Council, brought to the Society an invitation to undertake a study of what industry had done in the past and was doing to stabilize employment. The American Engineering Council had been asked by Col. Arthur S. Woods, chairman of President Hoover's Emergency Committee for Employment, to sponsor such a study. Colonel Woods addressed the Council of the Society and in the afternoon presented the problem to the members of the Society at a special conference.

The attitude of the Council toward the request for cooperation was expressed in the following resolution, which was endorsed by the Local Sections Conference:

Voted: That The American Society of Mechanical Engineers pledges its full cooperation and assistance in response to the request of Colonel Arthur Woods, Chairman of the President's Emergency Committee for Employment, transmitted by the American Engineering Council. The Society will undertake a program of:

(1) Urging industry to adopt measures now to relieve the winter emergency; and
(2) Compiling data as to effective policies and methods used to deal with the general question of irregular employment; and
(3) Assisting in all other practical ways.

The Council authorized the President of the Society to appoint a committee to organize and direct the work.[1]

A second important conference on the stabilization of employment in industry was held on Wednesday. This conference, arranged by the Management Division of the Society with the cooperation of the American Management Association, was attended by more than two hundred executives, engineers, and members of various commissions studying the employment problem. The presentation of three papers was followed by general discussion. The industrial depression, with its acute unemployment problem, was recognized by the conference as one solely of an economic nature. The causes that stood out clearly were summarized as being: (1) A certain amount of over-production; (2) strenuous but costly efforts to stimulate increased consumption; (3) unintelligent price cutting; (4) excessive wastes in distribution; (5) a general alarm over the acuteness of the situation that causes industrial plants to undertake drastic retrenchment; (6) a consequent reaction on the public that reduces sales and consumption; and (7) a repetition of the vicious cycle on decreasingly smaller production schedules that continuously reduce employment.

[1] Announcement of the personnel of this committee was made by President Roy V. Wright on December 13, as follows: Ralph E. Flanders, chairman, Dexter S. Kimball, Ely C. Hutchinson, J. W. Roe, Col. C. H. Crawford, and Col. W. A. Starrett, with President Wright and Secretary Rice as members ex-officio.

Social Engineering

Addresses on President's Night and at the Annual Dinner on Wednesday brought new light to the relation of the engineer to his fellow-men and their problems. On the former occasion Ralph E. Flanders, manager of the Jones & Lamson Machine Co., Springfield, Vt., and vice-president of the A.S.M.E., and Dr. Wesley C. Mitchell, director of the National Bureau of Economic Research, New York, delivered addresses on the subject of "Engineering, Economics, and the Problem of Social Well-Being," in which engineers were urged to join more fully with other professions working toward the solution of social problems. Mr. Flanders presented the point of view of the engineer, while Dr. Mitchell gave that of the economist.

Prof. Elliott Dunlap Smith, director of industrial investigations of the Institute of Human Relations and professor of industrial engineering at Yale University, in his address entitled "The Engineer Encounters Human Nature," at the Annual Dinner, presented the social responsibility of the engineer in another way, that of adapting mechanism to man.

"Talking With an Audience"

For many years the A.S.M.E. has been making a constructive and sincere attempt to improve the conduct of its technical sessions and the manner in which papers are presented. In this connection a series of three talks on "Talking with an Audience" were given by Dr. S. Marion Tucker, head of the department of English at the Polytechnic Institute of Brooklyn, on Tuesday, Wednesday, and Thursday mornings preceding the technical sessions. These talks were of a practical nature and very favorably received.

Exhibition of Art by Engineers

An event entirely new to programs of the A.S.M.E. was the exhibition of art by engineers. The formal opening of the exhibition on Monday evening was preceded by an hour of music by the "Bridge Engineers' Trio," composed of John E. Greiner, violin; Otis E. Hovey, flute; and Ralph Modjeski, piano, and an address by Dean Robert L. Sackett, of Pennsylvania State College, on "Art as an Engineer's Hobby." More than two hundred exhibits were on display in the galleries of the fourth floor of the Engineering Societies Building, and included sculpture, paintings, prints, line drawings, and photographs by more than seventy professional engineers. L. P. Alford, vice-president of The Ronald Press Company, New York, and past vice-president of the A.S.M.E., was chairman of the committee in charge of the exhibition.

Honors and Awards

The Fifty-First Annual Meeting was distinguished also by a number of important awards.

On President's Night, Elihu Thomson was made an honorary member of the A.S.M.E. Professor Thomson was presented by Ambrose Swasey, honorary member and past-president, A.S.M.E., and honorary membership was conferred by Col. Paul Doty, vice-president, A.S.M.E., acting for President Charles Piez.

The dinner on Wednesday evening was the occasion of the presentation of the John Fritz Gold Medal to Admiral David Watson Taylor "for outstanding achievement in marine architecture, for revolutionary results of persistent research in hull design, for improvement in many types of warships, and for distinguished service as chief constructor of the United States Navy during the World War." Lincoln Bush, chairman of the John Fritz Medal Board of Award, presided. The address on the career and achievements of Admiral Taylor was made by Walter M. McFarland, past-president of the Society of Naval Architects and Marine Engineers, and past vice-president of the A.S.M.E., and the medal was presented by Bancroft Gherardi, chairman of the board which made this award and past-president of the American Institute of Electrical Engineers.

At the dinner also special badges were presented by Charles E. Gorton, acting for President Piez, to those who had been members of the Society for fifty years, as follows:

Ellwood Burdsall	Henry Marx
John W. Cloud	H. F. J. Porter
J. S. Coon	Francis H. Richards
P. B. De Schweinitz	Albert W. Smith
Thomas A. Edison	Ambrose Swasey
Auguste A. Goubert	Edward N. Trump

Walter Wood

At the business meeting on Monday evening the Awards Committee, represented by Dean Arthur M. Greene, Jr., and Prof. H. L. Seward, conferred the following awards.

The Melville Medal, established in 1914 by the bequest of Rear-Admiral George W. Melville, honorary member and past-president of the Society, for an original paper or thesis of exceptional merit, was presented to Herman Diederichs, director of the Sibley School of Mechanical Engineering, Cornell University, and William D. Pomeroy, vice-president and general manager of Goulds Pumps, Inc., Seneca Falls, N. Y., as co-authors of a paper on "The Occurrence and Elimination of Surge or Oscillating Pressures in Discharge Lines from Reciprocating Pumps."

The Junior Award, an annual cash prize of $50, together with an engraved certificate, established in 1914 from a fund created by Henry Hess, past vice-president of the Society, for the best paper or thesis submitted by a junior member, was bestowed on Ed Sinclair Smith, Jr., of the Builders Iron Foundry, Providence, R. I., for his paper on "Quantity-Rate Fluid Meters."

Student Awards, two annual cash awards of $25 each, were also established in 1914 from a fund created by Henry Hess, to be presented with engraved certificates for the best papers or theses submitted by student associates. One of these for 1930 was presented to Gerard Eden Claussen, Polytechnic Institute of Brooklyn, class of 1930, and a graduate student at the Massachusetts Institute of Technology, for his paper on "High-Temperature Oxidation of Steel."

The second Student Award went to Harold L. Adams and Richard L. Stith, University of Washington, class of 1930, for their paper on "A Wind Tunnel for Undergraduate Laboratory Experiments."

The Charles T. Main Award for 1930 was conferred upon Jules Podnossoff, Polytechnic Institute of Brooklyn, class of 1931, for his paper on "The Value of the Safety Movement in the Industries." This prize of $150, given annually, was established in 1919 from a fund created by Charles T. Main, past-president of the Society, to be awarded to a student of engineering, preferably a member of a Student Branch of the Society, for the best paper within the general subject of "The Influence of the Profession upon Public Life."

The Annual Dinner

The Annual Dinner, held at the Hotel Astor, was attended by nearly one thousand members and guests. For several years past it has been customary to have the women attending the Annual Dinner seated at tables in the balcony. This year women were seated with the men on the main floor, a change in arrangements which brought expressions of approval from many.

The formal program of the evening was in charge of Ely C. Hutchinson, a manager of the Society, as toastmaster. Mr. Hutchinson presented Mr. Rice, secretary of the Society, who read the names of those who had become members during the year, and called upon them to rise in their places. He then introduced Conrad N. Lauer, vice-president of the Society, who delivered the charge to these new members.

After the presentation of the fifty-year badges and the address by Dr. Smith the floor was cleared for dancing.

Conferences and Committee Meetings

At the Monday meeting of the Council approval was given of the petition of the members in Eastern Connecticut for a Local Section with headquarters at Norwich, Conn., the territory to include the counties of Tolland, New London, and Windham in Connecticut, and Westerly Township in Rhode Island.

The Council also approved the establishment of a Student Branch at Harvard University.

The Local Sections held conferences on Monday and Tuesday and met with the Council for luncheon on Monday. Delegates were present from all of the Sections except Susquehanna and Utica. Group meetings were held on Tuesday morning for the selection of candidates for the Nominating Committee of the Society for 1931–1932. The personnel recommended by the groups was approved at the Tuesday afternoon conference.

At the general conferences on Monday and Tuesday representatives of several standing committees addressed the delegates and many subjects of common interest were discussed, including financing Local Sections, cooperation with the Society's Committee on the Economic Status of the Engineer, licensing and registration of engineers, and the relation of Local Sections to Student Branches.

The representatives of the Student Branches of the Society met with the Council at a luncheon on Wednesday, after which a conference was held for the presentation of several papers as listed in the accompanying technical program. The honorary chairmen of the Student Branches met at a luncheon on Thursday.

During the Annual Meeting the technical committees held forty-three meetings on Research, Standards, Power Test Codes, Boiler Code, and Safety. These meetings had an attendance of more than five hundred. Several of the Standing Committees of the Society held conferences, as did the majority of the executive committees of the Divisions.

Two important conferences were held relating to new Divisional work. A conference on Wednesday afternoon for the consideration of a Process Division resulted in the formation of a Process Industries Committee. A program of cooperation with the American Institute of Chemical Engineers was discussed with three representatives of that society, and an agreement was reached whereby the two societies would have joint meetings and papers committee covering the process and chemical industries. The programs for meetings of the process industries groups of the two societies would be worked out by this joint committee and each society would cooperate in the meetings of the other society.

Following the joint technical session with the A.S.R.E. a conference was held to discuss the formation of an Air Conditioning Division. After some discussion it was suggested by W. H. Carrier, chairman of the conference, that a division on thermal engineering or heat transmission be formed. It was

voted to ask the American Society of Refrigerating Engineers, the American Society of Heating and Ventilating Engineers, the American Institute of Chemical Engineers, and the A.S.M.E. each to appoint two representatives to meet to discuss cooperative action on heat transmission and the advisability of the formation of an A.S.M.E. division on this subject; the activities of such a division possibly to be supervised by a joint committee so as to assure more complete cooperation.

Business Meeting

At the business meeting on Monday evening the annual report of the Council and its standing committees was presented by Mr. Rice, Secretary of the Society, and the tellers reported the adoption through letter ballot of the members (by a vote of 4762 to 1376) of the amendment to the Constitution regarding initiation fees, as presented at the Detroit Semi-Annual Meeting.

After the conferring of awards the meeting was adjourned until Tuesday evening, when the report of the Local Section delegates naming the 1931–1932 Nominating Committee was received, as follows:

Group I: S. J. Teller, West Hartford, Conn.; R. E. Newcomb, Holyoke, Mass., first alternate; F. S. Clark, Boston, Mass., second alternate
Group II: C. P. Tolman, New York, N. Y.; A. A. Adler, New York, N. Y., alternate
Group III: Harte Cooke, Auburn, N. Y.; Alfred Iddles, Philadelphia, Pa., first alternate; F. A. Allner, Baltimore, Md., second alternate
Group IV: W. R. Woolrich, Knoxville, Tenn.; D. E. Kehoe, Savannah, Ga., alternate
Group V: A. E. White, Ann Arbor, Mich.; W. M. Taylor, Indianapolis, Ind., alternate
Group VI: W. C. Lindemann, Milwaukee, Wis.; C. A. Herrick, Minneapolis, Minn., alternate
Group VII: Dennistoun Wood, San Francisco, Calif.; A. J. Dickie, San Francisco, first alternate; R. L. Mahon, San Francisco, second alternate

The report of the tellers of election of officers for 1931–1932 was also heard at the Tuesday night meeting, as follows:

President: Roy V. Wright
Vice-Presidents: Harvey N. Davis, William A. Hanley, Thomas R. Weymouth
Managers: W. L. Batt, H. L. Doolittle, H. L. Whittemore

These officers were installed at a meeting of the Council on Friday morning.

Technical Sessions

Simultaneous technical sessions were held morning and afternoon of every day starting Monday and ending Friday. At these sessions, which numbered 32, 67 papers and 19 reports were presented. The usual joint meeting of the A.S.R.E. and the A.S.M.E. was held on Friday afternoon and was presided over by W. H. Carrier, a member of both societies.

On Wednesday afternoon there was a joint session of the Wood Industries Division with the American Society of Safety Engineers. The Rudolph Diesel award for the best paper delivered at the 1930 Oil and Gas Power National Meeting was presented to Geo. J. Dashefsky, assistant mechanical engineer, Diesel Engine Section, U. S. Navy Yard, Brooklyn, at the Oil and Gas Power session on December 4.

The complete program of the technical sessions follows:

Monday Morning, December 1

Lubrication Engineering

(Auspices of Petroleum Division)

Crane Lubrication, Eustis H. Thompson
The Work Factor of Lubricating Oil, James G. O'Neill
Evaluation of Steam Turbine Oil Stability, Clifford M. Larson

Applied Mechanics (I)

(Auspices of Applied Mechanics Division)

Determination of Stresses in Rotating Disks of Conical Profile, F. C. Rushing
Stresses in Retaining and Centering Rings for Turbine-Generator Rotors, R. Patterson and D. H. Harms

Monday Afternoon, December 1

Materials Handling (I)

(Auspices of Materials Handling Division)

Handling Materials at the Postum Company, P. P. Pratt
Material Handling in the Shoe Industry, Kenneth D. Hamilton
Materials-Handling Methods in the Fisk Tire Plant, Charles Edgar Maynard

Symposium on Industrial Accident Prevention

(Auspices of Standing Committee on Safety)

Economic Aspects of Industrial Casualty Reductions, L. W. Wallace
Engineering Revision an Essential Factor in Accident Prevention, Lucian W. Chaney
Management's Responsibility for Industrial Accidents, L. P. Alford

Applied Mechanics (II)

(Auspices of Applied Mechanics Division)

Plastic Torsion, A. Nadai
Vibrations of Railway Bridges, J. N. Goodier

Tuesday Morning, December 2

Machine-Shop Practice (I)

(Auspices of Machine-Shop Practice Division)

A Survey of Surface Quality Standards and Tolerance Costs Based on 1929–1930 Precision-Grinding Practice, R. E. W. Harrison, with appendix by C. B. Sawyer
Transmission of Torque by Means of Press and Shrink Fits, J. W. Baugher, Jr.
Progress Report of Machine Shop Practice Division, presented by C. de Zafra

Railroad (I)

(Auspices of Railroad Division)

Progress Report of Railroad Division
High-Pressure and High-Temperature Steam for Locomotives, C. F. Hirshfeld
The Stug System of Pulverized Fuel Firing on Locomotives, R. Roosen

Materials Handling (II)

(Auspices of Materials Handling Division)

Progress Report of Materials Handling Division, presented by George E. Hagemann
Materials Handling in Warehouses, N. E. Whittemore

Hydraulics

(Auspices of Hydraulic Division)

Progress Report of Hydraulic Division, presented by Byron E. White
Federal Relations to Water-Power Development, Frank E. Bonner
A Method for Standardization of Centrifugal Pumps, Jos. S. Stepanov

Tuesday Afternoon, December 2

Railroad (II)

(Auspices of Railroad Division)

Research Relating to the Action of 4-Wheel Freight-Car Trucks, T. H. Symington

Machine-Shop Practice (II)

(Auspices of Machine-Shop Practice Division)

The Uses of 16 Mm. Movies in Industry, Maynard L. Sandell
The Application of Spectroscopic Apparatus to Industry, Charles C. Nitchie

Materials Handling (III)

(Auspices of Manufacturers Committee of Materials Handling Division)

Report of Subcommittee on Classification of Materials-Handling Equipment and Nomenclature, G. L. Morehead

Report of Subcommittee on Performance Standards of Locomotive Cranes and Crawlers, H. H. PERRY
Report of Subcommittee on Capacity of Containers, W. E. FARRELL
Report of Subcommittee on Cross-Reference Index for Equipment and Materials Handling, M. W. POTTS
Cooperative Research, BRINTON WELSER
Report on Educational Possibilities, C. B. CROCKETT

INDUSTRIAL POWER

(Auspices of Power Division)

Engineering Aspects of Interchange of Power with Industrial Plants B. F. WOOD
Combined Heat and Power Supply in Industrial Plants, W. F. RYAN

Wednesday Morning, December 3

FUELS

(Auspices of Fuels Division)

Progress Report of Fuels Division, T. A. MANGELSDORF
Heat Absorption in Water-Cooled Furnaces, WM. L. DEBAUFRE
Radiant Heat Transmission between Surfaces Separated by Non-Absorbing Media, H. C. HOTTEL

STABILIZATION OF EMPLOYMENT IN INDUSTRY

(Auspices of Management Division, with cooperation of American Management Association)

Discussion of Manufacturing in Advance of Orders in Seasonal Industries, EDWIN S. SMITH
Discussion of Unemployment—Its Causes, Palliation, and Prevention, ROYAL MEEKER
Discussion of Employment Stabilization in the Proctor and Gamble Company, HARVEY C. KNOWLES

GENERAL

Machining Properties of Some Cold-Drawn Steels, O. W. BOSTON
Frictional Resistance and Flexibility of Seamless-Tube Fittings Used in Pipe Welding, SABIN CROCKER and ARTHUR MCCUTCHAN

TEXTILES

(Auspices of Textile Division)

Progress Report of Textile Division
Special Applications of Electric Motors in Cloth-Finishing Plants, A. M. MACCUTCHEON
Lubrication of Textile Machinery, L. A. BAUDOIN

Wednesday Afternoon, December 3

APPRENTICE TRAINING

(Auspices of Committee on Education and Training for the Industries)

Apprentice Training in Virginia, C. F. BAILEY
Apprentice Training Movement in Wisconsin Industry, HAROLD S. FALK
Opportunities for Aviation Training, JOSEPH S. MARRIOTT

SAFETY AND WOOD INDUSTRIES

(Joint Session of Wood Industries Division with American Society of Safety Engineers)

Dust Explosions, With Special Reference to Woodworking Industries, HYLTON R. BROWN
Research in Wood Products, JAMES W. LAWRIE
Progress Report of Wood Industries Division, presented by THOMAS D. PERRY

STEAM TABLES RESEARCH

(Auspices of A.S.M.E. Special Research Committee on Thermal Properties of Steam)

Additional Volume Data for Superheated Steam, L. B. SMITH and F. G. KEYES
Some Final Values for Saturated and Superheated Steam, F. G. KEYES and L. B. SMITH
Report of the Progress in Steam Research at the Bureau of Standards, N. S. OSBORNE
Thermal Properties of Compressed Liquid Water, J. H. KEENAN

STUDENT BRANCH CONFERENCE

Opportunities in Engineering, W. A. HANLEY
Engineers and Engineering in Foreign Lands, CHARLES E. GORTON
Engineering and Government, L. W. WALLACE

Thursday Morning, December 4

CENTRAL STATION POWER

(Auspices of Power Division)

Operating Experiences, Deepwater Station, K. M. IRWIN
Operation of the Holland Station, E. M. GILBERT

MANAGEMENT

(Auspices of Management Division, with cooperation of American Management Association)

American Management in Europe, WALLACE CLARK
Progress Report of Management Division, presented by C. W. LYTLE

AERONAUTICS

(Auspices of Aeronautic Division)

Airplane Cabin Engineering, PIERRE FREYSS and JOHN F. HARDECKER
Airplane Instrument Vibration (Report of A.S.M.E. Special Research Committee on Airplane Vibration with Special Reference to Instruments), FREDERICK K. TEICHMANN
Progress Report of Aeronautic Division, presented by C. H. COLVIN

CUTTING METALS

(Auspices of A.S.M.E. Special Research Committee on Cutting of Metals)

Tool-Steel Tools, A. H. D'ARCAMBAL
Cemented Tungsten Carbide as Applied to Cutting Tools, L. J. ST. CLAIR
Haynes Stellite Cutting Tools, W. A. BECKER, E. E. GORDON, and W. A. WISSLER

Thursday Afternoon, December 4

OIL AND GAS POWER

(Auspices of Oil and Gas Power Division)

Progress Report of Oil and Gas Power Division, presented by M. J. REED
Some Features of the Long-Distance Transportation of Natural Gas, GEO. I. RHODES and EDGAR G. HILL
A Simple Method for the Calculation of Natural Frequencies of Torsional Vibration, FREDERIC P. PORTER

BOILER FURNACE REFRACTORIES

(Auspices of A.S.M.E. Special Research Committee on Boiler Furnace Refractories)

Comparative Resistance of Refractories to Coal-Ash Slags, R. K. HURSH
Action of Slags on Firebrick and Boiler Furnace Settings, T. A. KLINEFELTER and E. P. REXFORD
Furnace-Gas Compositions and Temperatures in Underfeed-Stoker-Fired Boilers, and Their Effect on Boiler Settings, ALBERT C. PASINI and EDWARD M. SARRAF

Friday Morning, December 5

SYMPOSIUM ON FLAT-BED CYLINDER PRESSES (I)

(Auspices of Printing Industries Division)

Some Problems in Standardization, FRED S. ENGLISH
Design of the New Harris Automatic Two-Color Flat-Bed Press, ALFRED S. HARRIS
Progress in Printing, W. S. HUSON

PROPERTIES OF METALS

(Auspices of Joint Research Committee on Effect of Temperature on Properties of Metals)

Properties of Non-Ferrous Alloys at Elevated Temperatures, C. L. CLARK and A. E. WHITE
Comparative Physical Properties of Chromium-Nickel, Chromium-Manganese, and Manganese Steels, C. L. CLARK and A. E. WHITE

LUBRICATION RESEARCH

(Auspices of A.S.M.E. Special Research Committee on Lubrication)

On Problems in the Theory of Fluid-Film Lubrication, with an Experimental Method of Solution, ALBERT KINGSBURY
Lubrication Research Activities (Fifth Report of A.S.M.E. Special Research Committee on Lubrication) presented by MAYO D. HERSEY and A. E. FLOWERS

Friday Afternoon, December 5

SYMPOSIUM ON FLAT-BED CYLINDER PRESSES (II)

(Auspices of Printing Industries Division)

Five-Minute Talk on Safety, ROBT. R. ELBERTY
Sizes and Tolerances for Metal Fits, C. R. REIMAN
Design of the Miller Simplex Automatic Two-Revolution Cylinder Press, A. W. BARRETT
Forces in Connection With the Reciprocating Beds of Flat-Bed Cylinder Printing Presses, B. D. STEVENS and H. E. GOLBER

MECHANICAL SPRINGS

(Auspices of A.S.M.E. Special Research Committee on Mechanical Springs)

Elastic and Inelastic Behavior in Spring Materials (Progress Report No. 7 of Special Research Committee on Mechanical Springs), M. F. SAYRE
Design of a Conical Spring with Coils of a Uniform Slope (Progress Report No. 8 of Special Research Committee on Mechanical Springs), Jos. B. REYNOLDS and O. B. SCHIER

REFRIGERATION

(Joint Session with The American Society of Refrigerating Engineers)

The Effect of Humidity on the Heat Transmission of Galvanized Pipe (*Contributed by A.S.R.E.*), W. R. WOOLRICH
Psychometry and the Effects of Air Conditions on Some Familiar Products (*Contributed by A.S.M.E.*), DANIEL C. LINDSEY

COLLEGE REUNIONS AND POWER SHOW

As usual, Thursday evening was set aside for the reunions of various colleges. A number of college alumni associations held dinners on that date, and other groups met for luncheon or dinner during the week.

The Ninth National Exposition of Power and Mechanical Engineering was held at the Grand Central Palace during the week and afforded members and their guests an opportunity to view the most recent developments in that field.

EXCURSIONS

The excursions scheduled were exceptionally well attended. They included trips to the *Bremen* and the *Olympic;* the Westinghouse Lighting Institute; the Hell Gate Power Station; the Hudson Avenue Generating Station; the Western Electric Company's Kearny plant; the East River Generating Station; the plant of the G. J. Tagliabue Mfg. Co.; the Holland Tunnels; the Pioneer Instrument Company; the United States Navy Yard; and the laboratory of the St. John X-Ray Service Corporation.

THE WOMEN'S PROGRAM

A most efficient committee of women from the A.S.M.E. Woman's Auxiliary established headquarters in the lobby of the building and took splendid care of all their many visitors. In addition to the evening affairs which were part of the general program, there were several events especially for the women. On Tuesday at the Astor Hotel at the annual luncheon of the Auxiliary, Dr. Lillian M. Gilbreth, a member of President Hoover's Emergency Committee for Employment, gave a short talk in which she sketched briefly the part women should play and were playing to bring about normal conditions.

On Wednesday there was a special excursion to the new Riverside Church, followed by luncheon either at the International House or the Engineering Women's Club, while later in the afternoon a "Library Talk," led by Mrs. Frank Jewett, was given at the Engineering Women's Club on the book "Humanity Uprooted," by Maurice Hindus. Thursday morning's excursion to the Colgate-Palmolive-Peet Company in Jersey City was exclusively for the women and was particularly enjoyed, while in the afternoon the annual tea was held at the Museums of the Peaceful Arts, where a very enjoyable program was presented, with talks and motion pictures, and an opportunity was given to see a special exhibit of the works of Dr. Elmer A. Sperry, past-president of the Society.

An enjoyable visit to Princeton University under the personal guidance of Dean Arthur M. Greene, Jr., closed the trips on Friday.

Meetings of the Professional Divisions

Aeronautic Division

PITTSBURGH, PA., MARCH 12, 1930

Several valuable papers were presented at the Pittsburgh Aero Conference held at the William Penn Hotel on March 12, 1930. The meeting was sponsored jointly by the A.S.M.E. Aeronautic Division and the Pittsburgh Local Section, with the cooperation of a newly founded Aeronautic Section of the Engineers' Society of Western Pennsylvania. The conference consisted of morning and afternoon sessions with an interesting luncheon meeting.

TECHNICAL PROGRAM

The titles and authors of papers are given in the following summary of the program:

Wednesday Morning, March 12

Development of the Drop-Forged Metal Propeller, FRANK W. CALDWELL
New Aircraft Instruments, S. J. ZAND and FLOYD B. NEWELL
New Developments in Airport Lighting, H. C. RITCHIE

Wednesday Luncheon Meeting, March 12

The Future of Air Transport, THOMAS LANPHIER
Safety in Aircraft, HAROLD F. MARTIN

Wednesday Afternoon, March 12

Metalizing the Airplane, H. V. THALDEN
Some Aspects of All-Metal Airplane Construction, WELLWOOD E. BEALL
Some Aspects of Airplane Design, SCHUYLER KLEINHANS
Trend in Aircraft-Engine Design, C. H. SCHOWALTER
The Radiophone in Air Transport, R. H. FREEMAN

Aeronautic Division

DAYTON, OHIO, MAY 19–22, 1930

The Fourth National Technical Aeronautic Meeting of the Aeronautic Division, held at Dayton under the auspices of the Dayton Section, May 19 to 22, 1930, attracted several hundred members and guests. A most unusual feature of the meeting were the remarkable arrangements made at Wright Field for the inspection of its laboratories. Interesting pieces of machinery were labeled clearly and many of the labels carried photographs of apparatus in different positions so as to convey quickly as much engineering information as possible.

WRIGHT FIELD INSPECTION TOURS

The tours at the Field gave a choice between one general inspection trip and four special branch visits. The Aeroplane Branch provided some very interesting propeller and wind-

tunnel test explanations. The Power-Plant Branch had a number of engines on test. The Materials Branch was instructively labeled and proved unusually interesting. At the Equipment Branch visitors were entertained with the "flight tutor."

Flying Demonstration

The flying demonstration on Friday, at Wright Field, was unique in the history of aeronautics. The arrangements were carried through with military precision and thoroughness. On the Field was placed a double line of various types of airplanes, both for Government service and commercial use. It was an exceptional ground display, and the guests were privileged to study the planes and question the mechanics. When the flying program started, Lieut. S. P. Mills announced through a special radio broadcaster information of engineering interest and value about each airplane as it took the air. Among the unusual demonstrations was that of pursuit maneuvering by the "Boeing P-12," and the dropping of three parachutes simultaneously, giving decisive proof of the dropping qualities of each.

Dinner Program

The dinner proved one of the high spots of the meeting. The favor was an autographed composite photograph of the original Wright Brothers' plane in its first flight, with pictures of Orville and Wilbur Wright inserted in the upper corners. The photograph had been autographed by Orville Wright, the guest of honor at the dinner, and given to the Dayton Section of the Society for this purpose.

The speech of Captain Sir Hubert Wilkins was of unusual interest, as he told of his experiences in the Anarctic with Dr. Stefansson on foot, and then of his experiences with the airplane. General B. D. Foulois described his first cross-country flight with Orville Wright in 1909, when the Wright plane first passed the Government tests. The other banquet speaker was Casey Jones, president of the Curtis Flying Service and well-known racing pilot, who discussed many interesting developments in civil aviation. Chas. W. Ripsch, chairman of the Dayton Section, opened the dinner with a few remarks and introduced Charles F. Kettering, who was the toastmaster.

Technical Program

The number of papers presented was very large and the discussion noteworthy. The titles of the papers and names of the authors were as follows:

Monday Morning, May 19

What the Airplane Can Do in Central and South America, Roy V. Wright
Economic Aspects of the Rigid Airship, Carl B. Fritsche

Monday Afternoon, May 19

Design of Airplane from the Point of View of Cheap Production, Russell F. Hardy
Production Methods in Airplane Construction, R. S. Damon
Airplane Design, Manufacture, and Sales, Commercial vs. Military, Rex B. Beisel
Reduction of Airplane Production Costs, J. Don Alexander

Monday Evening, May 19

Accomplishments and Possibilities of Aerial Photography, A. W. Stevens

Tuesday Morning, May 20

German Metal Airplane Construction, Herbert Wagner
Airplane Wing Trussing, Richard Mock
Engineering Organization in the Airplane Factory, E. Molloy

Tuesday Afternoon, May 20

Fuel and Lubricants Session

The High Performance Gasoline Aircraft Engine and Its Fuel and Oil Problems, S. D. Heron
Some Aspects of Aircraft Lubrication, B. E. Sibley
The Present Status of Superchargers for Aviation Engines, Sanford A. Moss

Aerodynamics Session

Practical Airplane Performance Calculations, Michael Watter
The Airscrew with Minimum Loss of Energy, Enrico Pistolesi

Wednesday Morning, May 21

Silencing the Airplane, Hugh L. Dryden
The General Problem of Fire Hazard in Aircraft, C. G. McCord
Summary of Aerodynamics of Leonardo Da Vinci, R. Giacomelli

Wednesday Afternoon, May 21

Some Characteristics of Light Alloys for Aeronautics, H. W. Gillett
Aluminum Alloys for Pistons and Air-Cooled Cylinder Heads for Aircraft Engines, A. J. Lyon

Thursday Morning, May 22

The Artificial Horizon, Elmer A. Sperry, Jr.
The Economics of Airplane Transportation, Erich Offerman
Design and Development of Transatlantic Seaplane, E. Rumpler
Principles and Development of Air Law, André Henry-Courannier

Thursday Afternoon, May 22

Trend in Aircraft-Engine Development, Harold Caminez
Vibration Characteristics of Aircraft-Engine Crankshafts, F. L. Prescott
Installation of Radial Cooled Engines, P. B. Taylor

Aeronautic Division

SEATTLE, WASH., MAY 28 AND 29, 1930

The Aeronautics Meeting at Seattle, Wash., on May 28 and 29, 1930, was sponsored jointly by the Aeronautic Division and the Western Washington Section of the Society, and was held with the cooperation of the department of aeronautics of the University of Washington. The meeting had an average attendance at technical sessions of about 100, with a total registration of 139.

An informal luncheon was held on Wednesday in one of the rooms of the Home Economics Building of the University, after which trips were arranged to the plant of the Boeing Airplane Company and to the Municipal Airport. On Thursday a trip was made to the Sand Point Aviation Field.

Speakers at Dinner

A particularly enjoyable dinner was held Wednesday evening at the Seattle Yacht Club with E. O. Eastwood presiding as toastmaster. W. L. Dudley, vice-president and chief engineer of the Western Blower Company, Seattle, spoke on behalf of the A.S.M.E., while Commander J. D. Price represented the Navy, and Colonel H. C. Fiske the Army, in talks on aviation. Dean Leslie Ayer, of the University of Washington, took for his subject "Air Rights; Past, Present, and Future."

The papers presented at the technical sessions were as follows:

Wednesday Morning, May 28

Management and Operation of a Large Airport, W. D. Waterman
Air-Transport Management, D. W. Tomlinson
Air Design and Construction, W. L. Lewis

Thursday Morning, May 29

The Layout and Design of Modern Airplane Plants, G. W. Plaisted
Flying from the Private Owner's Standpoint, Earle Ovington
Interesting Engineering Problems in the Operation of Air Transports, J. C. Canney

Aeronautic Division

CHICAGO, ILL., AUGUST 25, 1930

A notable program of the Chicago Section with the Aeronautic Division cooperating was held on August 25, 1930, during

the 1930 National Air Races at the Curtiss-Reynolds Airport, Glenview, Ill., one of Chicago's suburbs. A morning technical session was held in the Airport Restaurant, and another smaller one in the evening at the Hotel Sherman.

Famous Flyers' Luncheon

An outstanding event was the Famous Flyers' Luncheon at which the Society was assisted by the Illinois Manufacturers' Association. About 800 listened to the brief talks and cheered the many aviation celebrities presented during the course of the luncheon. Dawson H. Skeen was toastmaster, and there were brief talks by C. B. Cole and Theodore R. Gerlach. The principal address was delivered by Edward S. Evans.

Technical Program

The following is a list of the papers delivered with the names of their authors:

Monday Morning, August 25

Construction and Operation of Gliders, Gilbert G. Budwig
Trend of Development in Aviation Gasoline, R. C. Alden

Monday Evening, August 25

Plywood in the Aircraft Industry, James R. Fitzpatrick
Stability and Controllability in Free Flight, Paul E. Hovgard
Future Aircraft Design Trends, Robert R. Osborn

Machine Shop Practice and Iron and Steel Divisions

CHICAGO, ILL., SEPTEMBER 22–26, 1930

More than 1400 members of the Society attended the Metal Congress held from September 22 to 26, 1930, at the Hotel Stevens, Chicago, Ill. The technical programs of the Machine-Shop Practice and Iron and Steel Divisions of the Society, The American Society of Steel Treaters, the American Institute of Mining and Metallurgical Engineers, and the American Welding Society brought out a total attendance for the Congress of nearly 6000. A Metal Industries Exhibit was held at the same time.

A.S.M.E. Dinner

Soviet Russia's program of industrial development in metal industries was the topic of the principal address by F. H. Wilcox at the joint dinner of the two Divisions and the Chicago Section on Wednesday evening, September 24. C. W. Bennett was toastmaster, and brief remarks were made by W. L. Abbott, W. W. Macon, W. W. Tangeman, Robert T. Kent, and Alex D. Bailey.

Technical Program

There was a generous turn-out of members of the Society augmented by many visiting members of other technical societies at the sessions of the Machine-Shop Practice and Iron and Steel Divisions. The following is a summary of the titles and authors of papers presented.

Tuesday Afternoon, September 23

Phenol Resinoid Molding Technique, Leon V. Quigley
Production of Plastic Telephone Parts, A. M. Lynn

Tuesday Evening, September 23

Flange Versus Foot-Mounted Motors, Herbert Chase
The Mechanical Design of Electric Motors as Regards Standardization and Interchangeability, J. L. Browne

Wednesday Morning, September 24

Fundamentals of Machine Polishing, Robert T. Kent
Repair of Worn Parts by Electrodeposition of Iron, T. P. Thomas

Wednesday Afternoon, September 24

Nitriding Analyses—Their Physical Properties and Adaptability, R. Sergeson and M. M. Clark
Case-Hardening with Ammonia Gas, Victor O. Homerberg and J. P. Walsted

Thursday Morning, September 25

Forces Acting on Rolled-Neck Bearings (A Report of the A.S.M.E. Research Committee on Heavy-Duty Anti-Friction Bearings), W. Trinks and John H. Hitchcock
General Design and Construction of Hot Saws for Cutting Heavy Structural Steel Sections, A. B. Pearson

Thursday Afternoon, September 25

The Manufacture of Large Weldless Forged-Steel Pressure Vessels, J. L. Cox
The Manufacture of Large Welded Pipe, Leon Cammen
Straightening of Steel by Rolling, J. Blair Sutton

Friday Morning, September 26

Recuperator Metallic Furnaces, G. D. Mantle
Continuous Reheating Furnaces for Rolling Mills, A. L. Culbertson

Friday Afternoon, September 26

Notes on the Production, Purification, and Uses of Blast-Furnace Gases, Wm. A. Haven and C. Brooks Thorne
Manual Semi-Automatic and Automatic Devices for the Protection Against Wind of Ore Bridges and Similar Structures, C. O. Burton

Materials Handling Division

CHICAGO, ILL., MARCH 5–7, 1930

"Organizing for Permanent Prosperity," which was the keynote of the week of March 3, 1930, in Chicago, proved to be an excellent drawing card for the Third National Meeting of the Materials Handling Division, held in that city in connection with the National Management Congress and under the auspices of the Chicago Section, from March 5 to 7. With a total registration of 800, all technical sessions were well attended and the plant-inspection trips proved to be very popular.

Technical Program

The titles and authors of papers are given in the following summary of the program.

Thursday Morning, March 6

Conveyor Handling Methods of the Chicago Daily News, M. W. Potts
Placing Wet Concrete With Belt Conveyors, E. L. Benson
Pneumatic Handling of Coal and Other Materials, H. H. Weiss

Thursday Evening, March 6

Shipment of Goods on Skid Platforms, F. J. Shepard, Jr.
The Industrial Tractor-Trailer Method of Materials Handling in the Meat-Packing Industry, A. D. Shanks
Industrial Plant Design and Operation as Effected by Transportation between Departments, Willard Brinton

Friday Morning, March 7

Material Handling in Production of Pork Products, A. W. De Vout
Recent Developments in Material Handling at the Western Electric Company's Merchandise Buildings at Kearny, New Jersey, C. K. Pevear

Friday Luncheon Meeting, March 7

Designing for Safety in Materials Handling, R. H. Hucke
Handling Materials in an Automatic Frame Plant, A. W. Redlin

Friday Evening, March 7

Effect of Modern Materials Handling on Materials Inventory and Scrap, E. J. Barney
Hidden Costs in Materials Handling, J. I. McCormick
What Does the Materials-Handling Equipment Manufacturer Need to Know to Make a Successful Installation? N. H. Preble

At Thursday's luncheon meeting, the question of standardization in the materials-handling field was discussed. It was decided that a report on the need for standardization would be presented at a future meeting.

Banquet

The banquet of the Materials Handling Division and the Management Congress was held at the Stevens Hotel on the evening of March 5. Dexter S. Kimball and Craig B. Hazlewood addressed the 400 in attendance. The toastmaster was Bernard J. Mullaney, president of the American Gas Association.

National Industrial Equipment Exposition

During the week there was held in the basement of the Hotel Stevens a National Industrial Equipment Exposition which was a combination exhibit of materials handling and management.

Oil and Gas Power Division

STATE COLLEGE, PA., JUNE 12–14, 1930

Gas turbines. Diesel-power costs, vibration, and nitriting were among the subjects covered in 17 papers presented at the Third National Meeting of the Oil and Gas Power Division held at Pennsylvania State College, from June 12 to 14, 1930, under the auspices of the Central Pennsylvania Section and the College. More than 300 were present at the technical sessions. The entertainment included a bridge party, dancing, a golf tournament, and a picnic. At the banquet Dean R. L. Sackett was toastmaster.

Technical Program

The following summary of the program gives the titles and authors of papers presented:

Thursday Morning, June 12

Address of Welcome, Ralph D. Hetzel
The Research of the National Advisory Committee for Aeronautics on Aircraft Diesel Engines, Carlton Kemper
Factors Affecting Nozzle Design in the Light of Recent Oil-Spray Experiments, P. H. Schweitzer
Pressure Variation in Common-Rail Fuel Injection System, Addison M. Rothrock

Thursday Afternoon, June 12

Progress Report on Research in Diesel Fuel-Oil Specifications, Wiley H. Butler
Report of Costs of Diesel Power, Franz Eder
Purification of Diesel-Engine Lubricating Oil, A. E. Flowers and M. A. Dietrich
The Lorensen Gas Turbine and Supercharger, C. A. Lorenzen

Friday Morning, June 13

Diesel Power-Plant Layout with Illustrations From Practice, E. W. Hammond
Joint Use of Diesel and Steam Engines to Balance Heat and Power, Edgar J. Kates
Economies of the Use of Electric Diesel Engines for Power Generation, T. A. Burdick

Saturday Morning, June 14

Nitride Hardening of Alloy Steels for Diesel-Engine Use, C. R. Alden
Some Phases of Light-Weight Diesel-Engine Design, P. B. Jackson
The Elimination of Torsional Vibration, Geo. J. Dashefsky

Saturday Afternoon, June 14

Natural-Gas Engines—Latest Gas-Engine Developments with Special Reference to Activities in California Oil Fields, V. L. Maleev
The Oil Engine in Aeronautics, E. E. Wilson
The Diesel-Engine Tractor and Excavator, C. G. A. Rosen
Gear Drives for Motorships, J. Barraja-Frauenfelder

Petroleum Division

TULSA, OKLA., OCTOBER 6–8, 1930

The first National Meeting of the Petroleum Division, held under the auspices of the Mid-Continent Section and the Petroleum Division in the auditorium of the Exposition grounds at Tulsa, from October 6 to 8, 1930, had an attendance of about 300.

Technical Program

The papers discussed pipe-line problems, pipe-line pumping stations, and refining. Each morning the speakers for that day gathered for a breakfast meeting at the Tulsa Club. The titles and authors of papers presented are given in the following summary:

Monday Morning, October 6

Purpose and Scope of the Petroleum Division, William G. Heltzel
Service Tests on Carbon Formation in Diesel Engines, E. H. Hillman
Lubrication of Power Cylinders of Diesel Engines and Causes of Cylinder Wear, J. M. McGregor and J. B. Harshman
Some Operating Data for Electrical Motor-Driven Reciprocating and Centrifugal Oil-Pipe-Line Pumps, W. H. Stueve

Monday Afternoon, October 6

Economic Design of Oil-Pipe-Line Transportation Systems, Oscar Wolf
Economics of Pumping Oil at Low Friction Losses, Fritz Karge
Report of Committee on Economic Analysis of Pipe-Line Pumping-Station Costs
Report of Committee on Fixed and Operating Charges for Diesel-Engine Pipe-Line Pump Stations, F. E. Waterfield

Tuesday Morning, October 7

Automatic Control of Pipe-Line Pumping Stations, J. B. Ford, J. B. McMahon, and T. D. Williamson
Temperature Observations for One Year on Streams of Petroleum Flowing in Mid-Continent Oil-Pipe Lines, Bert Martin and William G. Heltzel

Tuesday Afternoon, October 7

Effect of Hydrogen Sulphide on Wire Rope, Blaine B. Wescott and L. W. Vollmer
Use of Superheated Steam in Oil-Well Drilling, V. Weaver Smith
Report of Committee on Rotary-Drilling Equipment
Report of Committee on Unfired Pressure Vessels for Petroleum Industry

Wednesday Morning, October 8

Importance of Cracking Equipment in the Modern Refinery, Lyman C. Huff
Construction and Operation of Tube Stills for High Pressures and Temperatures, John Primrose
Stabilization and Absorption—Their Technical and Economic Positions in the Oil Industry, L. S. Gregory
Insulation of Cracking-Coil and Tube-Still Furnaces, E. V. Rinehart
Gasoline Recovery and Fractionation in the Refinery (*by title*), G. M. Jackson

Wednesday Afternoon, October 8

Improving Combustion Efficiency in Oil-Still Operation, Joseph R. Darnell
Reciprocating Hot-Oil Pumps, F. B. Applegate
Cottrell Process for Sulphuric-Acid Recovery, P. E. Landolt
Metallurgical Test Work Involved in Successful Adaptation of Alloy Steels to Industrial Purposes, R. L. Duff
The Flow of Steel at High Temperatures, F. H. Norton
Report of the A.S.M.E.-A.S.T.M. Joint Research Committee on the Effect of Temperature on the Properties of Metals, F. E. French

The International Petroleum Exposition held in Tulsa at the time of the meeting had many remarkable exhibits of production and refining equipment, and in addition there were some plant inspection trips on the program.

Printing Industries Division

NEW YORK, N. Y., APRIL 4, 1930

A very successful meeting of the Printing Industries Division was held in New York, April 4, 1930, under the auspices of the Metropolitan Section, in the auditorium of the Westinghouse Lighting Institute, Grand Central Palace. Leading printing-plant engineers described how plants are laid out and how production is conducted so that profitable operation will result.

Technical Sessions

There were two technical sessions. The papers presented and the authors are given in the following summary of the program:

Friday Afternoon, April 4

Engineering Research and the Publishing Industry, Samuel P. Weston
Printing-Plant Operation Without Alibis—Is It Possible? Hadar Ortman
Production Engineering in the Printing Plant, H. R. Lewis

Friday Evening, April 4

The Printing Engineer and Printing Profits, W. L. Churchill
The New Plant of the J. B. Lyon Company at Albany, Howard Chapman and Ernest A. Barvoets
The Printing Plant Engineer and His Profitable Work, O. J. Hutchinson

Textile Division

BOSTON, MASS., MAY 2, 1930

The Textile Division held a very successful National Meeting at Boston, Mass., on May 2, 1930, during the Textile Machinery Exposition. It was held under the auspices of the Boston Section and two technical papers were presented. They were:

Present Methods for Measuring the Physical Properties of Fabrics, W. F. Edwards
Theory and Practice of Textile Drying, B. R. Andrews

The afternoon was spent in a visit to the International Textile Exposition and in the evening a dinner was held at the Statler Hotel. The toastmaster was Henry M. Burke and the speakers Ray M. Hudson, who talked on "Progress and Stabilization in New England Textile Industries", and Ralph E. Flanders, who discussed "Engineering Approach to Continuous Prosperity for Industrial Plants."

Textile Division

GREENVILLE, S. C., OCTOBER 22, 1930

The Textile Division presented an interesting one-day program at Greenville, S. C., on October 22, 1930, in cooperation with the Greenville and Charlotte Local Sections, and during the Southern Textile Exposition.

Technical Session

The program opened with a session in the morning at the Poinsett Hotel. The papers presented and authors were as follows:

Humidification of Textile Plants, Edward D. Smith
The Treatment of Water for Bleaching and Dyeing, C. D. Blackwelder

The afternoon was spent by the visiting members and guests either in attendance at the Exposition or at a golf tournament which had been arranged by the Local Section.

Dinner Speakers

A dinner was held in the evening with David J. Kerr, chairman of the Greenville Section, presiding. The speakers included Wm. E. Mitchell, who gave an interesting talk on the development of public utilities in the South, and L. W. Wallace, who spoke on the subject of engineering in government. Short talks were given also by Henry M. Burke and James W. Cox, Jr. The dinner closed with a showing of the Japanese high-speed research film.

Wood Industries Division

NEW YORK, N. Y., OCTOBER 16-17, 1930

Splendid discussion and an unusually interesting exhibit were the high points of a National Meeting of the Wood Industries Division held at the Pennsylvania Hotel, New York, N. Y., on October 16 and 17, 1930, under the auspices of the Metropolitan Section.

At the dinner Friday evening there was lively discussion of "The Need of Forest-Products Engineers in the Wood-Working Industries," a paper presented by Nelson C. Brown and Raymond J. Hoyle. The toastmaster was Wilson Compton, who also contributed an interesting talk on the need of research and engineering development in the wood industries. On Thursday noon a luncheon was held, with Major Geo. P. Ahern as presiding officer, at which the topic of discussion was "Developments in Research in Tropical Woods and the Available Supply."

Technical Sessions

There were four technical sessions at which papers were presented. The authors and the titles of the papers follow:

Thursday Morning, October 16

Value of Wood Waste as Fuel, W. E. Biggs
Design of Fuel Feeders for Wood-Burning Furnaces, M. A. Hofft

Thursday Afternoon, October 16

The Science of Grading Timber for Strength, Leyden N. Erickson
Shrinkage in Wood, With Particular Emphasis on Longitudinal Shrinkage, Arthur Koehler
Curved and Bent Plywood, Thomas D. Perry

Thursday Evening, October 16

Opportunities for Utilization of Wood Waste in the Chemical Industries, B. B. Folger
Binders for Fibrous and Granular Woods, W. E. Emley
Developments in Stabilization of Painting Practice for Wood, F. L. Browne

Friday Afternoon, October 17

Abrasive Standards for Woodworking Operations, Elmer C. Schacht
Improvements in Steels for Wood Knives and Saws, Henry B. Allen

Plant Inspection Trips

On Friday morning, a number of inspection trips were made to factories in New Jersey and on Long Island where wood products were made. One of the unusual features of the meeting were the engineering exhibits. There were about fifteen of these which included samples of products made from wood waste, effects of seasoning of wood, mechanical tests, gluing of wood, samples of tropical woods, woodworking tools, and a historical exhibit.

Necrology

ARTHUR LEWIN ABRAHAMS

Arthur Lewin Abrahams, sales engineer for the Truscon Steel Company, Cleveland, Ohio, died on February 28, 1930, in Philadelphia, Pa. He was born in Lobsens, Germany, on January 23, 1888, the son of Morris and Natalia (Lewin) Abrahams. He received his education at the Central Manual Training High School, Drexel Institute, and the University of Pennsylvania, Philadelphia, Pa. He began his engineering work in 1904 as part-time apprentice toolmaker in a collar button works. In 1906 he became draftsman for the Warren Webster Company, manufacturers of steam specialties; in 1907 draftsman at the Baldwin Locomotive Works, Camden, N. J., working on electric mining locomotives; and in 1908 draftsman and subsequently assistant superintendent of the Bernstein Mfg. Co. in Philadelphia, for whom he designed and built sterilizers and operating tables. For ten years, beginning in 1910, he served successively as draftsman, chief estimator, and sales engineer for the Hale & Kilburn Corp., Philadelphia. During the early days of this connection he assisted in the design of pressed steel equipment for railroads, automobiles, and buildings. Later he concentrated on the development of the business and the capacity of the plant. In 1920 he engaged in export business, handling general mechanical products, and in 1924 became factory manager for the Kny-Scheerer Corporation of America, New York, N. Y., manufacturing a complete line of highly specialized hospital supplies and equipment. His connection with the Truscon Steel Company began in 1925 as sales engineer and eastern representative, located in New York. He transferred to Cleveland in 1930.

Mr. Abrahams joined the A.S.M.E. as an associate member in 1925. Fraternal organizations of which he was a member included the Elks and Masons.

Surviving Mr. Abrahams are his widow, Johanna Cohen, whom he married in 1911, and two children, Hermine and Naomi.

HENRY C. ACKERMAN

Henry C. Ackerman, mechanical engineer for the Municipal Water & Light Dept., Kansas City, Kan., died in that city on June 6, 1930, of pneumonia. He was born there on June 23, 1889, the son of Charles H. and Ida B. (James) Ackerman. His education was received at the Manual Training School of Kansas City and at the University of Kansas, at Lawrence, where he received the degree of B.S. in Mechanical Engineering in 1914. His early professional experience was secured as station attendant and field constructor for the Kansas Natural Gas Company, Independence, Kans., and as draftsman and designer in the bridge and mechanical departments of the Kansas City Terminal Railway Company.

Following his graduation Mr. Ackerman was employed in the mechanical department of the Kansas City Electric Light Company for a year, and in 1916 became maintenance engineer for the Hercules Powder Company, at Kenvil and Parlin, N. J., where he designed and installed a heavy hydraulic pressing and pumping system. In 1918 he entered the service of the Gorham Mfg. Co., Providence, R. I., as mechanical superintendent of the shell loading plant. A year later he became master mechanic of the By-Product Coke Plant of the Colorado Fuel & Iron Co., Pueblo, Colo. During the latter part of 1920 he was inspecting engineer on the construction of a power house for the Sinclair Refining Company, Kansas City, after which he spent two years as a member of the firm of Angevine & Ackerman, manufacturers' agents for power-plant equipment, Kansas City. In 1922 he became superintendent of construction of a new 800-kw. power plant at the State Penitentiary of Kansas at Lansing, where his work included the layout of a heating tunnel and the installation of a new electric distribution system. He had been with the Kansas City water and light department since 1923.

Mr. Ackerman became a junior member of the A.S.M.E. in 1916 and an associate member in 1923. He married Marianna Chase in 1923, and she, together with three children, Thomas James, Alice Marea, and Barbara Ann, survive him.

KILBURN ELIE ADAMS

Kilburn Elie Adams, superintendent of the Employment Department of the Edison Electric Illuminating Company of Boston since 1919, died on December 24, 1930, at his home at Waban, Mass. Mr. Adams was born at Cambridge, Mass., on January 18, 1882, the son of Kilburn and Cecelia Aurelia (La Pierre) Adams. He attended the Cambridge Latin School, Harvard College, where he received the degree of A.B. in 1902, and Harvard University (Lawrence Scientific School), where he was given the degree of S.B. in 1903. He also finished a course in Public Utility Management at the Harvard Graduate School of Business Administration in 1926.

Mr. Adams had a very broad engineering experience which began in 1903 when he had charge of the surveying for the Harvard Stadium. He spent a year as draftsman of pipe fittings and power-plant layouts for the Walworth Mfg. Co., Boston, Mass., and a little later was engaged by that company to make drawings for the 59th Street power station of the Interborough Rapid Transit Company in New York. He also had experience in building pumps and pumping engines for the Geo. F. Blake Mfg. Co., Cambridge, in 1904. In 1905 he became mechanical engineer for Sayles Bleacheries, Saylesville, R. I. From 1905 to 1907 he also assisted E. D. Leavitt, consulting engineer, Cambridge, Mass., in making computations and drawings for a stamp mill of the Calumet & Hecla Mining Co.; was assistant in charge of the engineering experimental laboratories at Harvard; and helped H. L. Gantt with the installation of the Taylor System at Stokes & Smith Co., Philadelphia, Pa. In 1907 he became connected with the firm of Wm. Underwood Co., Boston, Mass., as mechanical engineer and assistant manager of five canning factories in Maine and Massachusetts. For four years he was with the Boston and Albany Railroad as mechanical engineer in charge of design and construction work, which included the terminal at East Boston, passenger stations at Worcester and Pittsfield, Mass., and alternating-current and direct-current power plants, pumping and coaling plants, and fire-protection, power and light, and heating and ventilating systems. He also had charge of the design and construction of high-tension power-transmission lines owned by power and light companies where these crossed the railroad right of way. In 1913 he became head of the Incandescent Lamp Division of the Edison Electric Illuminating Company, Boston, Mass., where he had charge of the incandescent lamp work connected with the commercial and residential lighting in that territory.

Mr. Adams became a junior member of the A.S.M.E. in 1908 and a member in 1917. He also belonged to the American Management Association, Harvard Engineering Society, National Electric Light Association, and Associated Industries of Massachusetts. He was a member of the Committee on Employment of Rehabilitated Veterans for the Boston Chamber of Commerce, and was president of the Edison Employees Club in 1919–1920. He was much interested in athletics. His religious faith was Unitarian.

He married Elizabeth Florence Gilbert in 1908, and she, together with three children, Kilburn Elie, Jr., Gilbert Crocker, and Elizabeth Cecilia Adams, survive him.

DANIEL ADAMSON

Daniel Adamson, of Longlands, Hyde, Cheshire, England, head of the firm of Messrs. Joseph Adamson & Co., boiler makers and engineers, at that place, died on October 11, 1930, of heart failure following an operation.

Dr. Adamson came of a family conspicuous in engineering research and development in the North of England for more than a century. He was a grand-nephew of the pioneer of the Manchester Ship Canal and not only followed the family traditions, but explored new fields such as the electric overhead traveling crane and the harnessing of waste heat from boilers. He was considered an authority on spur gearing and won the Hawksley gold medal for a paper on that subject presented before the Institution of Mechanical Engineers in 1916. In 1929, during his year as president of the Institution of Mechanical Engineers, he was invested with the honorary degree of Doctor of Science by the University of Manchester in recognition of his services to engineering and engineering research.

Born at Newton Moor, Hyde, England, on August 26, 1869, the son of Joseph and Hannah (Platt) Adamson, his education was received in a private school in Hyde and at the College of Technology, Manchester. He served an apprenticeship with and subsequently worked as supervisor for Messrs. Scott & Hodgson, Ltd., Guide Bridge, near Manchester. He entered his father's company as foreman in 1889 and served in that capacity and subsequently as works manager until 1902, when he was made a partner. He became sole proprietor in 1925.

In 1894, Messrs. Joseph Adamson & Co. built the first electric three-motor overhead traveling crane, after Dr. Adamson had visited the United States to investigate its possibilities. Later he visited

the Continent to investigate a process in connection with boiler making, but owing to local conditions was unable to adopt it. About this time, Dr. Adamson was active on the Committee of the Manchester Association of Engineers, carrying out experiments showing the possibilities of high-speed steels which he had first seen at work in the Paris Exhibition of 1900. In 1912 he read a paper on conditions affecting the durability of wire ropes before the Institution of Mechanical Engineers. Among his other technical papers was one on the "Design and Construction of Electric Cranes" for which he was awarded the Constantine gold medal by the Manchester Association of Engineers in 1926. He contributed many other papers to the technical press and to engineering societies on subjects connected with power transmission, wire ropes, spur gearing, cranes, and engineering economics.

Dr. Adamson had been a member of the A.S.M.E. since 1901. Prior to his presidency of the Institution of Mechanical Engineers he had served on its council for thirteen years and been vice-president for six years. He was a member of the Institution of Civil Engineers and past-chairman of its Manchester Association, a member of the Institution of Electrical Engineers, and a life member of the Société des Ingénieurs Civils de France and of the American Institute of Electrical Engineers. Other engineering societies to which he belonged included the Association of Iron and Steel Electrical Engineers, Manchester Association of Engineers, of which he was past-president, the American Institute of Weights and Measures, the American Welding Society, the North East Coast Institution of Engineers and Shipbuilders, The Newcomen Society, the Literary and Philosophical Society of Manchester, and the Boiler Manufacturers' Association of Great Britain, of which he was chairman. He was an original member of the Engineers' Club of Manchester and served as its president in 1919–1921.

Socially Dr. Adamson was a staunch churchman and did a great deal of work on behalf of churches in his district. He was a trustee of the Hyde Lads' Club. As a member of the Federation of British Industries Delegates he visited the United States in 1927 on a tour of inspection of the State of Virginia.

He married Alice Maud Ryder in 1895 and is survived by her and two children, George Ryder and Joseph Adamson, who will carry on the business.

GEORGE VICTOR AHARA

George Victor Ahara, consulting engineer for The Canadian Fairbanks-Morse Co., Ltd., died at his residence in Toronto, Canada, of heart failure, on August 25, 1930. He was born at Evansville, Wis., on October 21, 1870, his parents being Hugh and Mary J. (Leighton) Ahara. He received his education at the Evansville Seminary and at the University of Wisconsin, by which he was given the degree of B.S. in Mechanical Engineering in 1895.

Mr. Ahara's engineering experience began in 1892 in the machine shop of the Berlin Machine Works, Beloit, Wis. Following his graduation he entered the testing department for internal-combustion engines and was subsequently assistant superintendent of the department for The Fairbanks-Morse Mfg. Co., at Beloit. In 1906 he became mechanical engineer of The Canadian Fairbanks-Morse Company at Toronto, and had charge of drawings and designs for internal-combustion engines for marine, portable, stationary, and tractor service, pumps, railway standpipes, and transmission machinery. He held patents on a number of improvements in gasoline engine carburetors. He became consulting engineer for the company in 1914.

His membership in the A.S.M.E. began in 1913. He was a member of the Methodist Episcopal Church and the Masonic fraternity. In 1898 he married Evelyn Ainsworth, who with three children, Edward Victor, Leroy Dale, and Robert Leighton Ahara, survive him.

WILLIAM HOWARD ARNOLD

After a few month's illness, William Howard Arnold died of blood poisoning at Hollywood, Calif., on January 4, 1930. He was born in Salt Lake City, Utah, on April 10, 1905, the son of Frederick E. Arnold. His education was received in the East High School at Salt Lake City, and at the University of Michigan, where he was given the degree of B.S. in Mechanical Engineering in 1926. After graduation he became sales engineer for Charles C. Moore & Co. and for a time was at the San Francisco office, but later was transferred to the Los Angeles office. He was a member of the Tau Beta Pi and Beta Theta Pi fraternities, and unmarried. He became a junior member of the A.S.M.E. in 1927.

Mr. Arnold is survived by his father, a brother, and a sister.

BENJAMIN ROBERT ATKINSON

Benjamin Robert Atkinson, chief engineer of the Morrison Machine Company, Paterson, N. J., died on April 11, 1930, following an operation for appendicitis. He was born in Paterson, N. J., on May 18, 1900, the son of Benjamin and Isabella (MacCandles) Atkinson. His education was received in the public schools of Paterson and at the Stevens Institute of Technology where he was given the degree of M.E. in 1921.

Mr. Atkinson's professional experience began in 1921 as traffic engineer with the Western Union Telephone Company, New York, N. Y. In 1922 he joined the General Electric Company at Harrison, N. J., as engineer in charge of production and development of ballast lamps. He became engineer for the Morrison Machine Company, manufacturers of textile machinery, in 1923 and was appointed chief engineer in 1928.

Mr. Atkinson became a junior member of the A.S.M.E. in 1925. He was very active in the work of the Wesley Methodist Episcopal Church at Paterson. He was president of the Paterson District of the Epworth League and a member of the Advisory Committee for the local troop of Boy Scouts. He married Eleanor L. Leather in 1928 and is survived by her.

CLARENCE MORSE BARBER

Clarence Morse Barber, chief engineer of the Michigan Copper & Brass Co., Detroit, Mich., died at his home on July 30, 1930. He was born at Berea, Ohio, on October 5, 1852, the son of Gershorn Morse and Huldah Lavinia (Seeley) Barber. He attended the Cleveland public schools and Rensselaer Polytechnic Institute, where he received the degree of Civil Engineer in 1878.

His professional experience began in 1878 as a draftsman for the King Iron Bridge Company, Cleveland, Ohio. From 1880 to 1885 he was chief engineer of the Cleveland, Lorrain & Wheeling Ry., and for the next two years engaged in private engineering practice at Cleveland. He then spent two years as superintendent of the Foxhall Tuning & Mining Co. and the Casino Mining Company in Colorado, and was superintendent and engineer for the National Carbon Company, Cleveland, from 1889 to 1895. From then until 1912 he served successively as engineer for the Brown Hoisting & Conveying Machinery Co., as constructing engineer of the Semet-Solvay Company, and as engineer for Smith, Hinchman & Grylls, architects and engineers, Detroit. During the next five years he carried on private practice in civil engineering. He had been connected with the Michigan Copper and Brass Co. for a number of years.

Mr. Barber developed and patented a machine for automatic electroplating of electric light carbons. Among his technical articles was one on "Fuel Briquetting in America," and he read a paper before the American Society of Civil Engineers at the World's Fair in Chicago in 1893, on "Carbon and Its Uses in Electrical Engineering." He became a member of the A.S.M.E. in 1904. He was also secretary and vice-president of the Cleveland Engineering Society, president of the Rensselaer Polytechnic Alumni of Detroit, and a member of the Detroit Engineering Society and the Ohio Society of Detroit. He belonged to the Methodist Church and was interested particularly in nature study, astronomy, and photography. He gave a great deal of his time to young men, helping many in connection with their college work. In 1882 he married Minnie Kate Brown, who died in 1905. One daughter, Grace L. Barber, of Detroit, Mich., survives him.

NEIL FRANKLIN BEESON

Following an automobile accident, Neil Franklin Beeson, assistant in mechanical engineering at the University of California, died on January 29, 1930. He was born at Albion, Iowa, on July 15, 1900, his parents being George Bernard and Lillian A. Beeson. His education was received at the High School at Marshalltown, Iowa, at the Iowa State College, and at the University of California, where he received the degree of B.S. in 1927.

Mr. Beeson began his professional work while still in college, during vacations serving as machine operator for the C. A. Dunham Co. and the Fisher Governor Company, at Marshalltown. He also worked in the machine shops of the Minneapolis & St. Louis R.R., and on automobile repair work, and from 1923 to 1925 he was a special apprentice on machine-shop work, layout and drafting, air-brake repair work, and car shop experience, in the shops of the Chicago & Alton R. R. at Bloomington, Ill. In 1927 he became teaching fellow, and in 1929 assistant in mechanical engineering at the University of California. He was a Christian Scientist in religion and was interested particularly in music, playing both the clarinet and piano, and in athletics. He was unmarried.

HANS C. BEHR

Hans C. Behr, retired, died at the age of 75, on March 29, 1930, at White Plains, N. Y., from injuries received when he was struck by an automobile earlier in the year. He was born in San Francisco, Calif., on February 9, 1855, his parents being Hans Charles and Agnes (Omilsky) Behr. He received his education in the public and Jesuit schools of San Francisco, the Gymnasium at Cöthen, Anhalt, Germany, and at St. Ignatius College, San Francisco.

His professional experience began as an apprentice and draftsman in the Union Iron Works, San Francisco, for which he later went to the Comstock mines to act as assistant to the chief engineer. He also served as assistant to the chief engineer, W. H. Patton, at Virginia City, Mo., in connection with design and erection of winding machinery, and as assistant to W. R. Eckert of San Francisco in the design and laying out of metallurgical plants. In 1899, after some private practice as a consulting engineer, he went to Johannesburg as consulting metallurgical engineer for the Consolidated Goldfields of South Africa. He took up consulting practice in New York again in 1912.

Mr. Behr had many American patents pertaining to percussion apparatus, pneumatic stamping, ore feeders, and mining equipment. He also had patents on valve gears and machines and equipment for separating liquids from solids. British patents included improvements in pneumatic percussion apparatus, pneumatic ore stamps, hammers, and the like. He contributed many papers to technical societies on mining methods and equipment, for several of which he was awarded gold medals. He was a life member of the A.S.M.E., which he joined in 1891, and of the South African Institution of Engineers, a member of the Institution of Civil Engineers, the Institution of Mechanical Engineers, and the Institution of Mining and Metallurgical Engineers in England, and a fellow of the Royal Society of South Africa. He had served as a member of the Patents Committee of the Transvaal Chamber of Mines, and of the Rand Mines Trials Committee, organized to experiment with new devices of interest to the mining industry. A son, Hermann Behr, of Watertown, Mass., survives him.

JOE A. BERGIN

As a result of a gas explosion during an inspection of new workings and methods of mining and preparation of coal, at Millfield, Ohio, Joe A. Bergin died on November 5, 1930. He was superintendent of The Ohio Power Company at the Philo Plant, Philo, Ohio.

Mr. Bergin was born at Hartland, Mich., on July 29, 1886, his parents being Frank M. and Mary (Rigney) Bergin. He received a high-school education. In 1914 he became operating engineer at the Delray Plant of The Detroit Edison Company, where he remained until 1920 when he was transferred to the Construction Engineering Bureau of the company, as a critic on the design of the Marysville steam electric generating plant. For three years, from 1921 to 1924, he was assistant manager of the Beech Bottom Power Company, during which period he served as combustion engineer and assistant manager in connection with the operation of the Windsor steam electric generating station, and a 60,000-kw. extension. He had been superintendent of The Ohio Power Company since 1924.

During the World War Mr. Bergin was in charge of steam-making equipment for the du Pont munitions operations near Nashville, Tenn.

He became a member of the A.S.M.E. in 1925 and was actively connected with the work of the Prime Movers Committee of the National Electric Light Association, having held the chairmanship of the Boilers, Superheaters, and Economizers Sections, and been a member of other sections. His club membership included the Zanesville Golf Club, Zane Club, Knights of Columbus, and Elks. He was a Roman Catholic in faith, a member of the St. Thomas Church in Zanesville, and was particularly interested in outdoor sports. He married Estelle M. Hogan in 1912 and she, together with one son, Robert Bergin, survive him.

WILLIAM C. BERRY

William C. Berry, designer and vice-president of the Berry Machinery & Supply Co., San Jose, Calif., died on July 24, 1930, in that city. He was born in Philadelphia, Pa., on March 12, 1882, the son of William C. and Lydia A. (Leach) Berry. He received his education at the Central Manual Training School, Philadelphia.

Mr. Berry entered the employ of the Falkenau-Sinclair Machine Company in Philadelphia, in 1900, and later worked in the crane and injector department of Wm. Sellers & Co. In 1906 he became connected with the Joshua Hendy Iron Works, San Francisco and Sunnyvale, Calif., in the design of waterwheels, ball and tube mills, stamp mills, and layouts for mill buildings, for a number of years being in charge of drafting and estimating. He was next associated, in 1919-1920, with J. H. McCullough, San Jose, Calif., working on the design of tractors and airplane engines. In 1920 he engaged in the design of pottery machinery for the Homer Knowles Pottery, Santa Clara, and in the following year designed a plant for Stanley Hiller, Inc., San Jose.

He was first connected with the Berry Machinery & Supply Co. in 1922, working on pumps and brine circulators for ice plants. In 1923 he designed tamping machinery and concrete molds for the Thermotite Construction Company, San Jose; in 1924 worked on screw presses for Stanley Hillier, Inc.; and in 1926 was engaged by the Standard Gas Engine Company of Oakland, on tractor design, and by Sanderson & Porter, San Francisco, in connection with fish meal and oil plant layouts.

He became an associate member of the A.S.M.E. in 1927, was a thirty-second degree Mason, and religiously was affiliated with the Rosicrucians. A son, William C. Berry, Jr., survives him.

ALEXANDER LESLIE BLACK

Alexander Leslie Black, vice-president of Ford, Bacon & Davis, Inc., died in San Francisco, Calif., on March 3, 1930. He was born in New Orleans, La., in January, 1871, and attended private preparatory schools in New Orleans and New York. He was graduated from the School of Mines, Columbia College, in 1890, and then engaged in mining work in the West and in Mexico for three years, subsequently acting as assistant engineer on the topographical survey of New Orleans. In 1894, Mr. Black took charge of the reconstruction for electric operation of the St. Charles Street Railroad Company in New Orleans and remained with that company, supervising operation and construction for this and other local companies, until 1901, when the New Orleans properties were consolidated. He then became engineer for the New Orleans Railway & Light Co. and its predecessors controlling the New Orleans Street Railways & Lighting Companies.

Mr. Black became identified with the firm of Ford, Bacon & Davis, Inc., in 1910. His first work was as engineer in charge of southern properties, supervising the reconstruction, maintenance, and operation of street railway, electric light and power, and water and gas properties. These activities engaged Mr. Black's time until 1914, when he became chief engineer of design and construction of public cotton warehouses and terminals in New Orleans. Two years later he was appointed chief engineer on the design and construction of the New Orleans Public Grain Elevator. The eight years following this engagement, which consumed only one year, were occupied with valuation and rate negotiations for various street railways and power companies.

In 1924 and 1925 Mr. Black was vice-president in charge of the Market Street Railway, San Francisco, and for two years following was chief engineer of the New Orleans Pontchartrain Bridge. Failing health caused Mr. Black to curtail activities during the three years previous to his death, and he alternated between the Corporation's New York and Birmingham offices. His last assignment was as consultant during the construction of the transportation system of the Southern Natural Gas Company.

Mr. Black became a member of the A.S.M.E. in 1915, and belonged also to the American Society of Civil Engineers, American Institute of Electrical Engineers, American Association of Engineers, and the Louisiana Engineering Society. He is survived by his widow, the former Virginia Bullitt Grant, and two sons, William Grant and Alexander Leslie Black.

HAROLD MICHAEL BRADY

Harold Michael Brady, assistant engineer of the General Petroleum Corporation, Los Angeles, Calif., died at his home in Los Angeles on January 25, 1930. He was born in Marion, Ind., on September 23, 1900, his parents being Alfred Tennyson and Jessie Anna (Barley) Brady. He received his education at the California Institute of Technology, obtaining the degree of B.S. in Mechanical Engineering in 1922. He began work with the General Petroleum Corporation of California as draftsman and later was designer and assistant engineer of design.

Mr. Brady became a junior member of the Society in 1922, and he also was a Mason. He was a Presbyterian in faith, and he was particularly interested in engineering and mathematical subjects, and in ancient and religious history. He was unmarried.

WILLIAM HENRY BRISTOL

William Henry Bristol, inventor of the Bristol phone and numerous recording instruments and president of the Bristol Company of Waterbury, Conn., died on June 18, 1930, in the New Haven Hos-

pital. He had been suffering for several months from a blood clot in the region of the heart.

Professor Bristol was a pioneer in the manufacture of recording instruments in America. In 1915 he conceived the idea of recording simultaneously sound and action. The invention and production of the Bristol phone, which synchronizes both in motion pictures, followed. To perfect this instrument he spent nearly a million dollars. A fully equipped motion picture laboratory and studio in Waterbury were constructed for this purpose. Other inventions included steel belt lacing and instruments for measuring pressure, temperature, electricity, speed, and time.

Professor Bristol was born on July 5, 1859, in Waterbury, the son of Benjamin Hiel and Pauline (Phelps) Bristol. He was graduated from Stevens Institute of Technology, at Hoboken, N. J., in 1884 with an M.E. degree. While a student there he organized and taught in the manual training department of the Workingman's School in New York. After his graduation he was appointed instructor and later, a professor of mathematics, at Stevens, where he taught until 1906.

He founded the Bristol Company in 1899 to manufacture and market his inventions. He held many medals awarded him at various expositions for his inventions. Among these were the John Scott Legacy medal, which he received from the Franklin Institute at Philadelphia in 1890, and one awarded at the sesquicentennial at Philadelphia in 1926; a medal and diploma at the Chicago Exposition in 1893, a silver medal at the Paris Exposition in 1900, a gold medal at the St. Louis Exposition in 1904, and a grand prize at the Panama Pacific International Exposition in 1915.

He was a member of numerous societies, including The American Society of Mechanical Engineers, which he joined in 1890, Society of Electro-Chemical Engineers, Society of Motion Picture Engineers, and American Institute of Electrical Engineers. He also was a fellow of the American Association for the Advancement of Science.

Professor Bristol's first wife was Miss J. Louise Wright, of New York, who died in 1888. His second wife was Miss Elise H. Myer of Jersey City, whom he married in 1899. He is survived by two brothers, Bennett G. and Edgar H. Bristol of Foxboro, Mass., and one sister, Mrs. Bertha Bristol Tracy of Wellesley, Mass.

WILLIAM MILTON BROCK

William Milton Brock died at his home in Paterson, N. J., on July 4, 1930. He was born in Brooklyn, N. Y., on November 3, 1856, the son of Samuel Gowan and Elizabeth Lamb (Docherty) Brock. His father being in the Union Army during the Civil War, Mr. Brock started work at an early age as slate picker in a coal breaker in Pennsylvania, where the family then resided. In 1886 the family returned to Brooklyn, where he attended public school for a time, sold newspapers, worked in a jewelry store, and was a blacksmith's helper. In 1869 the family removed to Shamokin, Pa. After again working for a time in a coal breaker he secured employment as a messenger for the Mineral Railroad & Mining Co., carrying reports between their offices and those of the Northern Central Railway Company.

About this time Mr. Brock became interested in electricity, and devoted the major part of his spare time to the study of telegraphy, mathematics, and mechanical drawing.

In 1873 the Mineral Railroad & Mining Co. connected its several collieries by telegraph with its own general office and those of the Northern Central Railway Company, and Mr. Brock was appointed operator at the Cameron office. In 1879 he accepted a position as car record clerk with the Northern Central Railway Company. During these years he carried on experimental work in telegraphy and telephony. He constructed a set of telephone instruments which he operated over an 18-mile telegraph line between Shamokin and Sunbury, Pa. He also constructed one of Mr. Edison's latest tin-foil phonographs during this period.

In 1879 he was appointed manager of the Shamokin Division of the Central Pennsylvania Telephone & Supply Co., a newly organized concern with headquarters at Williamsport, Pa., and while there invented in 1882 a central office telephone switchboard system for which he secured letters patent in 1883. After installing exchanges in Shamokin, Sunbury, and Mt. Carmel, all connected by trunk lines, Mr. Brock resigned in 1883 to accept a position with the newly organized Edison Electric Illuminating Company of Shamokin, to assist in the installation of equipment.

In 1886 Mr. Brock accepted the management of the Edison Electric Illuminating Company of Lawrence, Mass., one of the first installations of the Edison municipal system of series street lighting, and of some of the early Sprague motors. He resigned three years later to become secretary and general manager of the Edison Electric Illuminating Company of Paterson, N. J., where he had the acute competition of the Paterson Electric Company, which was furnishing the city with Thomson-Houston arc service and a three-wire commercial incandescent system using Sawyer-Man lamps.

In April, 1890, the two companies were merged, and by 1894 the current demand had so increased as to necessitate the erection of a new and up-to-date plant. Mr. Brock contributed many valuable ideas to the design and equipment of the new plant, which was put in commercial operation in 1896. From then until his retirement in 1926 Mr. Brock occupied the position of division superintendent of the Public Service Gas & Electric Corp. of New Jersey, with headquarters at Paterson.

He became a member of the A.S.M.E. in 1894 and was also a member of Edison Pioneers, of which organization he was elected a vice-president in 1926. For many years he was a member of the Hamilton Club. He belonged to the Church of the Messiah (Presbyterian) in Paterson. He was particularly interested in Japanese carvings and pottery, of which he had made a considerable collection.

In 1885 he married Florence Vincent Wilson, who, together with three daughters, Mrs. Elizabeth Rogers, Mrs. Mildred Simonds, and Mrs. Florence Huber, survive him.

VICTOR H. CARPLES

Victor H. Carples, secretary and treasurer of the L. J. Wing Mfg. Co., New York, N. Y., died on September 3, 1930. He was born in New York on January 7, 1886, the son of Emanuel and Anna (Brown) Carples. He attended the College of the City of New York, where he received the degree of A.B. in 1904, and Columbia University, securing the degree of E.E. there in 1910.

After graduation Mr. Carples became associated with P. R. Moses and the Engineering Supervision Company in New York, where he inspected and tested isolated power plants and was engaged in the laying out of new plants. In 1911 he joined the L. J. Wing Mfg. Co. His work involved layouts and tests of boiler plants with special reference to forced-draft systems. He supervised considerable research work on fans and blowers. He became secretary and treasurer of the company in 1917. Mr. Carples held a joint patent with A. E. Seelig on an air-blowing device. He joined the A.S.M.E. as an associate member in 1921, and became a member in 1923. He was greatly interested in music and was an able pianist. One daughter, Ann Barbara, survives him.

WALTER LEE CHENEY

Walter Lee Cheney, retired, died on August 15, 1930, at his home in Meriden, Conn. He was born at Greenfield, Mass., on October 7, 1854, the son of Ebenezer and Rowena (Hastings) Cheney. After receiving a high school education, he began his professional work as an apprentice machinist with the Pratt & Whitney Co., Hartford, Conn. He worked for four years in the shops and followed this with five years of drafting room experience. After being connected for a time with the Springfield Machine Tool Company, Springfield, Ohio, and with Warner & Swasey Co., Cleveland, Ohio, he became associate editor of *Machinery*. Under the pen name of Charles W. Lee he contributed articles to this and other technical publications. Following this connection he was engaged successively as foreman for the New Home Sewing Machine Company, Orange, Mass., assistant superintendent for the Hancock Inspirator Company, Boston, Mass., and superintendent for the June Sewing Machine Co., Chicago, Ill., and the American Sewing Machine Company, Philadelphia, Pa. His subsequent positions included that of mechanical engineer for the Westinghouse Electric & Manufacturing Co,. Newark, N. J., foreman for Moses G. Crane & Co., Boston, Mass., secretary of the Meriden Machine Tool Company, Meriden, Conn., salesman for the Walter H. Foster Co., New York, and for the Potter & Johnson Co., Pawtucket, R. I., and for more than twenty-five years, sales engineer for the Lucas Machine Tool Company, Cleveland, Ohio.

He became a member of the A.S.M.E. in 1883 and also was a member of the American Association for the Advancement of Science, the National Geographic Society, and the Machinery Club of New York. In 1879 he married Elizabeth Adams Whitney. The following children survive him: Rowena, Amos E., and William L. Cheney, and Mrs. Fred R. Collington.

CHARLES CLIFFORD COCHRAN

Charles Clifford Cochran, whose death occurred on January 28, 1930, had been associate professor of mechanical engineering at the Pennsylvania State College since 1920, and in charge of the mechanical laboratory under Professor Wood since 1922. He was born in Denver, Colorado, on November 26, 1870, his parents being Shelby and Susan (Ralston) Cochran. He received his education in the

Denver schools and at the University of Colorado, where he was given the degree of B.S. in Mechanical Engineering in 1906.

Prior to his graduation, Mr. Cochran served an apprenticeship in the machine shops of several railways in the Central West, and for two years he was acting foreman of the Denver and Rio Grande Southern Railroad. After graduation he became assistant professor of mechanical drawing at the University of Kansas, and for three years was engaged in selling educational courses for the Emerson Institute of Indiana and the La Salle Extension University, Chicago.

Mr. Cochran had several patents relating to motion reduction and to a mercury barometer with electric attachment for setting the scale by ear instead of by eye. He was the author of a thesis on the Proximate Analysis and Heating Value of Colorado Coals. He joined the A.S.M.E. as a member in 1922. He also belonged to the University Club of State College and the Tau Beta Pi fraternity. His first wife, Lucy Ballinger, died in 1916. Mary E. (Hoy) Cochran, whom he married in 1927, survives him.

GUY BAIN COLLIER

Guy Bain Collier, president and treasurer of the Collier Manufacturing Corporation, and a well-known consulting and designing engineer, died at his home in New York, on June 15, 1930. He was born in Kinderhook, N. Y., on July 12, 1877, the son of Gerrit Sager and Lydia (Bain) Collier. He attended Union College, Schenectady, N. Y., and subsequently Harvard University, where he was given the degree of S.B. in 1901 and an A.M. two years later.

For eight years beginning in 1901 Mr. Collier tutored in mathematics, engineering and physics, and astronomy at Harvard and the Massachusetts Institute of Technology. In 1906 he entered partnership with N. B. Wales, Boston, Mass., and was engaged in engineering and development work. Five years later he began a private practice in development work relating to dynamic heating systems, steam turbines, gas engines, hydrocarbon motors, valve mechanisms, and mechanical devices.

Mr. Collier joined the U. S. Shipping Board, Supply Division, District A, Boston, in 1918 as production expediter under H. L. Bond, supervising Shipping Board work at several plants. He served as senior examiner in the New York office of the Shipping Board in 1919.

He returned to private work as consulting and designing engineer with the Collier Motor Patents Corporation in 1919. His clients included the Eagle Picher Lead Company, Newark, N. J.; C. W. Short, Jr., architect of New York, for whom he designed trusses and structural steel; and the Sharples Specialty Company, of New York and Philadelphia, for which he designed two oil-refinery dewaxing plants. He also designed a 176-ton steel coal bunker, suspension type, for the power house of the Essex County Hall of Records, Newark, N. J., and the mezzanine floor and stairs of the Continental Bank in New York.

Mr. Collier held a number of patents relating to internal-combustion motors, reciprocating engines, aeroplane propellers, carbureters, and gas-lighting apparatus. Patents were pending on a gas-cooled valve, gas switch, a water-cooled valve engine with detachable cylinder head, and other developments in valve engines.

Mr. Collier became a member of the A.S.M.E. in 1922. Among his contributions to its publications was a paper on the Analysis of Strains and Stresses in a Wristpin, presented at the 1927 Annual Meeting. He was also a member of the Harvard Engineering Society, and he belonged to the Dutch Reformed Church. In 1924 he married Elvira Brewster, who survives him.

JACOB DOLSON COX

Jacob Dolson Cox, chairman of the Board of Directors of the Cleveland Twist Drill Company, died at Pasadena, Calif., on February 23, 1930. He was born in Warren, Ohio, on May 15, 1852, the son of Major-General Jacob Dolson and Helen Clarissa (Finney) Cox. After a common school education he entered the service of the Cleveland Iron Company in 1869 and successively held the positions of ore weigher, machinist, roll-turner, puddler's helper, and roller's assistant. He also worked with J. F. Holloway on marine engines at the Cuyahoga Steam Furnace Company. In 1876 he associated himself with C. C. Newton in the firm of Newton & Cox, manufacturing twist drills. His firm was located first at Dunkirk, N. Y., and then at Cleveland, Ohio. In 1879 Mr. Cox bought out Mr. Newton and continued the company as J. D. Cox until 1880, when he sold an interest to F. F. Prentiss, and the firm became Cox and Prentiss. This was incorporated in 1904 as the Cleveland Twist Drill Company. He retired in 1919, but served as chairman of the Board of Directors from then until his death.

Mr. Cox designed and built a variety of machinery for grinding, planing, and drilling, introducing many new features. He was awarded the John Scott Legacy Medal by the Franklin Institute for his grip-socket invention which consisted of a grip chuck for taper shanks to keep them from pulling out of the sockets. He was trustee of the Case School of Applied Science, chairman of the Cleveland Grade Crossing Commission, and director and vice-president of the Cleveland Chamber of Commerce and The Cleveland Trust Company. He became a member of the A.S.M.E. in 1881, and belonged to the Mayflower Society of New York, the Ohio, Union, Country, Mayfield, and Engineers Clubs of Cleveland, the Essex County Country Club in Massachusetts, the Midwick Country Club of Los Angeles, and the Engineers Club in New York. His religious faith was Episcopalian, and he was particularly interested in photography, yachting, and golf. In 1878 he married Ellen Atwood Prentiss, and she, together with three children, Samuel Houghton and Jacob Dolson Cox, and Jeanette Prentiss (Cox) Morrill, survive him.

EDWIN FRANCIS CREAGER

Edwin Francis Creager was born on September 24, 1866, at Harrisburg, Pa., the son of Calvin Wesley and Henrietta Maria (Culmery) Creager. From the age of eleven he earned his own living. He learned the drug business from J. W. Hill & Son of Senatobia, Miss., and subsequently worked for Charles Boyd, at Fort Smith, Ark., for three years as assistant registered pharmacist at Springfield, Ohio, and for H. B. Cochran, at Lancaster, Pa.

In 1886 and 1887 he was night operator and inspector for the Central Union Telephone Company. The next six years were spent in electric light and power work. After serving an apprentice he was advanced through various positions to that of plant manager for the Edison Electric Illuminating Company. Among the plants at which he was stationed were those at Renovo, Lancaster, Williamsport, and Danville, Pa. He combined two plants at Danville, and also did some work at the Sunbury plant. As field man for the southeastern district of the company he covered Delaware, Maryland, the Virginias, the District of Columbia, and the Carolinas. During this period the first electrically driven bridge reamer was designed and built at the Edgemoor Bridge Works, Wilmington, Del., in accordance with his suggestions. He also installed the first searchlights on several coastwise vessels.

Mr. Creager was transferred to the Pacific Coast in 1889. For a time he was in charge of wiring in San Francisco. He built and installed a system of lighting dimmers at the Alcazar Theater there, and designed several other theater lighting novelties still in use. He was in charge of the building of the first Sprague electric railway west of the Rockies, at Sacramento, Calif., and installed the first mine pumping plant electrically driven, at the Gover Mine, in Ione County, Calif.

Mr. Creager returned to the East in 1892 and opened a model shop, known as the Acme Electric Works, at Lancaster, Pa. He sold the business to the Hubley Manufacturing Company two years later, and from then until 1906 was employed by that company, being advanced from pattern foreman to manager. This company was known as the largest iron toy and novelty company in this country at that time. During these years Mr. Creager developed the manufacture of light gray iron castings for the electrical and specialty trade.

In 1906 Mr. Creager again went into business for himself in Lancaster, specializing in automotive and electrical contracting. He also did some consulting work, in connection with which he was engaged by the Hamilton Watch Company to move the plant of the American Telegraphone Company from Wheeling, W. Va., to Springfield, Mass. In 1910 he disposed of his Lancaster business and went to Springfield as general manager of the American Telegraphone Company.

Three years later he left Springfield to enter the engineering department of the Remy Electric Company at Anderson, Ind. He was soon made assistant factory manager and subsequently was promoted to the position of works manager. During the five years he spent with this company its output was increased eleven times and the number of employees two and one-half times. He developed a number of special machines and operations for coil winding, condenser making, presswork, etc.

In 1919 and 1920 he was engaged by the Ott Grinder Company, of Indianapolis, Ind., for which he increased the output from eight to twenty-five machines per month with no increase in the number of employees.

Mr. Creager next became works manager of the Hill Pump and Turbine Works Division of the Midwest Engine Company, at Anderson, Ind. He reduced the operating force materially without decreasing production, and increased the tensile strength of the iron castings from 18,000 to an average of 30,000 pounds. At the same

time he had charge of the buildings, machinery, and personnel of the Indianapolis plant and worked on various engineering problems, including the construction of fireboats for Philadelphia, New Orleans, Norfolk, and Baltimore. He had charge of the installation of the high-pressure fire station at Detroit and the sewage disposal plants at Spring Wells, Detroit, and Indianapolis, for which he built centrifugal pumps to a capacity of 25,000 gal. per min. He also supervised the installation of the city water pumping plant at Bismarck, N. D., and extensions at Springfield, Ill., and designed two 550-lb., 1500 gal. per min. bronze multistage pumps used for operating the hydraulic shears, etc., at the plant of the Otis Steel Company at Cleveland. These were the first pumps of this pressure and capacity used for such work in the United States.

In 1925 the Otis plant changed hands and Mr. Creager was engaged by the Barber Manufacturing Company at Anderson as designing engineer to develop springs and other parts for the automotive and furniture industries. Owing to poor health resulting from a nervous breakdown and heart trouble he resigned his position in 1927 and went to Springfield, Mass., for a rest. He returned to Lancaster late in 1928 and his death occurred there on April 28, 1930. Surviving him are his widow, Clara Augusta (Wettig) Creager, of Lancaster, whom he married in 1892, and one son, Frederick Leon, of Merchantville, N. J.

Mr. Creager joined the A.S.M E. as an associate in 1919 and was promoted to full membership in 1925. He also belonged to the Society of Automotive Engineers and the American Institute of Electrical Engineers, as well as the Masonic fraternity, Elks, and Odd Fellows. He was a member of the Presbyterian faith, fond of hunting and fishing, and interested himself in collecting early mechanical devices. He held the first United States patent to bear descriptive matter on the drawing. He contributed a number of articles to the *American Machinist*, among them one on the "Relation of the Stroke of the Press to the Life of the Die."

JAMES KENMORE CULLEN

James Kenmore Cullen, president of The Niles Tool Works Company, Hamilton, Ohio, and a member of the executive committee of The General Machinery Corporation, died at Hot Springs, Va., on July 31, 1930, of cerebral hemorrhage. He was born in Cincinnati, Ohio, on February 18, 1853, the son of William and Jane (Brocas) Cullen. He received his education at the Cincinnati High School, Currans Preparatory School in Cincinnati, and the Ohio Mechanics Institute. He also served an apprenticeship from 1870 to 1873 in the shops of the Cincinnati, Hamilton & Dayton Railway Co. He then entered his father's jobbing shop where he remained for two years. From 1875 to 1879 he was foreman and draftsman for the Cincinnati, Indianapolis, St. Louis & Chicago Railroad, at Cincinnati.

In 1879 he became foreman and superintendent of The Niles Tool Works Company, at Hamilton, where he remained until 1886 when he was made manager of the Chicago Branch. He was advanced to the position of secretary in 1894 and to that of president in 1900, when he was also elected vice-president of the Niles-Bement-Pond Company. He was president of the latter company from 1915 to 1927. Mr. Cullen had also served as president of Pratt & Whitney Co., Hartford, Conn., John Bertram & Sons Co., Canada, The Miami Foundry Company, Miamisburg, Ohio, and the Cullen & Vaughn Co.

He became a member of the A.S.M.E. in 1886 and also belonged to the Engineers Club, Lotus Club, Machinery Club, and Railroad Club, all of New York, N. Y. He was a thirty-second degree Mason and a Presbyterian. In 1879 he married Addie E. Barns, who died in 1928. He is survived by a son, William B. Cullen, of Springboro, Ohio.

WILLIAM WARREN CUMMINGS

William Warren Cummings, consulting engineer for the Industrial Appliance Company, Boston, Mass., died at Hanover, N. H., on April 5, 1930. He was born at Woburn, Mass., on September 13, 1864, the son of James Otis and Susan Celina (Bennett) Cummings. He was graduated from the Rensselaer Polytechnic Institute in 1884 with the degree of C.E.

Mr. Cummings began his professional experience as assistant professor of mechanics at Rensselaer following his graduation. In 1890 he conducted a private practice as consulting engineer at Woburn, Mass., and was also city engineer there until 1892. He was then assistant city engineer of Troy, N. Y., for a year, and assistant engineer to M. R. Sherrard and draftsman with L. E. Gurley in New York in 1893.

In 1894, Mr. Cummings returned to the teaching profession for a year as assistant professor of mathematics and surveying at the Colorado School of Mines in Golden. He again entered private consulting practice in 1895 at Woburn. He did work in connection with the Massachusetts State Boundary Survey in 1898, and was chief engineer in charge of erection for the New England Gas & Coke Co., Everett, Mass., and the Massachusetts Pipe Line Gas Company, Boston, from 1899 to 1901. In 1903 he became assistant (and later superintendent) of the Isolated Light and Power Department of the Edison Electric Illuminating Company in Boston. He was connected with the Boston Consolidated Gas Company as assistant manager of the commercial department from 1906 to 1910, as manager of the industrial fuel department from 1915 to 1921, and as engineer of utilization from then until 1924. At that time he became consulting engineer, specializing on the industrial use of gas, for the Industrial Appliance Company of New England.

Mr. Cummings constructed three tunnels under the Charles and Mystic Rivers and a 42-in. double pipe line in Boston's congested streets in winter. His work as consulting engineer also included coke oven and railroad and mill construction.

He became a member of the A.S.M.E. in 1905 and was also a member of the American Society of Civil Engineers, the American Gas Association, the American Society for Steel Treating, the Boston Society of Civil Engineers, and the American Institute of Electrical Engineers. He belonged to the St. Thomas Church at Hanover, N. H. In 1898 he married Alice Jeeves. She, together with four children, Carl Herrick, William Warren, Jr., Harry Blanchard, and Doris Elizabeth Cummings, survive him.

WARREN JOHN JOSEPH DARWENT

Warren John Joseph Darwent, whose death occurred in Schenectady, N. Y., on July 19, 1930, was born in Jersey City, N. J., on June 15, 1898, the son of John Peterson and Alice Maude (Sutton) Darwent. He received a degree of B.S. in mechanical engineering from Rutgers College in 1921, and took a summer course in chemical engineering at Columbia University.

Before graduation he was employed by the Wright Martin Aircraft Corporation, New Brunswick, N. J., and the Singer Manufacturing Company, Elizabethport, N. J., and he worked for the latter as draftsman until 1925. For the next two years he was connected with the Consolidated Gas Company in New York and from then until 1930 was engineer for the Certainteed Products Corporation of Philadelphia. At the time of his death he was in the employ of the American Blower Company, in Schenectady, N. Y.

Mr. Darwent became a junior member of the A.S.M.E. in 1921 and belonged to the Lambda Chi Alpha fraternity. He was an Episcopalian and interested particularly in music, playing several instruments. In 1927 he married Ruth L. Skidmore, and she, together with their daughter, Joan Ruth, survive him.

EZRA D. DAVIDSON

Ezra D. Davidson, a native of Ansonia, Conn., died in that city on December 30, 1930, after an illness of several months. Mr. Davidson was born on December 5, 1886, the son of James H. and Laura B. Davidson. After completing his high school education he entered the plant of the Farrel Foundry & Machine Co., later known as the Farrel-Birmingham Company, of Ansonia. He supplemented his early education with Y.M.C.A. and correspondence school courses, and at the time of his death had become sales engineer for the company.

For many years Mr. Davidson was prominent in athletics in Ansonia. He was a member of the championship team of the Farrel Foundry during the existence of the Industrial Basketball League in Ansonia and also played on the basketball and baseball teams of the local Y.M.C.A. In sports as in his business relations, he was popular for his fairness, and was known as a "square shooter." Mr. Davidson was a member of the Wepawaug Country Club of Milford, Conn.

Mr. Davidson became an associate member of the A.S.M.E. in 1921. He was an authority on rubber and rubber machinery, and in work on the Safety Code for Rubber Machinery represented the Society on the International Association of Industrial Accident Boards and Commissions and the National Safety Council.

In the Masonic fraternity Mr. Davidson, who had attained the rank of the 32d degree, was a very prominent figure, belonging to local groups in Mount Vernon, New Haven, and Bridgeport, as well as Ansonia. He was also a member of the First Baptist Church at Ansonia.

Mr. Davidson's wife, Louise H. Davidson, died about four years ago. He is survived by three daughters, Madeleine Huson, Lois Gertrude, and Marian Winifred Davidson.

WILLIAM J. DELLES

William J. Delles died suddenly of heart trouble at his home in Schenectady, N. Y., on May 22, 1930. He was executive engineer in the turbine engineering department of the General Electric Company in that city. He was born in Rochester, N. Y., on September 4, 1871, the son of Peter John and Antoinette (Spitzberg) Delles. He received his education at the Mechanics Institute at Rochester, N. Y. From 1892 to 1898 he served as apprentice and journeyman molder. He then entered the employ of the General Electric Company and until 1922 served successively as draftsman, section leader, and foreman in charge of mechanical design in the direct current department; mechanical engineer in the assistant manager's office engaged in the development of special machinery for the factory, and standardization and improvement of methods of production; and assistant engineer of the turbine engineering department. As executive engineer in the latter department he was responsible for the design, manufacture, installation, and operation of steam turbines.

Mr. Delles became a member of the A.S.M.E. in 1924 and was a member of the Quarter Century Club of the General Electric Company and the Knights of Columbus. He was married to Lenore C. Driscoll in 1918, and she, together with two children, William James, Jr., and Rose Margaret Delles, survive him.

FREDERICK WILLIAM DERBYSHIRE

Frederick W. Derbyshire, owner of the firm of F. W. Derbyshire, Waltham, Mass., died on December 30, 1930, following an operation. He was the son of William Henry and Ann (Briley) Derbyshire, and was born in Lowell, Mass., on September 23, 1859. He attended the public schools of Waltham, Mass., and after serving an apprenticeship with the American Watch Tool Company there, was employed by that company as foreman and later as assistant superintendent in connection with the design and supervision of lathes and automatic machinery used in manufacturing watches and clocks. In 1899 he became connected with the Pratt & Whitney Co., Hartford, Conn., as foreman of its model department and from 1901 to 1911 again was employed by the American Watch Tool Company in charge of the design and manufacture of machine tools. He established his own firm in 1911 to manufacture lathes and attachments for watch, clock, and instrument work.

Mr. Derbyshire became an associate member of the A.S.M.E. in 1918 and was also a member of the Engineering Societies of Boston and very active in the Masonic fraternity.

In 1885 he married Clara Jane Stackpole, who died in 1912. Two children, Frederick W., Jr., and Elna Derbyshire, survive him.

JAMES G. DORNBIRER

James G. Dornbirer, president of the Dornbirer Machine Tool Company, which he established in 1929, died on November 27, 1930. He was born in Huron County, Ohio, on March 4, 1867, the son of Jacob and Elizabeth (Trott) Dornbirer. After attending the public schools of Sandusky, Ohio, he served as an apprentice machinist with D. June & Co., Fremont, Ohio, and the Warner & Swasey Co., Cleveland. He then ran a machine shop at Marion, Ind., from 1889 to 1895. The next three years he spent at Rose Polytechnic Institute at Terre Haute, Ind. Completing his studies there he started the J. G. Dornbirer Machine Co. in Cleveland in 1898, for the manufacture of special machinery, and automatic and semi-automatic labor-saving machinery. He was associated with G. W. Ford in the organization of the Cleveland Planer Works, and designed a line of planers and served as general manager of that company. He also designed a line of horizontal boring machines built by the Cleveland Machine Tool Company, and invented and patented two prime movers.

Mr. Dornbirer was a contributor to the *American Machinist* and *Machinery*, an organizer and director of the Northern National Bank, and a director of the Equity Savings & Loan Co., the International Oil Corporation, the Northern Savings & Trust Co., the Cleveland Art Museum, and the Cleveland Chamber of Commerce.

He became a member of the A.S.M.E. in 1913 and also was a member of the Rose Tech Club, the Cleveland Athletic Club, and the Cleveland Engineering Society. He was a Lutheran by faith. He married Laura E. Ridenour of Cleveland, and she, together with three children, Stanton, Norman, and James Dornbirer, survive him.

HENRY DRESES

Henry Dreses, retired, died at the age of 77 at Marburg, Germany, on July 5, 1930, of cancer. He was born in Soest, Germany, on August 24, 1853, the son of Anton and Maria K. (Schaffstein) Dreses. After public school training in his home town, he attended the Technikum at Einbeck, Germany, and continued his studies in mechanical engineering at the Royal Polytechnical School at Aachen, Germany. He served as an apprentice in a machine shop at Soest for three years, and worked as a machinist on sewing machines and paper machinery for two years. He was draftsman and shop assistant in rolling and tin sheet mills at Husten, Germany, for a short time, after which, in 1881, he came to the United States and was employed as a machinist by Ohl & Co., manufacturers of machine tools and hydraulic presses, of Newark, N. J. Subsequently he was connected with Smith, Beggs & Rankin, St. Louis, Mo., manufacturers of Corliss and mill machinery, Fay & Co., manufacturers of wood-working machinery, Cincinnati, Ohio, and as machinist and draftsman for the Ahrens Fire Engine Company and Lodge & Barker, of Cincinnati. He became a partner in the firm of Dreses & Adams, in Cincinnati, in 1885, operating a machine shop, but gave up this connection in 1886 when he accepted a position as chief draftsman and designer for Lodge & Davis (now American Tool Works Company), in that city. In 1895 he became proprietor and manager of the Dreses Machine Tool Company, in Cincinnati, and continued in this work until his retirement in 1927.

Mr. Dreses took out numerous patents on lathes and radial drills. He was a director of the Cincinnati Altenheim and became a member of the A.S.M.E. in 1914. Other fraternal organizations and clubs to which he belonged included the Cincinnati Club, Western Hills Country Club, Masons, Germanistic Society, of which he was treasurer, and the Germany Literary Club. He took a keen interest in natural science, especially in astronomy and geology, on which he lectured repeatedly before the German Literary Club. He also was a familiar figure at Cincinnati concerts. He was unmarried.

JOHN A. DUGAN

John A. Dugan, associate professor of mechanical engineering at the Catholic University of America, died at the Georgetown Hospital, Washington, D. C., on June 19, 1930, following an operation for appendicitis. He was born in Washington, on February 19, 1890, the son of Patrick Henry and Nora (Feeney) Dugan. He received his education at Washington public and technical high schools, and at the Catholic University of America, which conferred upon him the degree of B.S. in M.E. in 1915, M.A. in 1924, and M.E. in 1925.

In 1915 and 1916 Mr. Dugan was connected with the Pennsylvania Iron Works Company, Eddystone, Pa., in charge of heat-treating shrapnel. He became assistant to the shop foreman of the Baldwin Locomotive Works at Eddystone in 1916, working on heat-treating 220 and 270-mm. French shells, and in 1917 was toolmaker and night foreman at the Remington Arms Company in that city.

From 1917 to 1919 Mr. Dugan served as captain in the Transport Service of the U. S. Army. After the war he returned to his alma mater as instructor in mechanical engineering. He was commissioned a major in the Officers' Reserve Corps in 1929.

In collaboration with Louis H. Crook, Mr. Dugan prepared a number of papers on stresses in rail joints and fish-plates due to welding which were part of the seventh annual report of the Welded Rail Joint Committee of the American Electric Railway Association.

Mr. Dugan became an associate-member of the A.S.M.E. in 1921 and was also a member of the Washington Society of Engineers. His fraternal and club memberships included the University Club, Congressional Country Club, American Legion, and Knights of Columbus. In 1919 he married Oriel Gulli, of Washington, by whom he is survived.

THOMAS COLEMAN DU PONT

Thomas Coleman du Pont, former Senator from Delaware and one of the foremost financiers of this country, died at his home in Wilmington, Del., on November 11, 1930. He had been in ill health since 1927 when he was operated upon for cancer of the throat.

He was born in Louisville, Ky., December 11, 1863, the son of Antoine Bidermann and Ellen Susan (Coleman) du Pont. He was a great-great-grandson of Pierre Samuel du Pont de Nemours, a distinguished French statesman and economist, whose son founded the du Pont powder industry in Delaware in 1802. Coleman du Pont (who dropped the "Thomas" from his name early in life) was educated at Urbana (Ohio) University, Chauncy Hall School, Boston, and the Massachusetts Institute of Technology, where he was graduated as an engineer in 1884. He was a prominent athlete in his college days, playing baseball and football, stroking the crew, and engaging in track events.

Mr. du Pont was predominantly a builder and organizer. He made one fortune after another in the coal-mining business, the steel industry, street railways, the du Pont explosive works, insurance, hotels, office buildings, and real estate. His was the instinct to create and organize which more than once brought him back to active busi-

ness when he had "retired." Except for the hotel and real-estate operations in his later years, however, he always disposed of a project as soon as he had put it on a successful basis, his interest turning to something new.

His career began with the mining industry, where he started at the bottom as a miner in the employ of the Central Coal & Iron Co., Central City, Ky. He dug coal, drove mules, and performed other similar tasks, and also became a member of the union, known as the Knights of Labor. He rose through various positions until he became president of the company and developed both the company and the town where it was located. At the age of thirty he abandoned the mining business and became manager of the Johnson Steel Company at Johnstown, Pa. This company afterward became the Lorain Steel Company, now a subsidiary of the United States Steel Corporation.

When in Johnstown, Mr. du Pont became interested in street railways and went into the business on a large scale, becoming president of the Johnstown line and purchasing other lines in New York, New Jersey, and Alabama. He left the steel business in 1900 and became president of various coal and iron corporations in Kentucky, including the McHenry Coal Company, and the Main Jellico Mountain Coal Company.

At the age of thirty-seven he determined to retire from business, and went to live in Wilmington, but two years later accepted the presidency of E. I. du Pont de Nemours & Co., at the request of his kinsmen. Eugene du Pont, head of the company, had died, and his brothers, who did not care to take his place, were about to sell the business outside of the family. Mr. du Pont and his cousins, Pierre S. and Alfred I. du Pont, agreed to take over the management in order to keep the business in the family.

Under Mr. du Pont's presidency from 1902 to 1915, the company was reorganized on a highly efficient basis which enabled it to produce an enormous amount of war materials when the World War began, and its by-products were developed to a point where it is now able to turn out an astonishing number and variety of synthetic products—leather and ivory substitutes—in addition to powder and explosives.

In 1915, Mr. du Pont resigned as president after selling his holdings in the company to a syndicate headed by Pierre S. du Pont. On leaving the business, Mr. du Pont, who had become chairman of the Equitable Office Building Corporation, began real-estate operations. He built the Equitable Building, at 120 Broadway, New York, and purchased the controlling interest in the Equitable Life assurance Society, mutualized the organization and then disposed of the stock to the policy holders without profit on the investment. In association with Lucius M. Boomer, Mr. du Pont organized a hotel chain, building some new hotels and buying others. These included the Waldorf, McAlpin, the new Savoy-Plaza in New York, the New Willard in Washington, and the Bellevue-Stratford in Philadelpnia. The Boomer-du Pont interests were also associated in the Louis Sherry and Savarin restaurants. Mr. du Pont built the du Pont Hotel and the du Pont office building in Wilmington, and was heavily interested in hotel and real-estate projects in Florida.

From the beginning of his residence in Delaware, Mr. du Pont manifested interest in state politics and by 1904 was recognized as one of the Republican leaders of the commonwealth. He held the rank of brigadier-general of the National Guard of Delaware under five governors, served for years as chairman of the Republican State Committee of Delaware, and from 1904 until 1924 was a member of the Republican National Committee. During the campaign of 1908 he was in charge of the speakers' bureau of the national organization.

In 1916 Mr. du Pont was a candidate for the Republic nomination for President and received thirteen votes on the second ballot in the national convention at Chicago. In 1921, Governor William D. Denny of Delaware appointed him United States Senator to fill the vacancy caused by the resignation of Senator J. O. Wolcott. At the expiration of his term he was nominated for election to the Senate, but was defeated. However, he was elected to the Senate for a six-year term in 1924. He resigned in 1928 because of ill health.

For years an enthusiast on the subject of good roads and a founder of the National Highway Association, Mr. du Pont, at his own expense, built and presented to the State of Delaware a $4,000,000 highway, known as the Coleman du Pont Boulevard, extending 100 miles from Wilmington to Selbyville. He was a generous giver to educational and philanthropic projects, his largest known donation having been $1,000,000 to the Massachusetts Institute of Technology, of which he was a trustee. In 1918 Mr. du Pont became president of the Industrial Finance Corporation, which controlled the Morris Plan of lending money to small borrowers.

He was a clever worker on wood and metal, indulging in this as a hobby. In his several residences were many examples of his handicraft.

Mr. du Pont became a member of the A.S.M.E. in 1906. He was also a member of the Engineering Association of the South, the American Academy of Political and Social Science, the Engineers and Architects' Club, and the American Institute of Mining and Metallurgical Engineers. His social clubs included the Rittenhouse, in Philadelphia; the Metropolitan, in Washington; the Metropolitan, New York Yacht, Union League, and Bankers, in New York; and the Wilmington and Wilmington Country, in Wilmington.

Mr. du Pont was married in 1889 while working in the Kentucky coal mines, to a second cousin, Alice du Pont. They had two sons and three daughters. He is survived by his widow and four children as follows: Mrs. H. S. Meeds, Mrs. C. Douglas Buck, Mrs. John Willcox Donaldson, Jr., and Frank V. du Pont.

WILLIAM P. EALES

William P. Eales, assistant superintendent of the Engineering and Inspection Division, Travelers Insurance Company, Hartford, Conn., died at East Hampton, Conn., on January 25, 1930. He was born at Alpena, Mich., on July 16, 1871. After receiving a high school education he became an apprentice machinist and boiler maker for Warren & McDonald, at Alpena, in 1885. From 1888 to 1890 he was employed by David Crippen, Alpena, as a machinist and boiler maker, and by the Walker Manufacturing Company, in Cleveland, Ohio. The next three years he spent as apprentice engineer on United States merchant ships, and from 1893 to 1896 he was assistant engineer in charge of watch for several steamships. For eight years, beginning in 1897, he was chief engineer of the steamships, *Sheriffs*, *City of London*, *Indiana*, and *Eastland*.

Mr. Eales joined the Travelers Insurance Company as an inspector at Chicago in 1905. He became supervising inspector of the Philadelphia territory in 1921, and was called to the home office in Hartford as assistant superintendent of the engineering and inspection division in 1916.

Mr. Eales, an associate of the A.S.M.E. since 1917, served on the Boiler Code Committees on Miniature Boilers and Rules for Inspection. For thirteen years he was chairman of the Examining Board for Boiler and Elevator Certificates for the State of Pennsylvania. He also acted as a consulting engineer for the Labor Department for the State of Pennsylvania in connection with the many outstanding safety questions of the department.

Mr. Eales was also a member of the Engineering Society of Western Pennsylvania, and a Knight Templar and thirty-second degree Scottish Rite Mason. He took a keen interest in farming, and possessed a farm of about 165 acres where he spent practically all his leisure time. He is survived by his widow. They had no children.

VICTOR BYRON FAULKNER

Victor Byron Faulkner, assistant plant manager for the National Aniline & Chemical Co., Buffalo, N. Y., died of pneumonia on November 15, 1928. He was born in Norwich, England, on July 1, 1890, the son of Frederick W. and Caroline B. (Dimbleby) Faulkner. He was educated at King Edward VI School, and the High School and Commercial School at Norwich, England, and after coming to the United States in 1907 took courses in factory and business management through the Alexander Hamilton Institute and Industrial Extension Institute.

His first business connection in this country was with the Eastman Kodak Company where he was engaged until the beginning of the World War. During the War he was located at the Niagara and Churchill plants of the Curtiss Aeroplane & Motor Corp., in charge of tool design and machine shops, engine shops, the wood-working shop, aeroplane assembly, heat treating, and the metallurgical laboratory. In 1919 he became associated with the National Aniline & Chemical Co. which he served successively as maintenance supervisor, plant engineer in charge of design, engineering development, construction, maintenance, and power plants, and assistant plant manager. He was recognized as one of the outstanding technicians in the American chemical industry.

He became a member of the A.S.M.E. in 1927. He was active in the Masonic fraternity and in religion an Episcopalian.

In 1919 he married Elizabeth L. Waterstraw, who, together with two children, Annette C. and Jeannette L. Faulkner, survive him.

WILLIAM EDWARD FINKERNAGEL

William Edward Finkernagel, assistant superintendent of power at the Hunts Point Station of the Consolidated Gas Company, New York, N. Y., died on July 14, 1930. He was born in New York on June 27, 1895, the son of Frederick William and Wilhelmina Elizabeth (Scheid) Finkernagel. He received his education in the Stuyvesant High School of New York and at Cornell University, from

which he was graduated with the degree of M.E. in 1920. Upon graduation he became engineer on heat power work and construction for Bradford & Tile, at Bradford, Pa. In 1921 he was made assistant superintendent of general engineering work for the Central Union Gas Co., New York, and in 1924 became assistant superintendent of the Astoria Light, Heat & Power Co., in charge of boilers, power house, and electric coal handling. His association with the Consolidated Gas Company began in 1926.

Mr. Finkernagel became a junior member of the A.S.M.E. in 1922 and an associate member in 1926. He married Frieda B. Bansemer in 1928, and she, together with two children, William E., Jr., and Robert Henry, survive him.

EDWARD CUMBERLAND FISHER

Edward Cumberland Fisher, district sales manager at St. Louis, Mo., for the American Locomotive Company, died at Rochester, Minn., on February 17, 1930. He was a Virginian by birth, having been born in Powhatan County, on May 2, 1875, the son of Charles and Maria (Jervey) Fisher.

Mr. Fisher supplemented his early education in the schools of Richmond, Va., with engineering courses at the Night School of the Virginia Mechanics Institute of Richmond, and later was night instructor there for several years.

After serving an apprenticeship as a machinist with the Framville & Powhatan R. R., at Chester, Va., from 1891 to 1896, Mr. Fisher secured employment at the Petersburg Iron Works for about a year. He was foreman on outside construction work for the Richmond Iron Works and in the erecting shop of the Southern Railroad at Spencer, N. C., from then until 1898, when he became shop engineer and instructor of an apprentice class in drawing and mathematics for the Chesapeake & Ohio R.R. at Huntington, W. Va.

He entered the employ of the Richmond Locomotive Works as draftsman in 1899 and was identified with that organization and its successor, the American Locomotive Company, continuously until his death. In 1910 he was transferred from Richmond to the Rogers Works at Paterson, N. J., as superintendent. In 1913 he was made manager of the Cooke Works, also located at Paterson, and in 1916 manager of both works. In 1917 he was transferred to Pittsburgh, Pa., as manager of the Pittsburgh Locomotive Works, also one of the plants of the American Locomotive Company.

During the World War Mr. Fisher was a speaker in behalf of the Liberty Loan campaign, and was a member of the Federal Secret Service.

After the War Mr. Fisher was sent on special work by the American Locomotive Company to South America, where he and his family made their home at Rio de Janeiro, Brazil. Later he was transferred to Johannesburg, South Africa, in the interests of the company. In 1922 he returned to the United States and opened offices in St. Louis, Mo.

Mr. Fisher became a member of the A.S.M.E. in 1917. He was a vice-president of the St. Louis Rotary Club, and while in South Africa he organized the first Rotary Club on that continent, at Johannesburg. He was a member of the St. Louis Chamber of Commerce, vice-president of the St. Louis Traffic Club, and a director of the St. Louis Railway Club. He was also a member of the St. Louis Engineering Society and Engineers Club of St. Louis and belonged to the Bellerive Country Club of St. Louis, the Missouri Athletic Association, the Louisville (Ky.) Country Club, the Pendennis Club of Louisville, and the Scottish Rite Club, being a Scottish Rite Mason and Shriner. He was a vestryman of St. Michael and St. Georges Episcopal Church, a member of the Missouri Society of the Sons of the American Revolution, and was a State Commander of the Sons of Confederate Veterans.

In 1905 Mr. Fisher married Anne Hinton Richmond. She and two children, Edward C., Jr., and Elizabeth Lewis, survive him.

CHARLES CARROLL GARDNER

Charles Carroll Gardner, superintendent of the Massachusetts Cities Realty Company, Haverhill, Mass., died on December 3, 1930, at the Gale Hospital in that city, following an operation. He was born at Hanover, Mass., on February 9, 1892, the son of John Davis and Bethia Cushing (Foster) Gardner. He received his education through the International Correspondence Schools.

Mr. Gardner's professional career began in 1910 as a power plant operator in Massachusetts. He advanced in grade to that of first class engineer. In 1917 he became chief engineer of the Taunton Gas Works, Taunton, Mass. Two years later he entered the employ of the Chandler Oil Cloth & Buckram Co., at East Taunton, where he installed new steam and power generating equipment. In 1920 he contracted with the Keene Woodenware Company and Keene Shoe Company at Keene, N. H., to revamp their power systems. In 1921 he became resident engineer for the W. H. McElwain Co., Manchester, N. H., and in the next year held a similar position with the International Shoe Co., at its Burke Tannery, Morganton, N. C. In 1923 he was sales representative for the Republic flow meters and recorders, and from 1924 to 1925 plant engineer and chief engineer of the National Fireworks Mfg. Co., Hanover, Mass. After two years as salesman for the Walworth Co., Boston, Mass., specializing in industrial and greenhouse heat layout work, he attempted contracting in this field but was unsuccessful because of insufficient capital. He therefore accepted a position with the Baker Supply Company, of Cambridge, Mass., a subsidiary of the R. H. Baker Construction Co., to develop and direct the mechanical and sales department of the firm.

Mr. Gardner became a member of the A.S.M.E. in 1929. He was also an active member of the National Association of Stationary Engineers, having served as chairman of the New England States Education Committee, as president in 1919, and as Massachusetts deputy at the New England Convention in 1920. He belonged to Masonic organizations in Taunton and the Rotary and Kiwanis Clubs of Haverhill, Mass., and was a member of the First Baptist Church of Hanover, Mass.

He married Maude Woodworth Shultz in 1911, and she, together with their children, Laura C., Lois C., Phyllis E., and Charles Robert Gardner, survive him.

WILLIAM LOWRY GILLETT

William Lowry Gillett, consulting engineer, New York, N. Y., died on February 24, 1930, of pneumonia. He was born at Evansville, Ind., on December 9, 1879, the son of Simeon Palmer and Grace Ann (Lowry) Gillett. He received the degree of A.B. from the University of the South, at Sewanee, Tenn., in 1900, and a B.S. from the Massachusetts Institute of Technology, three years later.

After graduation he entered the employ of the General Chemical Company of New York, where he held various positions in the construction department and had charge of mechanical and electrical power-house design and the operation of power plants. Later he was made chief engineer in charge of engineering and construction for the company. Since 1914 he had done consulting work, the Nichols Copper Company and the Phosphate Mining Company being among his clients.

Mr. Gillett owned or had pending several patents on chemical apparatus. During the World War he worked on air-nitrate at Sheffield, Ala.

He became a junior member of the A.S.M.E. in 1904 and a member in 1917. He also belonged to the Engineers Club, University Club, Nassau Country Club, and the Phi Delta Theta fraternity. He was a member of Christ Episcopal Church at Oyster Bay, Long Island. In 1909 he married Enid Locke Gillett, and she, with one daughter, Enid, survive him.

WALTER FRANCIS GOODRICH

Walter Francis Goodrich died at his home at Little Brickhill, Bucks, England, on July 21, 1930. Mr. Goodrich was born in London on January 7, 1872, and was privately educated. He secured experience in combustion engineering under Meldrum Brothers, Manchester, for two years, and then spent three years in Scotland as engineer representative of the company. He returned to London in 1898 to represent the company there, and remained in that position until 1908, when he founded the firm of Goodrich & Hamlyn, Ltd., for the design of furnaces and complete boiler installations for municipalities and industrial undertakings.

Mr. Goodrich served as director for this company until 1919, when he was appointed director of the Ferguson Superheaters, Ltd. During the six years of his association with the Ferguson Superheaters, he designed superheaters for special processes, introduced the use of superheated low-pressure steam in connection with vertical gas retorts for the production of water gas, and served as manager of the company for some time.

In 1920 Mr. Goodrich also became identified with the Spearing Boiler Company, Ltd., London, which later became the Vickers-Spearing Boiler Company, and still later the Vickers Boiler Co., Ltd. He served at first as contract engineer and manager, later chief engineer, advising upon questions of fuels, firing, and combustion, and responsible for the layout of boiler house equipment for large modern power stations. During the last few years of his life he practiced as a consulting engineer, with an office in London.

Mr. Goodrich became a member of the A.S.M.E. in 1926. He was also a Fellow of the Institute of Sanitary Engineers and a member of the Institute of Fuel Economy Engineers.

JOSEPH AIMÉ GODEFREY GOULET

Joseph Aimé Godefrey Goulet, mechanical engineer for the Canadian General Electric Company, Peterborough, Ontario, Canada, died suddenly of heart disease on December 16, 1929.

Mr. Goulet was a native of Canada, having been born at St. Eustache, Quebec, on October 22, 1868, the son of J. M. and Emma (Dorion) Goulet. He attended Bourget College, and received a B.Sc. degree in Mechanical Engineering from McGill University in 1890.

The first ten years of Mr. Goulet's engineering work were spent partly in the United States and partly in Canada. He was connected for a year each with the Deane Steam Pump Company, Holyoke, Mass., and the Northey Manufacturing Company, Toronto, was engaged in work for the Columbian Exposition at Chicago in the agricultural machinery department in 1893 and 1894, and spent some time in taking soundings of the Saguenay River. From 1894 to 1896 he was assistant superintendent of dredging and also was in charge of designing and construction at the government shipyard at Sorel, Quebec. The next three years were spent as mechanical engineer and chief designer with The Northrup Loom Company of Canada, Valleyfield, Quebec, and in 1899-1900 he was employed in a similar capacity by The Draper Corporation, located at Hopedale, Mass.

From 1900 to 1901 Mr. Goulet was connected with Isaac Mautner & Sohn, of Vienna and Budapest, as master mechanic. Since then he had been located in Canada, for two years as designing draftsman at the Montreal plant of the Canadian General Electric Company and the remainder of the time in the position he held at the time of his death.

Mr. Goulet became a member of the A.S.M.E. in 1924 and also belonged to the Engineering Institute of Canada. He is survived by a son, Sifroy Goulet.

MAURICE RODNEY HAMILTON

Maurice Rodney Hamilton, whose death occurred at Upper Montclair, N. J., on November 19, 1930, was a native of Montclair, where he was born on January 21, 1902, the son of William Hamilton and Nellie May (Garrabrant) Hamilton. He attended the Montclair Academy and Stevens Institute of Technology, from which he was graduated with an M.E. degree in 1927. After a few months as apprentice engineer in the shop course of Babcock & Wilcox, Bayonne, N. J., ill health forced him to give up work.

Mr. Hamilton became a junior member of the A.S.M.E. in 1928 and also belonged to the Masonic order. He is survived by his widow, Verna Esther (Frey) Hamilton, whom he married in 1924.

VINCENT G. HAZARD

Vincent G. Hazard, mechanical engineer with the Pusey and Jones Corporation and prominent in the affairs of Wilmington, Del., died at his home at Claymont, Del., on April 13, 1930, after a brief illness. He was born on January 20, 1853, in Philadelphia, the son of Willis Pope and Susan Robinson (Gilpin) Hazard. After studying in a number of different schools, he came under the tutorship of J. Hunter Worrall, graduate of Yale University and later instructor there, and partly through his influence entered the Sheffield Scientific School, Yale University, from which he was graduated in 1874, receiving the degree of Ph.B. in the Mechanical Engineering course. A little later he entered the employ of Pusey, Jones & Co., the name of which was subsequently changed to The Pusey and Jones Company and then to its present form. His first work was that of a draftsman and later he was chief of draftsmen designing paper machinery, field engineer in charge of paper machinery erectors, director of technical correspondence, and editor of *The Super-Calendar*, a monthly house magazine published by the company.

Mr. Hazard was a member of the Central Presbyterian Church in Wilmington and for a number of years was a member of the Board of Trustees, and of the corresponding board of the United First-Central Church. For 16 years he was head of the Wilmington Institute Drafting School, a night school for shop apprentices and others. He was for 22 years a member of the Board of Managers of the Wilmington Institute Free Library and for half that period was also chairman of the Board. He was interested in the Boy Scout movement and had served as a member of the Court of Honor of the Wilmington Council of that organization. He was a life member of the A.S.M.E., having joined the Society in 1882.

Mr. Hazard is survived by one daughter, Mrs. Robert F. Brinton, of Westchester. He was twice married. His first wife was Miss Maria D. Clould and his second wife Miss Anna S. Gelpin, both of Wilmington.

ERNEST K. HEERING

Ernest K. Heering, whose death occurred on February 28, 1930, was born at Osnabouck, Germany, on June 6, 1878. He studied mechanical engineering at the Technische Hochschule, Hanover, Germany, being graduated in 1899 and receiving the degree of Diplom-Ingenieur in 1901.

Mr. Heering was employed in Germany and Austria for some years. After two years as assistant to the chief of the engineering laboratory at the Technische Hochschule he went to Diez, Germany, where he associated himself with a consulting engineer in the design of bridges, ship elevators, and other assignments. From 1903 to 1906 he was employed with Amme, Giesecke & Konegan in the design of hydraulic turbines and dams; during the last year of this connection he was assistant manager of the shops of the company. Subsequently he was located for a time at Hohenelbe, Austria, where he was engaged in the design of hydraulic turbines and governors, and testing of turbines.

After coming to the United States, where he took out citizenship papers in 1916, Mr. Heering was connected for some years with the I. P. Morris Co. (subsequently The William Cramp Shipbuilding Company and now Cramp Morris Industrials, Inc.), at Philadelphia. He was design engineer and later assistant chief draftsman in the hydraulic division.

Mr. Heering returned to Germany for a few years, practising as a hydraulic engineer at Dresden until 1926. He then accepted a position as design engineer with the Birdsboro Steel Foundry & Machine Co., Birdsboro, Pa. Following this he was located for a time in Wilkinsburg, Pa., and then went to the Pacific Coast, where he entered the employ of the Pelton Water Wheel Company in San Francisco. Ill health forced his retirement from active business during the latter part of his life.

Mr. Heering had been a member of the A.S.M.E. since 1917.

WINTER D. HESS

Winter D. Hess, western sales manager, with headquarters at Chicago, for the Builders Iron Foundry, of Chicago, the Glamorgan Pipe & Foundry Co., of Lynchburg, Va., and the Darling Valve & Mfg. Co., of Williamsport, Pa., died of heart failure on February 27, 1930. He was born at Arcola, Ill., on December 14, 1865, the son of Abraham W. and Mary Vail (Marston) Hess. He received his education in the public schools at Evanston, Ill.

He became western sales manager for the Builders Iron Foundry in 1901 and cooperated with civil, gas, mechanical, and hydraulic engineers in solving problems involving the measurement and rate control of the flow of liquids and gases. He specialized particularly in apparatus for pumping stations, filter plants, sewage treatment, chemical works, gas plants, and power plants.

He became a member of the A.S.M.E. in 1921. He was also a member of the Western Society of Engineers. His club memberships included the Big Foot Country Club, Lake Geneva, Wis., the Lake Shore Athletic Club, Chicago, and the Evanston Golf Club, Chicago, of which he was a director. He was a member of the First Congregational Church at Evanston. His widow, Pearl (Nightingale) Hess, together with four children, Chase N., Richard D., Frederick W., and F. Romeyn, survive him.

SAMUEL MURRELL HEULINGS

Samuel Murrell Heulings, whose death occurred at his home in Haddonfield, N. J., on May 15, 1930, was born in Philadelphia, Pa., on October 5, 1859. His parents were Samuel Murrell and Sarah Champion Heulings. He is survived by his sister, Harriet A. Heulings.

Mr. Heulings was well known throughout the dairy world for his sanitation work in that field. The Star Milk Cooler Company was formed at Haddonfield in 1899 for the manufacture of the Star Cooler, invented and patented by Mr. Heulings, and he served the company as general manager until 1910.

The line of Star sanitary dairy apparatus and machinery included, in addition to coolers, strainers and sterilizers, and bottle washers, fillers, and cappers. The first application of hydraulics to dairy machinery was made by Mr. Heulings in automatic hydraulic bottle fillers and cappers. He also designed, constructed, and installed cableways for milk transmission from barns to dairy buildings, and ventilating systems for supplying filtered air. He installed and supervised the operation of power refrigerating and other electrical equipment in dairy plants, and cooperated with architects in the design and construction of a number of dairy buildings and certified milk plants adapted to the sanitary handling of milk and economic operation.

In 1911, Mr. Heulings accepted a position as dairy engineer for the Sheffield Farms of the Slawson-Decker Company, New York. During the twelve years which he spent with this company he made further outstanding contributions to methods and equipment for milk sanitation. He designed, constructed, installed, and operated air filtering and ventilating systems and sterilizing equipment in the Sheffield plants throughout the City of New York and had charge of experimental shops for the company. His process of pasteurizing milk was tested at a plant designed and constructed by him at Bloomville, N. Y., with such success that a similar plant was later erected in the Bronx, N. Y. He gave invaluable assistance to the health commissioner of New York in raising the standards of purity of milk in that city.

Mr. Heulings was also consulting engineer for the United Dairies, Ltd., London, England, for four years.

The American Public Health Association, of which Mr. Heulings became a member in 1917, asked him to serve on its committee on pasteurization, and made him a delegate to the World's Dairy Congress in 1923 where he gave an address describing his continuous holding tanks for the milk pasteurizing process. He was a fellow of the Sanitary Engineering Section of the Association, and had been a member of the A.S.M.E. since 1916.

MERRILL HIBBARD

Merrill Hibbard, president of the Middle States Construction Company, Columbus, Ohio, died on October 16, 1930, at the Grant Hospital in that city, of nephritis. He was born in Cincinnati, Ohio, on December 25, 1875, the son of Samuel E. and Julia E. (Swasey) Hibbard.

Mr. Hibbard was a graduate of the University of Cincinnati, where he obtained the degree of B.S. in C.E. in 1897. For the next three years he worked as rodman, levelman, transitman, and draftsman on new water works at Cincinnati, and on the construction of a pumping station at California, Ohio. From 1900 to 1904 he was connected successively as draftsman on hoisting and conveying equipment for Heyl & Patterson, Pittsburgh, Pa.; erecting engineer of steel structures for McClintic, Marshall Construction Company; and erecting engineer of locomotive and gantry cranes for the Interstate Engineering Company, Cleveland, Ohio.

From 1904 to 1925 Mr. Hibbard was identified with the Jeffrey Manufacturing Company, in which he rose from the position of draftsman to that of chief engineer. He had been with the Middle States Construction Company since 1925, for the past two years as president.

Mr. Hibbard became a member of the A.S.M.E. in 1920. He also belonged to the American Society of Civil Engineers, Tau Beta Pi fraternity, the Masons, Players Club, Athletic Club, Columbus Country Club, and Ohio Society of New York. He was a member of the Trinity Episcopal Church.

He married Emma Copman in 1903, and she, together with a daughter, Adelaide, and his mother, survive him.

CAMPBELL P. HIGGINS

Campbell P. Higgins, for many years connected with Babcock & Wilcox Co., Bayonne, N. J., died at his home in Roselle, N. J., on May 29, 1930.

Mr. Higgins gained national recognition for his work in improving steam boilers and other apparatus, and had to his credit a total of 81 inventions.

He was born in Ballston Spa, N. Y., on August 20, 1857, and received his education in public and private schools. Before locating in Roselle he lived for several years in Glascow, Scotland, where he conducted experimental work for the Babcock & Wilcox Co. He joined that company in 1881 in charge of the erecting department and was a member of its Board of Directors at the time of his death.

Mr. Higgins became a member of the A.S.M.E. in 1893. He was also a member of the American Society of Naval Engineers, New York Flute Club, Roselle Golf Club, and the Harvard Club of Roselle. He had resided in Roselle for thirty years and had been a member of the Borough Council and Board of Health, and a trustee and church master of the First Presbyterian Church there. He was a frequent contributor to charitable organizations. He is survived by his widow, Ella R. Higgins.

JAMES HOGG

James Hogg, a member of the A.S.M.E. since 1913, died at Amsterdam, N. Y., where he was consulting engineer and wool expert for Stephen Sanford & Sons, Inc., on December 31, 1930.

Mr. Hogg was born at Rawdon, England, on November 10, 1851. Following a common school education he spent about twelve years in England learning the woolen and worsted manufacturing business.

In 1880, Mr. Hogg came to the United States where he secured employment as overseer at the Globe Worsted Mill, Lawrence, Mass. He remained there until 1888, during which time he developed an improved slide rule.

Mr. Hogg's first association with Stephen Sanford & Sons was in 1888. He served the company as superintendent until 1906, largely employed in machinery and power construction work. From then until 1913 he held a similar position with the Bigelow Carpet Company at Lowell, Mass., and did consulting work on machinery and power problems. He returned to Amsterdam in 1913. He is survived by his widow, four sons, and two daughters.

HENRY HOLGATE

Henry Holgate, consulting engineer, Montreal, Quebec, Canada, died on January 21, 1930.

Mr. Holgate was born at Milton, Ontario, on September 14, 1863, the son of John and Jane (Browne) Holgate. He attended grammar and high school in Toronto, after which he served an apprenticeship to the Northern Railway of Canada. For five years following the completion of his training he was employed by that railway as chief assistant engineer, and retained that position for four years with the Grand Trunk Railway, into which the Northern Railway was merged in 1888.

During the years from 1892 to 1901 Mr. Holgate was connected successfully with the Central Bridge Works as engineer; engineer in charge of construction and plant for the Royal Electric Company of Montreal; and manager and engineer of the suburban electric railways of Montreal and of the West India Electric Company of Jamaica, for which he built a hydroelectric and long-distance transmission system.

From this time until his death Mr. Holgate was identified with hydroelectric work. For ten years, in partnership with R. A. Ross, he engaged in general hydroelectric engineering practice. Since 1911 he had practiced independently. His projects included the Cedar Rapids Power development, which entailed the design and construction of hydroelectric plants and the dam on the Spanish River at Big Eddy and he served as president of the Cedar Rapids Power Company in 1911. He was vice-president of the Bridge River Power Company, Ltd., of British Columbia, and consulting engineer to the Province of New Brunswick. He served as chairman of the Royal Commission to investigate the collapse of the Quebec bridge in 1907, and was one of a government commission to advise on the expansion of the Montreal harbor. He was director of the Canada Grip Metal Company and managing director of the Serge Island Estates, Ltd. The last important work undertaken by Mr. Holgate was an exhaustive study of and report on the proposed St. Lawrence deep waterway, which he carried out in association with J. A. Jamieson, of Montreal, at the request of the Montreal Board of Trade.

Mr. Holgate became a member of the A.S.M.E. in 1921. He also belonged to the American Society of Civil Engineers and the Engineering Institute of Canada, which he had served as councillor and vice-president, was president of the Engineers Club of Montreal, and a member of the board of management of the Montreal General Hospital.

Surviving Mr. Holgate are his widow, formerly Bessie Bell Headley, whom he married in 1888, and two sons, Henry W. and Edwin H. Holgate.

IRA NELSON HOLLIS

"Ira Nelson Hollis has lived that others might live better." These words, first printed nine years ago in their class book by seniors at Worcester Polytechnic Insitute, of which he was then the president, aptly epitomize the character of the distinguished engineer and educator who died at his home in Cambridge, Mass, on August 15, 1930. His career, begun with nineteen years of service in the United States Navy, and continued through twenty years as professor of engineering at Harvard University, reached its culmination in the presidency of the Worcester Polytechnic Institute, which he held from 1913 to 1925. During the year 1916-1917 he was also president of The American Society of Mechanical Engineers, of which he had been a member since 1884. On resigning the presidency of the Worcester engineering college because of failing health, he was elected by special action of the trustees to the honorary office of president emeritus. He returned to Cambridge, where he established a home at 985 Memorial Drive. His closing years were happily occupied with occasional travel, lecturing, and writing, and in the serene enjoyment of his books, his friendships, and rich memories. He is survived by four children, Janette R., Oliver Nelson, Elinor V.,

and Carolyn. His wife, who was Miss Caroline Lorman, of Detroit, died several years ago.

Dr. Hollis was the recipient of many academic honors, among them being the degrees of A.M. from Harvard University, L.H.D. from Union College, Sc.D., from the University of Pittsburgh, and D.Eng. from the Worcester Polytechnic Institute. He was a fellow of the American Society of Arts and Sciences, and a member of numerous scientific and engineering societies.

As president of The American Society of Mechanical Engineers, Dr. Hollis, at enormous expenditure of time and energy, visited in person nearly every Local Section of the Society, exemplifying thereby an ideal of service that has been a lofty challenge to his successors in that office. At the meetings of the Society he was always the central figure, constantly surrounded by hosts of fellow-members, who were drawn to him less by his official position than by his strong and appealing personality. For some years, both before and after his term of office, he served on the Council, and for a time was chairman of the important Committee of Awards, which position he resigned at the last Annual Meeting. He was made an Honorary Member of the Society in 1928.

He was born at Mooresville, Indiana, on March 7, 1856. His parents were in such straightened circumstances that the boy was often sent to gather driftwood along the bank of the Ohio river to keep the home fires burning. He received his early education in the public schools of Louisville, Ky., and at an early age went to work in the railroad offices there. At this time he chanced to hear of an examination which was shortly to be given at Annapolis for admission to the Naval Academy, and determined to try for acceptance. As his preparation in some of the required subjects had been insufficient, he borrowed a number of books on mathematics, and resolutely set himself to master them. He had no money to defray the expenses of the journey East, but as an employee of the railroad was able to secure a pass. He took the examinations, received the highest rank of any of the 125 candidates, and was admitted to the Academy along with twenty-four others. He maintained first place throughout his course, and was graduated at the head of his class.

Assigned to the Engineering Corps, he was commissioned an assistant engineer in 1880, and a passed assistant engineer in 1888. One of his memorable experiences at sea was the chase of the filibuster *Itata* by the U.S.S. *Charleston*, the flagship of the Pacific Squadron, on which he was then the chief engineer. For his service on this occasion he was officially commended to the Navy Department by Admiral McCann. During his naval career he was detailed for a time as professor of marine engineering at Union College. Following his work at the college he became a member of the Advisory Board which built the White Squadron. During the summer of 1892 he delivered at the Naval War College a course of lectures on "The Ships of Our Modern Navy," and these lectures were afterward issued to the service in book form.

His brilliant reputation as an engineer in the Navy was recognized by Harvard University in 1893, when he was offered the position of professor of engineering in that institution. He thereupon resigned from the Navy, and devoted the rest of his life chiefly to the cause of engineering education.

At Harvard he at once manifested unusual abilities as a teacher. He remodeled and greatly developed the department of engineering, and became an outstanding figure in the Harvard faculty. He was chairman of the athletic committee for several years, and it was under him that the Harvard Stadium was erected. His services were not entirely lost to the Navy, however, as in 1898 he was associated with Rear Admiral Wainwright in the reorganization of the personnel of the Navy, and the bill written by them was used as a basis for action in Congress. He also served twice on the board of visitors at the Naval Academy.

In 1913, after twenty years of teaching at Harvard, Professor Hollis was called to the presidency of the Worcester Polytechnic Institute. It was characteristic of the modest and retiring disposition of the man that he refused to sanction any public and formal exercises of inauguration, but, on July 1 of that year, quietly took up the duties of his office.

Soon after he arrived at the Institute he was called to face one of the severest crises that have confronted the college. The withdrawal of financial aid from the state left many of the colleges of the commonwealth, the Worcester Polytechnic Institute among them, in serious straits. President Hollis met the situation with courage, wisdom, and rare skill, and successfully piloted the Institute through the perils of inadequate finance to a sound and secure position among the engineering colleges of the country. A little later the Institute, along with other colleges, was plunged into new and distressing, if less critical, difficulties on the entrance of the United States into the World War. Only those who were then responsible for the safe conduct of the institutions of higher learning through a period when the students became soldiers, and responsibility was shared in strange and curious ways between the military officers and the officers of instruction, can adequately realize the delicacies and difficulties of the situation. Again Dr. Hollis was equal to the emergency. Through diplomacy and tact he succeeded in affording complete cooperation with the Government, while still insisting on maintaining sound scholastic standards. At the same time new financial problems were encountered in the necessity of advancing salaries to keep pace with the growing cost of living; and in the solving of these problems President Hollis was also eminently successful.

During his administration the Institute celebrated its fiftieth anniversary with elaborate ceremonies, participated in by representatives of the leading educational institutions of the country. On this occasion the corner stone of the alumni gymnasium was laid, thus opening a new era of athletic progress at the Institute, in the advancement of which President Hollis played a conspicuous part. It was under him, too, that the Tech Council was established, and won for itself an important role in governing student life and activities.

But great as were the achievements that have been enumerated, one even greater remains to be mentioned. "It was not long after his arrival," wrote the seniors of 1916 in their class book, "before we learned that the Office . . . .was to be a place where our difficulties could be cleared up. We had only to state the extent of these, and 'Prexy' could immediately find a way out of them. Through his energy a change was made in the attitude of the upper classmen toward the freshmen. Class rushes were abolished; freshman rules were toned down; and many other changes made to increase the kindly feeling between classes. In his heart he had the welfare of every student; a kindly word of encouragement to the disheartened, or a well-meant reproof to the backward student, was all that was needed to point out the way he should go." The marked simplicity of his manner, the kindly sympathy of his speech, and his evident sincerity commanded the confidence and loyalty of the students, while their admiring respect was captured and held by his lofty attainments. The example he afforded them of real greatness combined with modesty of bearing and zealous will to serve, have left an ineffaceable impression upon the characters of them all.

Upon these engineering students, immersed in the pursuit of science, and often boasting their materialistic tendencies, President Hollis gained his commanding influence by the steadfast manifestation of a lofty idealism. His closing words in delivering the commencement address on the year of his coming to the Institute are an eloquent expression of the deeper philosophy of his life. "It seems to me," he said, "that we are on the entrance to a great moral and religious growth. Man is completely freed from his material environment by steam and water power, and he will grow rapidly into that faith and love which will solve most of our problems, if only he does not turn back. Let us not be led away by that common objection raised among self-styled practical people against all ideals, 'Oh, that would be the millenium.' Is the millenium the false fire that hovers over marshy ground, and that precedes us and vanishes as we are engulfed? Is it not rather the hope and goal of mankind, made possible and even probable by the proper use of man's time? I must believe that in this new freedom our descendants will gain a spiritual faculty over and beyond reason, that will teach them to follow and to understand instinctively the law of Christ given to us as the result of his ripe experience of life. When the lawyer asked him, 'Master, which is the great commandment in the law?' He replied, 'Thou shalt love the Lord, thy God, with all thy heart and with all thy soul and with all thy mind; this is the first and great commandment; and the second is like unto it: 'Thou shalt love thy neighbor as thyself. On these two commandments hang all the law and the prophets.' If the race comes to the practice of these two commandments as law, it will deserve the earth, and national, social, and industrial problems will dissolve in man's highest happiness. They are, in reality and truth, all the law and the prophets. Follow them as men, and you cannot fail to inherit the earth."

It was in the spirit of this philosophy that President Hollis devoted his life to the service of his students and his fellow-men. But his service was never limited to the individual: it was always freely extended to the collected individuals that make up the State. In his speech accepting the presidency of The American Society of Mechanical Engineers he urged his hearers to regard their work as an obligatory service of the state. "That," he said, "is our motto, and that is what we must strive toward during the coming year and all time as we must pass on into the higher atmosphere of goodwill, service, and cooperation."

CHARLES J. ADAMS.[1]

[1] Professor of English, Worcester Polytechnic Institute, Worcester, Mass.; prepared in cooperation with Ralph Earle, president, and Charles M. Allen, professor of hydraulic engineering of the Institute.

EDWARD ISAIAH HACKER HOWELL

Edward Isaiah Hacker Howell, retired, died on November 2, 1930, in Philadelphia, Pa. He was born in Philadelphia on October 20, 1843, the son of William and Rebecca (Hacker) Howell. He received his education at the Germantown Academy, the Eagle's Wood School, Perth Amboy, N. J., and the Polytechnic College of the State of Pennsylvania, which gave him the degrees of M.E. in 1862, and M.M.E. in 1866.

After serving an apprenticeship with Reaney Archibald & Co., Chester, Pa., and I. P. Morris & Co., Philadelphia, he worked in the drawing room and as assistant superintendent for W. B. Le Van, of Philadelphia, on steam engines, pumps, governors, and elevators, and in general practice connected with steam and hydraulic machinery until 1874, when health and eyesight necessitated his retirement. He served in the Civil War in the Germantown Home Guard.

Mr. Howell became a member of the A.S.M.E. in 1889, was one of the founders of the Geographical Society of Philadelphia, and a member of the Historical Society of Pennsylvania and the Historical Society of Germantown. He also belonged to the Colonial Club, the Art Club of Philadelphia, and the Germantown Unitarian Society, and he was a founder of both the Science and Arts Club of Germantown and the Ausable Club of New York. These memberships indicate his interest in historical organizations, art and music, and forest preservation, as well as engineering.

ALLEN HUBBARD

Allen Hubbard, member of the Boston consulting engineering firm of Hollis French and Allen Hubbard, died on December 14, 1930, at the Newton Hospital, from a hemorrhage. He was born in Westfield, Mass., on December 9, 1860, the son of George and Clara (Edy) Hubbard. He was educated in the Westfield schools and at Sheffield Scientific School, Yale University, from which he was graduated with the degree of Ph.B. in 1883. After some early experience as draftsman and engineer with two Providence firms, the Riverside & Oswego Woolen Mills and the H. B. Smith Co., he went to Boston where he was employed for some years by Albert B. Franklin, steam heating contractor. He had been a member of the Hollis French and Allen Hubbard firm since 1898.

Mr. Hubbard devoted himself to consulting work connected with the design of steam power plants, heating and ventilating systems, mill work and general consultation. Yale, Harvard, Wellesley, Mount Holyoke, William and Mary, and other educational institutions engaged his services in their building programs, and he also served as consulting engineer on the construction of the Boston Opera House, the Art Museum, Public Library, and other public and business buildings in Boston.

He was director of the Exolon Company and president of the Wm. L. Gilbert Clock Co.

In addition to the A.S.M.E., of which he had been a member since 1910, Mr. Hubbard held membership in the American Society of Heating and Ventilating Engineers and the American Institute of Consulting Engineers, and at one time was chairman of the Affiliated Technical Societies of Boston. He belonged to a number of clubs, including the Engineers, Yale, University, and Exchange of Boston, and the Charles River Country Club, for the beauty of the development of which he was largely responsible. He was a vestryman of the Trinity Episcopal Church at Newton Centre, Mass.

Surviving Mr. Hubbard are his widow, formerly Edna L. Woodruff, whom he married in 1896, and two sons, Allen Hubbard, Jr., and Gilbert Hubbard.

CHARLES TRIPLER HUTCHINSON

Charles Tripler Hutchinson, president and general manager of the McGraw-Hill Company of California, editorial director of *Electrical West*, died on February 12, 1930, at Oakland, Calif.

Mr. Hutchinson was born in San Francisco on January 31, 1876, the son of Frederick Winslow and Ellen Cass (Tripler) Hutchinson. He received his education in the Boys' High School and the Commercial High School in San Francisco and through the International Correspondence School. He began professional work in 1894 with the Union Iron Works in San Francisco, and advanced through various positions to that of general manager of the mining machinery department. He was responsible for the design, construction, and erection of equipment for metal mines, as well as sales of such equipment. In 1907 he took a similar position with the Joshua Hendy Iron Works of San Francisco. He entered the technical publishing field in 1912 as editor of *Western Engineering* and was also editor of *Metal Trades*. In 1915 he became vice-president and general manager of the Dewey Publishing Company, San Francisco publishers of *Mining and Scientific Press*, *Western Engineering*, and *Metal Trades*. He joined the McGraw-Hill Publishing Company in 1922, at which time the *Mining and Scientific Press* was purchased by them. They were already publishing the *Journal of Electricity*, which later grew into *Electrical West*.

Mr. Hutchinson wrote many articles for the technical press and was a contributor to McFarren's "Stamp Milling" and to Janin's "Mining Engineers' Handbook." He also designed improvements in automatic ore feeders, rock breakers, and stamp mills. He was a member of the Jury of Awards of the Department of Mining and Metallury of the Panama-Pacific International Exposition in 1915, and was awarded a medal for his services to the mining and metallurgical exhibit of the Exposition. He became a member of the A.S.M.E. in 1910, was secretary of its San Francisco Section in 1913-1914, and represented the Society on the Board of Managers of the 1915 International Engineering Congress. He was also a member and past-president of the Engineers Club of San Francisco and the San Francisco Electrical Development League; a member since 1923 of the Executive Committee of the Pacific Coast Electrical Association; and chairman since 1925 of the Advisory Committee of the California Electrical Bureau. He was a member of the Masonic order and also belonged to the Bohemian Club and Commonwealth Club of San Francisco, the Claremont Country Club of Oakland, Mt. Diablo Country Club of Diablo, and the Sons of the American Revolution. He married Gertrude Allen in 1907, and is survived by her.

E. A. W. JEFFERIES

E. A. W. Jefferies, whose death occurred in Worcester, Mass., on October 20, 1930, was born in Malmsbury, England, on February 23, 1862, the son of John and Sarah Grayel Jefferies. He received his technical education at University College, London, and served an apprenticeship and worked in the drafting room of Fielding & Platt, London, from 1877 to 1880. He then spent a year as draftsman for R. H. Tweddell, London, and returned to Fielding & Platt in 1882 as assistant superintendent.

Mr. Jefferies came to the United States in 1883 to become chief draftsman for the Morgan Engineering Company at Alliance, Ohio. After advancing to the position of chief engineer he became associated with the R. D. Wood Company of Philadelphia, Pa., with which company he first became interested in the development of producer gas machines. He spent the greater part of his life in this field and was recognized as an authority on both the theory and practice of making producer gas. At the time of his death he was head of the Gas Producer Department of the Morgan Construction Company of Worcester, Mass., which position he had filled since 1904.

Mr. Jefferies became a member of the A.S.M.E. in 1892. He is survived by his second wife, and by two daughters and a son, Mrs. Jerome R. George, Mrs. Arthur D. Sykes, and Ernest Smith Jefferies.

PETER JUNKERSFELD

Colonel Peter Junkersfeld, vice-president of the Stone & Webster Engineering Corp., died suddenly at his home in Scarsdale, N. Y., on March 18, 1930.

Colonel Junkersfeld was born in Sadorus, Ill., on October 17, 1869, the son of Peter Joseph and Mary Josephine (Schmitz) Junkersfeld. He attended the Champaign, Ill., High School, and Northern Indiana Normal School, at Valparaiso, and was graduated from the University of Illinois in 1895, with a B.S. degree. In 1907 the degree of E.E. was conferred upon him by that institution.

After a few months with the Fred W. Wolf Co., Chicago, as draftsman on refrigerating machinery, he became connected with the Chicago Edison Company. He remained with this company and its successor, the Commonwealth Edison Company, for nearly 24 years. He began as an assistant in the power plant and at the time of his resignation in 1919 was assistant vice-president.

In 1916 Mr. Junkersfeld was elected president of the Association of Edison Illuminating Companies. Following his resignation from the Commonwealth Edison Company Colonel Junkersfeld was associated with the Division of Construction and Engineering of Stone & Webster, Inc., until 1922, when he became a member of McClellan & Junkersfeld, Inc., engineers and constructors. In 1928 this firm was merged with the Division of Construction and Engineering of Stone & Webster, Inc., to form the Stone & Webster Engineering Corporation, of which Colonel Junkersfeld was appointed a vice-president.

In 1916, Josephus Daniels, then Secretary of the Navy, appointed Mr. Junkersfeld to the Naval Consulting Board as an associate member. He entered the U. S. Army, Construction Division, as a Major in the Engineers Reserve Corps in 1917, rose to the rank of Colonel, and was actively engaged in building cantonments,

camps, hospitals, port terminals, warehouses, and munition plants. In 1919 he was awarded the Distinguished Service Medal by Newton D. Baker, then Secretary of War.

Colonel Junkersfeld was a past vice-president of the American Institute of Electrical Engineers, was the first president of the Construction Division Association and a past vice-president of the Western Society of Engineers. He became a member of the A.S.M.E. in 1910 and also belonged to the American Society of Civil Engineers and the Franklin Institute. His clubs included the Engineers (New York and Chicago), Lawyers (New York), Western Universities Club of New York, and Scarsdale Golf Club.

His widow, Mrs. Anna C. (Boyle) Junkersfeld, whom he married in 1901, and two daughters, Florence Rita and Mary Josephine Junkersfeld, survive him.

WILLIAM CONRAD KOCH

William Conrad Koch, since 1918 vice-president, treasurer, and general manager of the Twin City Brick Company, St. Paul, Minn., died on December 10, 1930, at the Miller Hospital in that city after an illness of several weeks. He was born in Geneseo, Ill., on October 30, 1889, but spent the most of his life at St. Paul. After attending high school there he entered Harvard University, from which he received the degree of S.B. in 1913. He spent the following year at the Harvard School of Business Administration and then took a position as assistant superintendent of the Twin City Brick Company.

During the Mexican border troubles in 1916 he served with Battery D of the Minnesota National Guard. In 1917-1918 he was chairman of the Minnesota State War Inventions and Research Committee by appointment of the governor, and also was a member of the United States War Industries Board, Washington, D. C., in 1918.

In his work with the Twin City Brick Company Mr. Koch was in charge of operations and construction of two plants at St. Paul, two at Des Moines, and one at Red Wing, Minn.

Mr. Koch was keenly interested in general business conditions. He attended the National Business Survey Conference held at Washington the winter preceding his death under the auspices of the U. S. Chamber of Commerce, and had but recently returned from a business leaders' tour sponsored by the National Research Council.

He became a member of the A.S.M.E. in 1927, and also belonged to the American Society for Testing Materials, American Ceramic Society, and the St. Paul Engineers Society. His term as president of the American Face Brick Association expired shortly before his death. He was the youngest man ever to have held that office. He was a former secretary of the St. Paul Institute, commodore of the White Bear Yacht Club and was active in the St. Paul Association and United Improvement Council. He was a member of the Minnesota Club and the University Club.

In 1919 he married Margaret Paine of Cambridge, Mass. Surviving him are his widow and four children, Mary Adams, William C., Jr., James L. P., and Frederick Karel Koch.

EMIL KWARTZ

Emil Kwartz, designing and consulting engineer of Seattle, Wash., died at the home of his sister, Emma O. Kwartz, in Los Angeles, Calif., on November 28, 1930. A brother, Ernest G. Kwartz, in Oakland, Calif., also survives him. He was unmarried.

Mr. Kwartz was born at Westmanland, Sweden, on September 29, 1876, and was graduated in 1898 from the four-year course in mechanical engineering at the Stockholm technical school. He came to the United States in 1900, after several years' experience in diamond drilling in Swedish mines, electrical drafting for Luth & Rosen, in Stockholm, and erecting buildings and machinery at the World's Fair in France in 1899-1900. His work in this country, beginning as mechanical draftsman for the Western Electric Company in Chicago, gave him experience on a variety of machinery, including machine tools and railway specialities for the Railway Appliance Company, Chicago; presses and dies for E. W. Bliss Co., Brooklyn, N. Y.; experimental machinery for the Mergenthaler Linotype Company, Brooklyn; tools for the E. M. F. Auto Co., Detroit, Mich.; and plasterboard manufacturing machinery for the Gypsum Products Corporation in Seattle. He also engaged in structural drafting for the J. B. & J. M. Cornell Co., New York, and plant layout work for the Duplex Metals Company, Chester, Pa., in 1907, and was sales engineer for the Jacobsen Engine Company of Chester for a time.

From 1910 to 1915 Mr. Kwartz was located at Chicago, devoting his time to machine and die design. During this period he invented a large machine for cutting off cardboard tubes of from two to six inches diameter for paper cans. He also designed a voting machine and all of the dies, etc., for producing its parts, and a special press and dies for the manufacture of hose clamps.

Mr. Kwartz went to Seattle in 1915. His work there included inspection of heavy oil engines; a power house addition for the Tacoma Smelting Company; a continuous oil press for the Sea Products Company; and machinery for the Bemis Bros. Bag Co. His death resulted from burns suffered while designing machinery for the Puget Sound & Alaska Powder Co.

Mr. Kwartz had been a member of the A.S.M.E. since 1925.

EDWARD POWELL LEWIS

Edward Powell Lewis, managing director of Messrs. Geo. W. Kelly & Lewis Pottery, Ltd., of Spring Vale, Victoria, Australia, who for some years had been in ill health, died on January 10, 1930. He was born at Heidelberg near Melbourne, on July 24, 1863. At the age of 17 he was indentured with the engineering firm of Wright & Edwards, at Melbourne. After a five-year apprenticeship he entered the drawing office of that company, where he remained until 1892, being promoted to the position of head draftsman and assistant manager. During this time he designed mill engines and was responsible for the designing and construction of a large portion of the street cable plant for the City of Melbourne. As there were no public technical institutions in Victoria he supplemented his practical experience during these years by private tuition and study.

In 1892 Mr. Lewis was appointed works manager and superintendent for Messrs. Thompson & Co. of Castlemaine, Australia, a position which he retained for about seven years. He was responsible for the design and construction of pumping plants for town water supplies and designed numerous high-pressure boilers, among which were those for the Melbourne metropolitan sewerage pumping plant. He was also responsible for the design of the large gate valves (88-in. diameter) used for the rising mains at that plant, as well as steam winding plants, two-stage air compressors, Corliss engines, and surface and jet condensing plants.

About thirty years ago he entered into partnership with the late Mr. Geo. W. Kelly of Melbourne, and the firms name became Geo. W. Kelly & Lewis. Modern tools and equipment were installed and the company engaged in the design and construction of general machinery covering a very wide range and including mining, milling, and pumping equipment. On the death of Mr. Kelly the business was absorbed by Mr. Lewis and his sons. Increasing business and the congestion within the city area eventually led to the erection of a new plant at Spring Vale, about sixteen miles from Melbourne. The business will be carried on by his two surviving sons.

Mr. Lewis became a member of the A.S.M.E. in 1919.

WILLIAM LINDHORST

William Lindhorst, consulting engineer for the Semet-Solvay Engineering Corporation, New York, N. Y., died on January 12, 1930. He was born in Brunswick, Germany, on September 21, 1877, the son of William August and Friederike (Reinhart) Lindhorst. He attended Hanover College, Hanover, Germany, where he received the degree of M.E.

In 1900 Mr. Lindhorst became assistant erecting engineer for the Brunswick Machine Company, and during three years with this company assisted in the erection of beet sugar factories and refineries in Germany, Italy, and Russia. In 1903 he joined the Novelty Steam Boiler & Construction Co., Brooklyn, N. Y., as draftsman and designer of steam boiler chemical apparatus, gas and by-product apparatus, and copper furnace plants. He became connected with the Semet-Solvay Engineering Corporation, a division of the Allied Chemical & Dye Corp., in 1912, being located first at the Solvay, N. Y., office and later in New York.

Mr. Lindhorst became a member of the A.S.M.E. in 1922. He was also a Mason and a Presbyterian. He married Gertrude Helen Egerland, who, together with two daughters, Florence and Gertrude Lindhorst, survive him.

EDWIN HOYT LOCKWOOD

Edwin Hoyt Lockwood, Higgins professor of mechanical engineering at Sheffield Scientific School, Yale University, died on April 16, 1930, at the New Haven Hospital, Conn., of heart disease. He was born on October 31, 1866, at New Canaan, Conn., the son of Samuel Kellogg and Mary (Hoyt) Lockwood. He received his early education in the public schools of New Canaan and at the New Canaan Seminary and was graduated from the Sheffield Scientific School in 1888 with the degree of Ph.B.

After a year as mechanical draftsman of special machinery for the Diamond Match Co. he returned to Yale for further study and be-

came an instructor in mechanical drawing. During the summer of 1895 he secured practical experience as draftsman at the Southwark Foundry, Philadelphia, and he worked in a similar capacity for the Deane Steam Pump Company, at Holyoke, Mass., in the summer of 1900.

In the latter year he was made an assistant professor of mechanical engineering and in 1924 an associate professor. In 1927 he was appointed Higgins professor of mechanical engineering. He was given the degrees of M.E. in 1892 and Ph.D. in 1901. During his long career on the Yale faculty Professor Lockwood taught nearly every subject in mechanical engineering and had become known throughout the country for his important investigations on fuel combustion in power and heating and in automotive engineering. In 1928 he completed experiments in the use of exhaust gases to increase automobile mileage and had done much other research work. He took an important part in planning the Mason Laboratory and Winchester Hall at Yale, and was the author of papers on automobile engineering and heating and ventilation.

Professor Lockwood was affiliated with many engineering societies. He joined the A.S.M.E. as a junior member in 1890 and was promoted to full membership in 1903. He was also a member of the Connecticut Academy of Arts and Sciences, the Society for the Promotion of Engineering Education, the Society of Automotive Engineers, the Society of Heating and Ventilating Engineers, and the Yale Engineering Association. He was a fellow of the American Association for the Advancement of Science.

In 1900 he married Elizabeth Pendleton, who, together with a son, Edward H. Lockwood, Jr., and a daughter, Mrs. Elizabeth P. Parker, survive him.

HENRY NICHOLAS LONG

Henry Nicholas Long, chief engineer of The Viscose Company, Parkersburg, W. Va., died in the Johns Hopkins Hospital, Baltimore, Md., on May 5, 1930. He was born in Deal, England, on November 27, 1879, the son of John and Elizabeth (White) Long. His education was received at the Brooklyn Technical and Trade School.

His professional experience began in 1894 as marine engineer apprentice at Glasgow, Scotland, and later he served several years at sea as engineer's apprentice. In 1901 he entered the British Navy as Junior Engineer, and in 1907 he became connected with the assembling department of the General Electric Company, Lynn, Mass. For two years he worked on general construction for the Edison Company, Brooklyn, N. Y. From 1910 to 1916 he engaged in the erection and installation of mechanical equipment in various cities throughout the United States. He then joined The Viscose Company as erecting engineer at Roanoke, Va. He was appointed chief engineer of the company in 1926, to build and equip the plant at Parkersburg. This work involved problems in refrigeration, steam circulation, water softening, sewage disposal, power production, etc.

Mr. Long was the inventor of a ratchet pipe wrench and was Corporal of the National Guards at Roanoke, Va. He became a member of the A.S.M.E. in 1928. He was also a member of the Masonic fraternity and the Elks. He was an Episcopalian. He married Annie Pearl Griffin in 1917, and is survived by her.

FREDERICK GUNARD LUNDGREN

Frederick Gunard Lundgren, assistant chief engineer for the American Dressler Tunnel Kilns, Inc., Cleveland, Ohio, died of pneumonia, on April 16, 1930, in that city. He was born at Kalmar, Sweden, on June 1, 1894, and received his education at the University of Illinois, where he obtained the degree of B.S. in 1915, and later the degree of M.E.

His professional experience began in 1903 with the Mills Novelty Company, Chicago, Ill. In 1907 he joined the Pope Manufacturing Company, Chicago, Ill., and was engaged in estimating and systematizing the manufacture of bicycles and automobiles. He also did similar work for the Orr & Lockett Hardware Company, Chicago, Ill., from 1908 to 1911.

Following his graduation from the University of Illinois he was employed by the American Car and Foundry Company, at Terre Haute, Ind., Milton, Pa., and Detroit, Mich., the Grasselli Chemical Company, Grasselli, N. J.; and the Ford Motor Company, Detroit. He designed and supervised the construction of factory and mill buildings and power plants, and built many special devices for performing mechanical work quickly and economically. In 1920 he became a partner with Lundgren and Deardorf, general contractors and engineers, Terre Haute, Ind., with which he remained until he joined the American Dressler Tunnel Kilns, Inc., in 1929.

Mr. Lundgren became an associate member of the A.S.M.E. in 1916 and a member in 1922.

DONALD DWIGHT LYNCH

Donald Dwight Lynch, research assistant, Technical Research Department, International Combustion Engineering Corporation, Newark, N. J., died on April 26, 1930. He was born at Oakland, Iowa, on January 22, 1899, and received a B.S. degree in mechanical engineering from the University of Nebraska in 1925. He remained at the university for about a year, conducting experimental tests on insulation at low temperatures, and then accepted a position with the International Combustion Engineering Corporation, in its New York office. He was transferred to the Newark office shortly before his death.

Mr. Lynch became a junior member of the A.S.M.E. in 1926.

RUDOLPH EDWARD LYON

Rudolph Edward Lyon, whose death occurred on February 28, 1930, was born at Ogden, Utah, on July 20, 1905. He attended the University of Utah, completing his work there in 1927. He then became connected with the Westinghouse Elec. & Mfg. Co., at East Pittsburgh, Pa., as a graduate student, and at the time of his death was one of its student salesmen.

Mr. Lyon became a junior member of the A.S.M.E. in 1928.

DONALD MacARTHUR

Donald MacArthur, vice-president and director of the Koppers Gas & Coke Co., and an officer of many other subsidiaries of the Koppers Company, died at the Mountainside Hospital, Montclair, N. J., on July 24, 1930, following an operation. He was born in Glasgow, Scotland, on August 30, 1880, the son of Angus and Mary (MacAlpin) MacArthur. He received his education at the Superior High School, Superior, Wis., and at the University of Wisconsin, where he was graduated with the degree of B.S. in Mechanical Engineering in 1904.

Mr. MacArthur's professional experience began after graduation with the Laclede Gas Light Company of St. Louis, Mo., where he was engaged in the design of station gas meters, and later was superintendent of the gas plant for this company. This latter position included the supervision of operation of all the company's manufacturing stations, making coal gas, water gas, and Pintsch gas. In 1916 he became connected with The Koppers Company as manager of the Seaboard By-Product Coke Company in charge of engineering at the Jersey City coke oven plant. He also did work in connection with light-oil and distillation plants in various cities. He became vice-president of the Seaboard By-Product Company in 1928 and vice-president and director of the Koppers Gas & Coke Co. in 1929.

Mr. MacArthur became a member of the A.S.M.E. in 1918. He was also a member of the Society of Gas Lighting. His club memberships included the Glen Ridge Country Club and Newark Athletic Club. He was an elder in the Central Presbyterian Church, Montclair, N. J., and a member of the Boy Scout Council of Glen Ridge, N. J. In 1905 he married Georgia Jane Doey, and she, together with a son, Donald MacArthur, survive him.

FRANCIS MacLEHOSE

Francis MacLehose, superintendent of the Waterside Stations of the New York Edison Company, died on November 17, 1930. He was born at East Orange, N. J., on September 13, 1885. His education was received in the East Orange schools, Stevens Preparatory School, and Stevens Institute of Technology, which awarded him the degree of M.E. in 1906.

His professional experience began with work for the New York Edison Company, as substation operator, in which capacity he served until 1908, when he was promoted to the position of central station operator. In 1910 he became assistant electrical foreman at the Waterside Station and in 1913 was "loaned" as superintendent of the Hales Bar Power Station of the Chattanooga & Tennessee River Power Co. He returned to New York two years later as assistant superintendent at the Waterside Station. His promotion to superintendent of Stations Nos. 1 and 2 came early in 1926.

He became a member of the A.S.M.E. in 1920, and was also a member of the American Institute of Electrical Engineers, the New York Electrical Society, the National Electric Light Association, and the Canadian Club. He was unmarried.

HERMAN H. MANGELS

Herman H. Mangels, engineer for the United Light & Power Engineering & Construction Co., Kansas City, Mo., was killed in an automobile accident near Denver, Colo., on September 7, 1930,

when returning from a vacation trip. He was the son of Mr. and Mrs. Ben Mangels of Davenport, Iowa, and was born there on June 9, 1896. He attended the Chicago Technical College and after two years as draftsman with the Tri-City Railway & Light Co., of Davenport, began work in a similar capacity with the United Light & Power Co. He was promoted to the head of the drafting department after a few years, and later was transferred to the construction department as a superintendent. His first project was a concrete dam at Coralville, Iowa, after which he built power plants for the company at Fort Dodge and Davenport, Iowa, and at Columbus, Ohio. Mr. Mangels returned to the Davenport offices for a time, but in 1927 was put in charge of the Kansas City office.

Mr. Mangels became a member of the A.S.M.E. in 1929 and was active in the Kansas City Section of the Society. In 1917 he married Ruth Hokinson of Moline, Ill., who, together with one son, Warren, survive him.

JOHN A. MARCATO

John A. Marcato, who had become a member of the A.S.M.E. early in 1930, died of heart disease at his home in New York on June 25.

Mr. Marcato was born in New York on August 23, 1880. He supplemented his public school education with private tuition, and at the age of 23 became assistant engineer for the Marcato Elevator Company. After three years he was made chief engineer of the company, and retained that position until his death. For several years he was associated in a similar capacity with the Alloy Metal Wire Company, and during the last ten years of his life he did consulting work, made reports and appraisals, and gave expert testimony in regard to elevators and hoisting equipment.

Mr. Marcato belonged to the Knights of Columbus and Elks, and was an active member of the Holy Trinity Roman Catholic Church. He was very much interested in the political life of Alfred E. Smith and had stumped for him many times in his campaigns.

Surviving Mr. Marcato are his widow, Kathleen G. (King) Marcato, whom he married in 1907, and five children, Grace, John, Edward, William, and Robert.

WILLIAM GRANT MATHESON

William Grant Matheson was born on August 1, 1848, at Albion Mines, Nova Scotia, the son of Isaac and Hanna Matheson. He received his education at the public schools of Chatham, New Brunswick, and the University of New Brunswick; ill-health, however, prevented him from finishing his college course. After a year in a machine shop in Nova Scotia he went to Scotland where he was apprenticed to Baxter Brothers, Dens Works, Dundee (1868–1870) and R. Napier & Sons, Glasgow (1870-1871). He then returned to Canada and entered the employ of I. Matheson & Co., New Glasgow, N. S., in January, 1872. He became manager of this firm in April, 1874, which position he held until he left in June, 1914, to enter the employ of the Nova Scotia Steel & Coal Co. In 1921 the state of his health compelled his retirement from all active work. He died on September 12, 1930.

Mr. Matheson was greatly interested in regulations for the construction and inspection of steam boilers, having taken a prominent part in the formulation of a uniform set of rules for the provinces of Canada as the representative of Nova Scotia. He also took a keen interest in the work of the A.S.M.E. Boiler Code Committee.

He took an active part in town affairs, particularly the construction of public works, and also in connection with the School Board, on which he served for some years. He was also prominent in church work, having been a member of the Session of Westminster Presbyterian Church since 1900. He had been a member of the A.S.M.E. since 1891, and also belonged to the Engineering Institute of Canada and the Association of Professional Engineers of Nova Scotia.

Besides his widow, Annie Parks Matheson, whom he married in 1902, he leaves a daughter, Hannah Matheson, and two sons, W. Drummond and J. H. Parks Matheson.

FRANK ELLIOTT MATHEWSON

Frank Elliott Mathewson, director of the department of technical-industrial and special-trade education at the Dickinson High School, Jersey City, N. J., died of sudden attack of heart disease on May 13, 1930.

Mr. Mathewson was born in Chicopee Falls, Mass., on October 28, 1869, the son of Henry Stewart and Mary. L. (Bullock) Mathewson. After leaving high school he worked for five years as an apprentice, machinist, and draftsman for the Chicopee Manufacturing Company, in repair work for cotton mills. From 1889 to 1899 he was employed as draftsman and designer for the Lamb Manufacturing Company, makers of Spalding bicycles and gymnasium equipment, at Chicopee Falls.

Mr. Mathewson entered the teaching profession in 1892 as an instructor in mechanical drawing in evening schools in Chicopee and Chicopee Falls. Three years later he was made principal of the evening drafting school at Springfield, Mass. He resigned that position in 1899, when he accepted an instructorship in mechanical drawing and machine shop practice at the Mechanics Arts (subsequently Technical) High School and Evening School of Trades in Springfield. From 1902 to 1908 he was head of the drawing department of that institution.

In 1908 Mr. Mathewson went to Cleveland, Ohio, as assistant principal in charge of all shop work and drawing at the Cleveland Technical High School. He was located there until 1911, when he spent six months as head of the drawing department of Wentworth Institute, in Boston.

Mr. Mathewson entered the Jersey City school system in 1912 when he accepted the position of director of industrial training in the Dickinson High School where he planned and purchased all equipment and organized the courses of study. During the war he was made district educational director of vocational instruction in the War Department committee on education and special training.

On Oct. 6, 1926, he was elevated to the position he was holding at the time of his death.

Mr. Mathewson was the author of a number of books on mechanical drawing. He became a member of the A.S.M.E. in 1913. He had also served the Eastern Arts Association as president, and for the last nine years of his life was its secretary and treasurer, contributing greatly to the development of the Association.

Mr. Mathewson is survived by his widow, Emily L. (Forbes) Mathewson, whom he married in 1892.

RICHARD KIDDER MEADE

Richard Kidder Meade, of Richard K. Meade & Co., Baltimore, Md., died on October 13, 1930. He was born at Charlottesville, Va., on November 28, 1874, the son of Rev. Francis Alexander and Martha B. (Mosby) Meade. He was graduated from the University of Virginia in 1893, and was given the degrees of B.S. in 1899 and honorary M.S. in 1908 by Lafayette College. He was an honorary Phi Beta Kappa.

After a few years' experience as city editor of the *Independent-Herald*, Hinton, W. Va., and as chemist for the Longdale Iron Company, Allegheny Co., Va., Mr. Meade became instructor in chemistry at Lafayette College in 1897. Beginning in 1902 he served successively as chief chemist for the Edison Portland Cement Company, chief chemist and superintendent of the Northampton Portland Cement Company, chief chemist of the Dexter Portland Cement Company, director of the Meade Testing Laboratories, Allentown, Pa., and manager of the Tidewater Portland Cement Company, Baltimore. In 1912 he took up consulting practice in Baltimore, specializing in the design of cement, lime, and plaster plants. He was the founder and first editor of *The Chemical Engineer* and took out many patents and improvements in cement manufacture, processes for waterproofing concrete, and apparatus for drying coal. He designed and built several cement plants, many lime plants, plants for producing potash, carbon dioxide, whiting, clay, and many chemicals. He was the author of the Chemists' Pocket Manual (3d edition), Portland Cement (3d edition), Design and Equipment of Small Chemical Laboratories, The Chemical and Physical Examination of Portland Cement, and Brass and Alloy Analysis (with William B. Price).

He became a member of the A.S.M.E. in 1912 and had served on a subcommittee on cement manufacture. He was also a member and one of the founders of the American Institute of Chemical Engineers, and a member of the American Chemical Society and the American Electrochemical Society. His club membership included the Baltimore Country, Engineers (Baltimore), and Chemists (New York). He belonged to the Episcopal Church and the Sons of the American Revolution.

In 1899 he married Fannie Louise Thomas and she, together with two children, Mrs. Martha Haskins Baughman and Francis Alexander Meade, survive him.

GEORGE EDMUND MERRYWEATHER

George Edmund Merryweather, president of the Motch & Merryweather Machinery Company, died at Cleveland, Ohio, on June 8, 1930. He was born in Cincinnati, Ohio, on August 28, 1872, the son

of George Neave and Ellen L. (Beaman) Merryweather. He received his education at the Massachusetts Institute of Technology, which gave him the degree of B.S. in 1896. He was with the Brown & Sharpe Manufacturing Company of Providence for five years and had charge of the company's exhibit at the Paris Exposition in 1900. He became superintendent of the Overman Automobile Company at Chicopee Falls, Mass., in 1901, and when that company merged with the Locomobile Company of America he became superintendent of the combined firm. In 1904, with Edwin R. Motch, he organized the Motch & Merryweather Machinery Co.

He became a member of the A.S.M.E. in 1903; was an ex-president of the Technology Club of Northern Ohio; and director of the Central United National Bank of Cleveland, the P. A. Geier Company, and the Davenport Machine Tool Company of Rochester, N. Y. He was also a member of the Society of Automotive Engineers; the Engineering Society of Cleveland; the Cleveland Chamber of Commerce; and the University, Union, Mayfield, and Philosophical Clubs in Cleveland.

During the World War he was chief of the machine tool section of the War Industries Board. He held many patents in the machine tool industry.

In 1908 he married Laura Esselborn, who, together with five children, Janet, George E., Constance, Hubert Orr, and Laura Merryweather, survive him.

JOHN HENNON MITCHELL

John Hennon Mitchell, sales manager for the Standard Steel Car Company, central district, with headquarters at Pittsburgh, Pa., died suddenly on January 16, 1930, in New York where he had gone with other officials of his company to attend a convention of the master car builders.

Mr. Mitchell was born in New Brighton, Beaver Co., Pa., August 30, 1872, a son of Joseph F. and Margaret Hennon Mitchell. He was educated in the public schools of Beaver County and studied mechanical engineering at Cornell University. He served as an apprentice for about three years with the Penn Bridge Works at Beaver Falls, Pa., and had two years' experience in the structural engineering department of the Carnegie Steel Co., Ltd., at Pittsburgh, as a designer and estimator. He then entered the motive power department of the Pittsburgh & Lake Erie R. R., at McKees Rocks, Pa., designing locomotives, passenger and freight equipment, shop and road machinery, and making tests of locomotives and materials. He was in complete charge of this work when he left the company to become manager of sales for the Pressed Steel Car Company, in its western district, with headquarters at Chicago. Subsequently he was also appointed sales manager for the Western Steel Car & Foundry Co. After nineteen years in Chicago Mr. Mitchell went to Havana, Cuba, as acting president of the American Steel Company. He returned to this country three years later to become sales manager for the Standard Steel Car Company.

Mr. Mitchell belonged to the Presbyterian Church, Evanston, Ill.; Allegheny Country Club, Edgeworth Club, Sewickley, Pa.; Duquesne Club, Keystone Athletic Club, Chicago Athletic Club, Pittsburgh Chamber of Commerce, Illinois Chapter of the Sons of the American Revolution, the Railway Men's Traffic Club, and the A.S.M.E., which he joined in 1900 as an associate. He is survived by his widow, Mary Morrison Mitchell, whom he married in 1898, and by one son, H. Morrison Mitchell.

RICHARD MOLDENKE

Dr. Richard Moldenke, one of the leading metallurgical experts of the country, died at the Muhlenberg Hospital in Plainfield, N. J., on November 17, 1930, following a major operation. He was sixty-six years old. He was born at Watertown, Wis., on November 1, 1864, the son of the Rev. Dr. Edward F. Moldenke, and Elise (Harder) Moldenke. The family moved to Plainfield in 1870, and his father was at one time pastor of St. Peter's Lutheran Church in the City of New York. He attended the Columbia Grammar School in New York and later the School of Mines of Columbia University, from which he was graduated in 1884. Two years later he returned as an instructor at Columbia and studied for his Ph.D. degree, which he received in 1887.

For a time he was employed by the United States Coast and Geodetic Survey and was identified with some of the early work in electric power development. In 1889 he organized the Mechanical and Engineering Department of the Michigan College of Mines, at Houghton, Mich. He entered the foundry industry in 1890 when he became connected with the McConway & Torley Co., of Pittsburgh, Pa. A year later he was prominent in organizing the Pennsylvania Malleable Company, at Pittsburgh, which he served as superintendent.

Dr. Moldenke became a member of the American Foundrymen's Association in 1897, when that organization was only a year old. As secretary and treasurer of the Association from 1900 to 1914, when he resigned to devote himself to his consulting practice, he built up the association from scarcely more than a trade organization to a scientific society of wide-spread influence and value. In 1925 he was awarded the Joseph S. Seaman Gold Medal of the Association in recognition of his contributions to the foundry industry. He had also been elected to honorary membership in the Association.

Through his membership in the American Society for Testing Materials, of which he was vice-president, and in the International Society for Testing Materials, Dr. Moldenke was very active in establishing specifications for foundry materials. An international standard for the comparison of cast irons was the latest work in which he played an important part.

President Roosevelt appointed him as a member of his Conservation Commission to investigate safety devices for workers in mines throughout the country. The reports which he submitted on this investigation resulted in many improvements in safety devices.

During the World War he was called upon to assist in the production of flawless castings for war materials. Among other things he specified the analysis of iron used in various castings in the Liberty motor.

Dr. Moldenke was consulting metallurgist for many companies, including the Worthington Pump & Machinery Corp., the Bethlehem Steel Company, the United States Cast Iron Pipe & Foundry Co., the American Cast Iron Pipe Company, and the Babcock & Wilcox Company.

He was a prolific writer on foundry and metallurgical subjects. Among the best known of his works are his books entitled "The Production of Malleable Castings" and "The Principles of Iron Founding."

During the latter part of his life, when not traveling in the interest of his profession, he busied himself in experimenting with metals in the small foundry in the rear of his home at Watchung near Plainfield.

Dr. Moldenke became a member of the A.S.M.E. in 1900. He also belonged to the American Electrochemical Society, the American Institute of Mining and Metallurgical Engineers, the Newark, New England, Pittsburgh, and Southern Foundrymen's Associations, the British Iron and Steel Institute, the Verein deutscher Eisen Huttenleute, and the Institute of British Foundrymen, of which he was an honorary member.

He also was active in civic and church affairs, being a member of the Kiwanis Club, the Society of Older Graduates of Columbia University, the Columbia Alumni Association, the Lutheran Society of New York, and treasurer of St. Peter's Lutheran Church, Plainfield.

His widow, Mrs. Anna (Heins) Moldenke, whom he married in 1891, two sons, Richard, Jr., and Edel Moldenke, and a daughter, Mrs. Paul Noh, survive him.

ARLINGTON G. MOLER

Arlington G. Moler, Captain, Engineers Corps, U.S.A., who served overseas during the World War and was gassed and otherwise injured, died of tuberculosis in Salt Lake City, Utah, on August 22, 1930. He was buried in the Fort Douglas cemetery with military honors.

Captain Moler was born at Brunswick, Md., on June 25, 1891. He followed his high-school education with three years at the Maryland Institute and a four-year apprenticeship with the Baltimore & Ohio R.R., in its Riverside and Mt. Clare shops. He was employed by that road during the next three years successively as gang foreman, machine-shop foreman, and general foreman, at the Mt. Clare shops.

Severing his connection with the Baltimore & Ohio, Captain Moler was for a year tool room foreman for the Eddystone Ammunition Company, Philadelphia, and subsequently assistant superintendent in charge of the manufacture of automobile wire wheels for the E. G. Budd Wheel Corp. of that city.

Since the War Captain Moler had held positions as superintendent of motive power for the Denver & Salt Lake (Moffat) Railroad, manager of the machinery department of the Salt Lake Hardware Company, and superintendent of the Williams Pipe Machine Plant at Erie, Pa.

Captain Moler became an associate member of the A.S.M.E. in 1920. He is survived by his widow.

CHARLES BREARLEY MOORE

Charles Brearley, son of Josiah and Jennie (Lindsay) Moore, was born at Macomb, Ill., on August 28, 1874. He received an M.A.

degree from Lake Forest University, Lake Forest, Ill., in 1896 and in the same year entered the contracting and building business under the name of C. B. Moore & Co., later engaging in the manufacture of heating apparatus with the Columbia Heating Company. In January, 1902, Mr. Moore joined in the organization of the American Locomotive Equipment Company, of which he was general manager until 1910. At that time he organized the American Arch Company of New York and served as vice-president until 1912, when he assisted in the organization of the Oxweld Railroad Service Company, Chicago, occupying the position of vice-president until September of that year, when he was elected chairman of the board.

From 1912 to 1917 Mr. Moore was also vice-president of the Boss Nut Company. In 1922 he organized the Ajax Hand Brake Company, of which he was president at the time of his death. In 1924 he was made vice-president of the Youngstown Steel Door Company of Cleveland, Ohio, and held that position until his death.

Mr. Moore became a member of the A.S.M.E. in 1914. He was a Presbyterian by faith, belonging to the First Presbyterian Church at Evanston, Ill., where he made his home. He held membership in the Union League Club, University Club, Collegiate Club, and Press Club of Chicago, and several country clubs. His death on November 9, 1929, was caused by heart failure. Surviving him are his widow, Fay (Harvey) Moore, whom he married in 1906, and two sons, James Herbert and Robert Brearley Moore.

ROBERT S. MOORE

Robert S. Moore, retired president of the Pacific Securities Company, San Francisco, Calif., died on February 16, 1930. Mr. Moore was born in that city on March 22, 1857, the son of Joseph and Anne Moore. After some early experience in mechanical engineering at the Reardon Iron Works, San Francisco, he entered the University of California, from which he received a B.S. degree in 1881.

Mr. Moore entered the shops of the Risdon Iron Works following his graduation, and worked up to the position of superintendent. He left that firm to found the Moore & Scott Iron Works at San Francisco. Later he founded the Moore Dry Dock Company and served as chairman of its board. This company built a large number of steamships during the World War. He also served as chairman of the board of the Paraffine Companies, Inc., San Francisco, and assistant to the president of the Moore Investment Company.

Mr. Moore became a member of the A.S.M.E. in 1892. He served as a manager of the Society in 1901–1904, and as a member of its committee on the 1915 International Engineering Congress. He also belonged to the Masonic fraternity, and a number of clubs. He married Florence Howe in 1887.

MAX PHILLIP MORRISON

Max Phillip Morrison, head of the Tramway Department of the American Steel & Wire Co., Worcester, Mass., died at Charleston, W. Va., on February 28, 1930, of heart disease. He was born in Moscow, Russia, on December 16, 1878, and came to America as a young man. He studied at Drexel Institute, Philadelphia, and was graduated from the University of Pennsylvania with the degree of B.S. in mechanical engineering in 1906. He received his M.E. degree in 1909. While working for the latter degree, Mr. Morrison was employed as plant engineer of the Chester Steel Castings Co., Chester, Pa., in 1906, and the following year by the Pennsylvania Steel Company, Steelton, Pa., as draftsman. He was evening instructor in mathematics and head of the Mechanics Department of the School of Industrial Arts, in Trenton, N. J., in 1908 and 1909 and was also employed by the Trenton Iron Company, now the American Steel & Wire Co., as a draftsman during that period.

His advancement in this company was rapid and led to his transfer to the Worcester Works as head of the Tramway Department. He designed and installed overhead tramway systems for handling materials, including many systems is mining regions.

Mr. Morrison became a member of the A.S.M.E. in 1914. He was also a member of the Worcester City Club. A daughter living in Trenton, N. J., survives him.

CHARLES LEONARD NEWCOMB

Charles Leonard Newcomb, former manager and vice-president of the A.S.M.E., consulting engineer, well known for his long connection with the Deane Steam Pump Company, of Holyoke, Mass., died on March 13, 1930, at his home in Holyoke.

Mr. Newcomb was born at West Willington, Conn., on August 7, 1854. He was the son of Charles Leonard and Martha Jane (Hudson) Newcomb. His early life was divided between working in a glass factory during the winter months and on a farm during the summer months, and he had slight opportunity for attending the district school of the locality. He was at an early age employed with the Hall Thread Company, South Willington, Conn. Later he was an apprentice in the Murless Foundry and at the Senior Machine Shop, and afterward was employed as a machinist with the Rock Manufacturing Company, Rockville, Conn., and the American Clutch Company, Middletown, Conn.

In 1874 he entered the employ of Pratt & Whitney Co., Hartford, Conn. In 1880 he was graduated from the Worcester Polytechnic Institute with the degree of M.E. He was subsequently employed as superintendent of the American Electric Lighting Company, New Britain, Conn., which afterward became the Thomson-Houston Electric Company of Lynn, Mass.

Mr. Newcomb became superintendent of the Deane Steam Pump Company in 1881. The company was acquired in 1899 by the International Steam Pump Company, and in 1914 was merged into the Worthington Pump & Machinery Corp., as the Deane Works of the corporation. Mr. Newcomb's entire connection with this plant extended over a period of 47 years, during which time he became its president and general manager, a position which he retained until he retired in 1927.

As a mechanical engineer Mr. Newcomb specialized in steam and hydraulic engineering and was a very active factor in the upbuilding of the Deane plant. During his residence in Holyoke he also acted as consulting engineer for various manufacturers of the state, and was employed as an expert in various lines of engineering work. He was associated with many valuations of plants, among which was the Holyoke Water Power Company, Gas and Electric Branch, which was taken over as a municipal plant by the city of Holyoke. He was a frequent contributor to the engineering press. In 1927 Mr. Newcomb was elected a trustee of the Worcester Polytechnic Institute.

Mr. Newcomb was instrumental in organizing the National Founders Association in 1898 and was elected its first vice-president. In 1899 he was one of those who helped to form the National Metal Trades Association, and of this organization he also became the first vice-president. In 1919 he was one of the organizers of the Engineering Society of Western Massachusetts, which he served as its first president. Through the Associated Industries of Massachusetts, which he helped to organize and which he served as a director and member of the executive committee until his death, he was active in promoting the industrial growth of New England. He became a member of the A.S.M.E. in 1883 and served as manager from 1918 to 1921, and as vice-president from 1926 to 1928. He also belonged to the Society of Naval Architects and Marine Engineers and the New England Foundrymen's Association, the Masonic fraternity, and a number of clubs.

Mr. Newcomb was specially interested in human relations in industry, and was an executive in the annual conferences of the Silver Bay Industrial Conference Board. He took an active part in the municipal affairs in the city of Holyoke, acting as councilman during the years 1886 and 1887, and as alderman in 1888. He became a member of the Fire Commission of that city and was named its chairman in 1893, serving in this capacity for 17 years. During this service he invented a widely adopted rotary deluge nozzle for fire-fighting purposes on the top of an aerial ladder. He organized the Holyoke Cooperative Bank and was its president until his death.

Surviving Mr. Newcomb are his widow, Inez L. (Kendall) Newcomb, whom he married in 1874, and six children.

HENRY C. ORD

Henry C. Ord, mechanical engineer, Tacoma, Wash., died at his home on March 7, 1930. He was born at Stockton on Tees, Durham, England, on February 20, 1867. He attended the public schools and the Toronto Art School, and served a four-year apprenticeship with the Napanee Paper Company. From 1887 to 1890 he engaged in boiler and sheet iron work with the Cleveland Shipbuilding Company and other firms. In 1890 he became draftsman for the Gobeille Pattern Company, Cleveland, Ohio, and in 1895 foreman of boiler and sheet-iron work for the McKinnon Manufacturing Company, Bay City, Mich. For several years he was draftsman and designer for the Gibbs Electric Company, Milwaukee, Wis., engineer and designer for the Vulcan Iron Works, Chicago, Ill., and engineer and designer for the Bucyrus Company, South Milwaukee, Wis. He also served as mechanical engineer and designer of engines and special machinery for the Allis-Chalmers Company, Milwaukee, Wis., the General Electric Company, Lynn, Mass., the Dominion Bridge Company, Ltd., Montreal, Canada, and the Puget Sound Iron & Steel Works, Tacoma, Wash.

He became a member of the A.S.M.E. in 1905. He was a Methodist in religion and a member of the Tacoma Revolver and Gun Club. His widow, Della (Cummings) Ord, survives him.

T. ELLIOTT PAYSON

T. Elliott Payson, engineer for special equipment with the International Motor Company, Long Island City, N. Y., died on September 14, 1930. He was born in New York, N. Y., on November 26, 1870, the son of Thomas and Lillian (Gordon) Payson.

Mr. Payson supplemented his public school education with two years at Cooper Union and private instruction. His engineering experience, beginning with the Neptune Meter Company, Long Island City, N. Y., as chief draftsman and designer, was varied. During the first fifteen years he had experience not only in drafting and designing, but also in machine shop and toolmaking. Among the companies with which he was connected during this period were the Mergenthaler Linotype Company, Brooklyn, N. Y., Randolph Clowes Company, Waterbury, Conn., Remington Typewriter Company, Ilion, N. Y., and Ideal Opening Die Company, New York, N. Y.

From 1906 to 1907 Mr. Payson was engaged in the design of machinery for the Eton-Hurlbut Paper Company, Pittsfield, Mass. He then returned to New York as assistant superintendent and production engineer for the Joseph Schneible Company. For a time in 1909 he was again located in Pittsfield, with the Alden Sampson Manufacturing Company, and during the next two years was works manager and general superintendent for The Edengraph Manufacturing Company, New York.

Mr. Payson was located in Newark and West Orange, N. J., in 1911 and 1912, part of the time at the Edison Laboratory and The Edison Storage Battery Company, in West Orange, and the remainder with the Lansden Company, Newark. He next went to Seneca Falls, N. Y., as general superintendent and mechanical engineer, engaged in the manufacture of engine lathes, machine tools, etc., for The Seneca Falls Manufacturing Company. Prior to his connection with the International Motor Company he had been located at the Presto Machine Works, in Flushing, N. Y.

Mr. Payson became an associate of the A.S.M.E. in 1906 and a full member in 1914. Surviving him are his widow, Julia (Lynn) Payson, and two daughters, Vivienne Lynn (Payson) Miller and Ruth Lynn (Payson) Stelzer.

NATHAN WAITE PERKINS

Nathan Waite Perkins, designer and consulting engineer for the National Cash Register Company, Dayton, Ohio, died on December 1, 1930, of heart disease. He is survived by his widow, Alice E. (Waite) Perkins, whom he married in 1889, and by a son, Raymond C. Perkins, and two daughters, Margaret W., and Mildred E. Perkins.

Mr. Perkins was born in St. Louis, Mo., in December, 1860. He attended Washington University in that city, from which he received the degree of M.E. in 1881. During the most of the time from then until 1906, he worked as draftsman and designer for different companies in St. Louis, among which were the American Brake Company, American Arithmometer Company, Standard Adding Machine Company, American Car Company, and Universal Adding Machine Company.

Early in 1906 Mr. Perkins left St. Louis for Newark, N. J., where he accepted a position as chief draftsman and engineer for the Ellis Adding Typewriter Company. This company was later purchased by the National Cash Register Company, by whom he was retained as designer and consulting engineer.

Mr. Perkins became a member of the A.S.M.E. in 1913. He was president of the New York Alumini of Washington University for a year, and a member of the First Unitarian Church of Orange, N. J.

ROBERT W. PETTIGREW

Robert W. Pettigrew, technical student of the Westinghouse Elec. & Mfg. Co., South Philadelphia Works, died on November 28, 1930, at Moores, Pa. He was born at Wilmore, Pa., on October 5, 1902, the son of John W. and Ada (Crum) Pettigrew. He received his high-school education at Beaverdale, Pa., and was graduated from the University of Pittsburgh, with the degree of B.S. in M.E., in 1930. He had served in the Aircraft Division of the U. S. Navy. He became a junior member of the A.S.M.E. in 1930.

ALBERT C. PICARD

Albert C. Picard, whose death on June 17, 1930, was caused by heart disease, was a native of Detroit, Mich., and had spent a large part of his life there. He was born on September 3, 1882, the son of Albert and Emily (Joliet) Picard, and after completing his studies became assistant to the secretary of the Michigan Lubricator Company. In 1910 he was made traveling sales representative of the Detroit Lubricator Company, a position which he retained for two years. Since then he had been general manager of the Lubricator Division of the McCord Radiator & Mfg. Co., of Detroit. He was in charge of design, production, and sales, and under his supervision the department became one of the most important units of the company.

Mr. Picard was always active in any development that had to do with mechanical lubrication, and contributed in no small measure to its wide use in the oil field. He designed force feed pumps, adjustable nozzles for atomizing oil, and lubricating pumps for motor vehicles.

Mr. Picard became an associate-member of the A.S.M.E. in 1929. He belonged also to the Knights of Columbus and the Detroit Golf Club, and was a Roman Catholic. His widow, Margaret F. (Foley) Picard, whom he married in 1914, survives him.

FRANCIS COLE PRATT

Francis Cole Pratt, former vice-president and chairman of the manufacturing committee of the General Electric Company, Schenectady, N. Y., died on January 26, 1930, in New York, N. Y., after an illness of six weeks.

Mr. Pratt was born in Hartford, Conn., on January 19, 1867, the son of Francis A. and Harriet Cole Pratt.

He attended the Hartford public schools and was graduated from the Sheffield Scientific School of Yale University with the degree of Ph.B. in mechanical engineering in 1888. After graduation he was associated with the Pratt and Whitney Company, Hartford, Conn., machine-tool manufacturers, of which his father was president and one of the founders, continuing with them until he became vice-president. He made several trips to Europe for the company, studying processes of treating metals, equipment of armories and factories with machinery for producing interchangeable parts, and other problems.

Mr. Pratt joined the General Electric Company in 1906 as assistant to E. W. Rice, in charge of manufacturing and engineering. He was made assistant to the president in 1913 and was elected vice-president in 1919. In this capacity he at first had charge of engineering and later of both engineering and manufacturing. He retired in 1927.

Mr. Pratt was a member of the munitions standards board of the United States council of national defense in 1917, a trustee of the Sheffield Scientific School, where he established the Francis A. Pratt scholarship fund as a memorial to his father, a trustee and former head of the Hospital Association of Schenectady, a former trustee of the Albany Medical College of Union University, and former president and member of the executive committee of the Yale Engineering Association. The honorary degree of M.A. was conferred upon him by Yale in 1925. He became a junior member of the A.S.M.E. in 1892 and was promoted to full membership in 1897. He was a chevalier of the Legion of Honor.

His widow, Mrs. Bertha De Witt Pratt, a son, Francis De Witt Pratt, and a daughter, Mrs. Charles Hooker Talcott, survive him.

AUGUSTE C. E. RATEAU

In the death of Auguste Camille Edmond Rateau, which occured in Paris on January 13, 1930, the A.S.M.E. lost one of its most eminent foreign members; one who, passing at the comparatively moderate age of 67 years, might have been expected to continue longer in its work and its activities.

Born at Royan, in the Department of Charente-Inférieure, on October 13, 1863, Auguste Rateau received his technical education in the famous École Polytechnique in Paris, being graduated at the head of his class (1881–1883), after which he passed three years at the École Supérieure des Mines, followed by a year of active service in the Government Mining Engineering Corps at Rodez. For the ten years between 1888 and 1898 he served as professor in the School of Mines at Saint Étienne, and during the years from 1902 to 1910 as lecturer upon industrial electricity in the High School of Mining Engineering at Paris.

It was during these latter years that Rateau began to devote his energies to his special inventions, and to their industrial and commercial development in France and elsewhere in Europe. The result of this work was the inception, with only five associates, in 1903 of the great Société Rateau, which, at the time of his death, engaged more than 4000 employees, with branches in most of the industrial centers of Europe. Of this great corporation he was the Chairman of the Board, and was also actively and officially connected with other industrial organizations.

As a professor he always exercised a most stimulating influence upon the students under his charge, while at the same time employ-

ing his original genius upon the subject of the mechanics of fluids and its application to steam turbines, to centrifugal compressors, and to centrifugal pumps. Centrifugal compressors of the Rateau type have come into general use in France and elsewhere for blast furnaces and steel converters; while his device of the steam accumulator has enabled the exhaust steam of reciprocating engines to be successfully utilized in low-pressure steam turbines.

In 1900 he published his treatise on turbo machines, a work which still retains its value for engineers in this department of practice.

During all the period in which Rateau was occupied with the development of the great industrial organization of which he was the head, he found time to conduct technical researches of fundamental value in the department of engineering to which he was devoted. The pages of the leading engineering publications of France are filled with communications of the highest scientific character from his fertile brain, and deal with turbo machines, pressure blowers, air screws, flow of gases through nozzles, ejector condensers, etc.,

More recently he gave much attention to the mechanics of aviation and the reactions of air resistance to the wings of airplanes.

Twice he was laureate of the Academy of Sciences, receiving the Fourneyron Prize in 1899, and the Poncelet Prize in 1911; at which time he was chosen a Member of the Insitute of France, one of the highest honors to which a citizen of France may aspire; and to this was added that of Commander of the Legion of Honor.

When the Great War burst upon France, Rateau, although beyond the call for active military service, at once offered himself to the National Defense, and in connection with the Manufacture d'Armes at St. Étienne, he organized a model workshop, which under his able personal administration, produced more than four million shells. At the same time he developed his remarkable invention of the automatic supercharger for the motors of airplanes, enabling higher altitudes to be attained than had hitherto been possible, and thus giving French military airplanes a distinct advantage.

In connection with the ordnance department of the French army, Rateau developed improvements in the control of pneumatic recoil mechanism in artillery, of such importance that these devices have been kept secret by the government as valuable contributions to the national defense.

As an indication that his activities were unimpeded to the last, his latter days were devoted to the development of a most effective system of supercharging for the Diesel motor—researches of which the effects are yet to be made public.

Space will not permit an enumeration of the many contributions to engineering knowledge which have emanated from the fertile brain of Auguste Rateau—they fill a considerable volume, separately published, and sought and appreciated by the members of the profession; many of them are highly technical and analytical, showing an intimate knowledge of mathematical theory combined with practical application.

Many honors were conferred upon Auguste Rateau; it is necessary here to mention only that he received the doctorate from four institutions in as many countries: from America (University of Wisconsin), from England (University of Birmingham), from Belgium (University of Louvain), and from Germany (Technische Hochschule, Charlottenburg).

In all his active career, Rateau was always genial, courteous, and accessible, even to the least important members of his organization; never egotistical or dogmatic, always friendly and affectionate.

Often he repeated his controlling thought:

"Happy is he who succeeds in delivering his message!"

Auguste Rateau was elected Honorary Member of the A.S.M.E. in 1919, and always manifested a great interest in its work and its members.

HENRY HARRISON SUPLEE.[1]

OLIVER PERRY REESE

Oliver Perry Reese, general superintendent of the southwestern division of the Pennsylvania Railroad since June, 1929, died at his home in Indianapolis, Ind., on November 14, 1930, as the result of heart disease.

He was born in Louisville, Ky., on May 29, 1876, and was graduated from Purdue University in 1898, with a B.S. degree in mechanical engineering. He served an apprenticeship with the Louisville and Nashville Railroad at Louisville during the next two years and entered the service of the Pennsylvania Railroad as a draftsman at the Allegheny shops in 1900. During the next fifteen years he served the company in special work at Fort Wayne, Ind., as gang foreman of the machine shop at Allegheny, Pa., general foreman and master mechanic of the E. and A. Division and at the Ally Shops, and assistant engineer of motive power of the northwestern system.

In 1917 he became superintendent of motive power at Toledo, and in 1921 was transferred in the same capacity to Chicago. In 1927 he was made general superintendent of motive power at Pittsburgh.

Mr. Reese was a member of the Masonic fraternity, Columbia Club, Indianapolis Athletic Club, and Highland Golf and Country Club. He had been a member of the A.S.M.E. since 1916.

KNIGHT CHENEY RICHMOND

Knight Cheney Richmond, consulting engineer and architect, Providence, R. I., died on December 22, 1930, of heart disease.

Mr. Richmond was born in Brooklyn, N. Y., on April 18, 1864. He received a B.P. degree from Brown University in 1885 and five years later a B.S. from the Massachusetts Institute of Technology. He had also served an apprenticeship with the Providence Steam Engine Works.

Following graduation, Mr. Richmond entered the office of Nier, Hartford and Mitchell, at Chattanooga, Tenn., as a draftsman. The following year he became treasurer of the P. A. Demens Woodworking Co., at Asheville, N. C., where he remained for two years. He then was appointed resident engineer for the Crompton Company, textile manufacturers, at Crompton, R. I. He resigned this position in 1899 to become associated with F. P. Sheldon, mill engineer of Providence, as draftsman and engineer, and retained that position until he opened his own office in 1903.

Mr. Richmond's consulting work included steel and reinforced concrete construction, power equipment, reports and estimates, and textile mills and factories. A paper by him on Saw-Tooth Roofs for Factories, presented at the 1906 Annual Meeting of the A.S.M.E., was published in the Transactions for 1907. He became a junior member of the Society in 1891, and a member in 1908. He also belonged to the American Concrete Institute.

ANDREW LAWRENCE RIKER

Andrew Lawrence Riker, engineer and inventor, and a pioneer in the development of the automobile in this country, died suddenly of heart disease on June 1, 1930, at his home in Fairfield, Conn. Mr. Riker was a native New Yorker, and was born on October 22, 1868, the son of William J. and Charlotte L. R. (Stryker) Riker. He received his education at Columbia University.

From youth Mr. Riker showed his inventive ability, having designed and built a tricycle propelled by electricity when only 16 years old. In 1895 he produced a four-wheeled electric motor car and in 1902 a car using gasoline for fuel. In 1908 the Vanderbilt Cup race was won by a car of his design, driven at a speed of 64.5 miles per hour.

At the age of 20, Mr. Riker was president of the Riker Electric Motor Company, which introduced commercially the first toothed electric armature. Among the first electric automobiles and trucks used in New York were those of the Riker design.

In 1902 Mr. Riker joined the Locomobile Company of America and became its vice-president and chief engineer. The company abandoned its popular-priced steam cars for the gasoline-fueled type of vehicle, the first of which was designed by Mr. Riker. It had many engineering features, new at that time, including sliding gear transmission, steel frames, and high-tension ignition.

In 1900 the French government awarded Mr. Riker a medal for his part in the growth of motor-car science. He was appointed a member of the Naval Consulting Board in 1915 and became chairman of its committee on internal combustion motors.

Mr. Riker became an associate member of the A.S.M.E. in 1897 and a member in 1899. He served as manager from 1906 to 1909. He was the first president of the Society of Automobile Engineers and held that office for three terms. He also belonged to the American Institute of Electrical Engineers, the Automobile Club of America, the British Institute of Automobile Engineers, the New York Electrical Society, and the Society of Mayflower Descendants. His club memberships included the Engineers, University, Transportation, Fairfield Country, Pequot Yacht, and the Pootatuck Yacht Club.

He is survived by his widow, Edith (Whiting) Riker, whom he married in 1890, and by three children, Edith Whiting, Charlotte Lawrence, and Andrew Lawrence, Jr.

EDWARD AUSTIN RIX

Edward Austin Rix, whose death following a stroke occurred on January 8, 1930, at Oakland, Calif., was born at San Francisco, Calif., on January 29, 1855. He was graduated from the University of

[1] Paris, France.

California with the degree of Ph.B. in 1877, and spent the following six months as an apprentice at the Phoenix Iron Works, San Francisco. After being employed there as foreman for a little more than a year, Mr. Rix started a small shop of his own in May, 1879. About 1881, he assisted in the conversion of the Idaho plant at Grass Valley, Calif., from steam to water power. It was at this plant that the first tests of the Pelton wheel were made.

In 1883 Mr. Rix became the proprietor of the Phoenix Iron Work and in conjunction with J. K. Firth, designed, built, and operated pneumatic machinery. In 1888 they undertook also the building of locomotives and refrigerating points on the Linde system. The company furnished and erected structural steel work for many of the principal city buildings, designed and erected hoisting works, pumping plants, and pneumatic plants for mines, designed and successfully operated the first pneumatic locomotive ever operated on the Pacific Coast, built stamp mills and power tramways, and built Corliss engines and many slide valve engines of its own design.

Mr. Rix sold out his share in the business to Mr. Firth in 1890 and founded the Rix Compressed Air Machinery Company, of San Francisco, subsequently known as the Rix Company, Inc. The Company had its own shop for light construction work, and heavier work was done by the Fulton Engineering and Shipbuilding Works under his supervision.

Mr. Rix introduced the system of economy guarantees for steam plants; designed and erected near Lima, Peru, extensive works for manufacturing lard and curing meats; designed and superintended the construction and testing of the pneumatic plant at the North Star Mine, Grass Valley, Calif.; designed and furnished the power plant for the Alaska Treadwell Mill, Alaska; designed and superintended the erection of the pneumatic plant for the U. S. Government at Presidio, Calif.; and installed a steam and condensing plant and the first motion Corliss hoisting works for the S. F. and S. J. Coal Co., at Livermore, Calif.

Mr. Rix was known throughout the world as one of the outstanding authorities on the uses and development of compressed air as a unit of power. He held 35 patents on his inventions. Among these are included the compressed air automatic hammer; the first directly connected tangential water wheel on an air compressor, 1880; the air compressors for the dynamite gun plant at Ft. Riley, 1896; the first liquid air on the Pacific coast; the first air lift test plant used by Dr. Poehl, the inventor; the first variable volume air compressor, 1899; and the first supercharger air compressor.

He was awarded the gold medal of the Pacific Gas Association for his treatises on gas transmission and compression; was the reader of the first paper in California on liquid air at Stanford University in 1895; and published the first handbooks on compressed air engineering and the use of hammer drills in mining.

Mr. Rix was one of the founders of the famous Olympic Club of San Francisco and belonged to the Athens Club and the Claremont Country Club. He also was a member of the American Society of Civil Engineers, The American Society of Mechanical Engineers, which he joined in 1896, the Durant Rhetorical Society, and other scientific organizations.

Surviving Mr. Rix are his widow, Gail Wheeler (Shipman) Rix, of Emerson, Iowa, whom he married in 1913, and one daughter, Elizabeth.

EDWARD PARKINSON ROBERTS

Edward Parkinson Roberts, consulting engineer and statistician, member of the firm of Roberts & Abbott, Cleveland, Ohio, died on October 20, 1930. He was the city's first smoke commissioner (1912–1914) and was president of the Cleveland Engineering Society from 1911 to 1913.

Mr. Roberts was born in New York, N. Y., on August 29, 1857, and was graduated from the Stevens Institute of Technology with the class of 1877. For the next two years he was employed successively as lathe hand by the Singer Sewing Machine Company; draftsman by T. S. Crane, patent agent, Newark, N. J.; and machinist and superintendent by George Yale, Newark. During the winter of 1878-1879 he also taught evening classes in mechanical drawing. In the Fall of 1879 he secured employment as draftsman for Hewes and Philips, Newark, but left there not long afterward to learn the business of incandescent lamp manufacturing at the U. S. Electric Light Company, New York. After some training there and with Edward Weston in his laboratory at Newark, he became superintendent and electrician of the incandescent department of the American Electric Light Company, New York. Early in 1883 he was sent to California by a syndicate of this company. His next connection was with the Swan Lamp Company, Boston, which lead to his engagement by the Rocky Mountain Brush Company to erect and start in operation electric light plants of the Brush-Swan system throughout their territory. Among others he installed the incandescent system for the Cheyenne Elec. Light & Gas Co., and was engaged by them as general manager and electrical engineer. He also was vice-president of the Fort Collins, Colo., Elec. Light Co.

In 1888-1889 Mr. Roberts was an associate professor of electrical engineering at Cornell University and for the next four years was manager of the Swan Lamp Manufacturing Company of Cleveland. He had been engaged in consulting practice since that time.

Mr. Roberts was a member of the electrical jury which passed on displays for the St. Louis World's Fair in 1904, and was secretary of the Section on Practice of the International Electrical Congress held at the Chicago World's Fair. He had contributed many articles on smoke abatement, economic operation of electric light plants, and electric railways to the technical press and to meetings of technical societies.

Mr. Roberts became a member of the A.S.M.E. in 1889 and served on special committees for the Cleveland meeting in 1912. He is survived by his widow and two children.

WILLIAM S. ROUX

William S. Roux, designer for the National Cash Register Company, Dayton, Ohio, died in that city on April 13, 1929. He was born at Chillicothe, Ohio, on July 2, 1879, and received his education in the high school and at the Ohio Mechanics Institute.

His professional experience began as designer of electric motors and dynamos for the Barriet Electric Company (now B. A. Wesche Elec. Co.), Cincinnati, Ohio, in 1899, and in 1903 he became machine-shop foreman for that company. For two years he was draftsman for the Bullock Electric Company, Cincinnati, Ohio. He joined the National Cash Register Company in 1906. His work consisted of making layouts of mechanism and supervising the detail and assembly drawings for making model parts and assembling model machines.

Mr. Roux became a member of the A.S.M.E. in 1927. He also belonged to the Masonic fraternity. He was unmarried.

WILLIAM NEWTON RYERSON

William Newton Ryerson, president of the Trojan Engineering Corporation, and a director of the Peoples Light and Power Corporation, New York, N. Y., died at his residence in the Hotel Shelton, on the morning of July 7, 1930, after an illness of several months.

He was born in New York on December 7, 1874, the son of William Tunis Ryerson and Julia Hart (Newton) Ryerson. He attended the New York public schools, Columbia Grammar School, and the School of Mines of Columbia University, from which he was graduated in 1896 with the degree of Electrical Engineer.

Following his graduation, Mr. Ryerson was employed by the Sprague Electric Elevator Company, Bloomfield, N. J., on electrical testing and drafting, from November, 1896, to January, 1898. In the same year, 1898, he worked as draftsman for the Western Electric Company, New York, and as assistant to the chief engineer of the Waldorf Astoria Hotel.

In October, 1898, Mr. Ryerson became associated with the Metropolitan Street Railway Company of New York on construction and power work and substation operation, remaining with them until June, 1901, when he left to form a connection with the Manhattan Railway Company as chief operator of their steam electric generating station.

His chief interest at that time seemed to be in electric railways and subways and in October, 1901, he became superintendent of the substations for the Interborough Rapid Transit, with which concern he remained until April, 1905.

About that time, some of the big hydro developments on the Canadian side of Niagara Falls were started, and Mr. Ryerson became assistant superintendent of construction for the Niagara Construction Company, and later in the same year, superintendent of construction for the Ontario Power Company, Niagara Falls, Ontario, which position he held until January, 1909.

He then left the East to become general manager and chief engineer, and also a director, of the Great Northern Power Company, at Duluth, Minn. He was in this position for more than thirteen years, and it was here that he became well known among the light and power companies of the country, serving on several committees of the National Electric Light Association. About the time the Duluth properties were acquired by the Electric Bond & Share Company, Mr. Ryerson left to form a connection with Day & Zimmermann of Philadelphia, as assistant manager of the Public Utility Management Department, where he supervised the details of operation of all the utility properties, budgets, new business, rates, public relations, accounting, and major construction progress.

In January, 1925, the United Gas Improvement Company of

Philadelphia made him assistant to the vice-president, in charge of operations and engineering. His duties involved supervision of operations of gas and electric properties, budgets, rates, and engineering projects. One of his principal undertakings while there was an investigation and preparation of a report on a superpower scheme, involving the pooling of resources of several electric utilities in New York, New Jersey, and Eastern Pennsylvania.

When the Trojan Engineering Corporation was organized in September, 1928, Mr. Ryerson became its president, which position he held at the time of his death. He also served for a brief period as vice-president and general manager of the Green Mountain Power Corporation of Vermont, a subsidiary of the Peoples Light and Power Corporation, of which he was a director.

Mr. Ryerson was a fellow of the American Institute of Electrical Engineers and a member of The American Society of Mechanical Engineers, which he joined in 1906, the National Electric Light Association, the International World Power Conference, the American Gas Association, and The Engineering Institute of Canada.

He married Miss Martha Taft, of Brooklyn, in 1900. His widow, two sons, William Newton Ryerson, Jr., and Philip Ryerson, and a daughter, Mrs. Charles W. Newkirk, of Philadelphia, survive him.

GEORGE DE GROAT RYTHER

George De Groat Ryther, president of Ryther & Pringle Company, Carthage, N. Y., died at his home on April 20, 1930. He was born at Theresa, N. Y., on June 27, 1864, the son of Charles Peter and Mary (De Groat) Ryther. He received his education in the Carthage High School and at Cornell University, where he was graduated in 1887.

Following graduation he became draftsman for the Rome, Watertown and Ogdensburg Railroad, at its shops in Oswego, N. Y. Since 1892 he had been identified with the Ryther & Pringle Company, serving successively as machinist, draftsman, foreman, superintendent, and president. He was the inventor of a sectional cable conveyor, a material shredding machine, and a paper stock refiner.

Mr. Ryther became a member of the A.S.M.E. in 1918, and also belonged to the Masonic fraternity and several clubs. He was an Episcopalian in religion. In 1892 he married Jennie Isabel Cutler, who survives him.

JAMES EDWARD SAGUE

James Edward Sague, for many years connected with the Worthington Pump & Machinery Corporation, died at Cliffdale, his Poughkeepsie, N. Y., home, on May 9, 1930.

Mr. Sague was born at Poughkeepsie on July 20, 1862, the son of Horace and Harriet Jane (Kelsey) Sague. He was graduated from the Stevens Institute of Technology at Hoboken, N. J., in the class of 1883, receiving the degree of M.E. His graduation thesis covered "A Report on the Trial of the Steamer *City of Fall River*," and was published in the *American Engineer* and the *Journal of the Franklin Institute*.

From 1883 to 1892 he was engaged in railroad work. During this time he spent two years as mechanical engineer for the West India Improvement Company and master mechanic of the Jamaica Railroad, Jamaica, W. I., following which he was engaged with the Schenectady Locomotive Works from 1892 to 1901.

From 1901 to 1907 he was chief mechanical engineer and later was vice-president of the American Locomotive Company.

During the first administration of Governor Hughes in 1907, Mr. Sague was appointed a member of the Public Service Commission for the Second District, controlling all public utilities in New York State outside of New York City. He held this office for seven years with great credit to the Commission and himself. While with the Public Service Commission, he was chosen chairman of the Committee on Rails and Equipment of the National Association of Railroad Commissioners.

In 1916 the American Manufacturers Export Association organized the American Industrial Commission. This commission visited France to ascertain how American resources might best be made available for the reconstruction of the devastated regions and with the hope of furthering Franco-American trade relations. Mr. Sague was a member of this commission.

In June, 1916, he was chosen chief consulting engineer of the Worthington Pump and Machinery Corporation. In March, 1918, he was elected a member of the board of directors and vice-president in charge of engineering and manufacturing, and as such directed Worthington's large production of war material.

Mr. Sague resigned as vice-president of Worthington in 1926, but remained a director of the company until his death.

For several years prior to his death he was chairman of the Reorganization Committee of the Middle States Oil Company, and upon its rehabilitation in 1930 as the Middle States Petroleum Company he became a member of the board of directors and a voting trustee. He was at the same time president of the Sague Realty Company of Poughkeepsie.

Mr. Sague was married in 1890 to Miss Jeanette Kenyon of Brooklyn, N. Y.; and after her death to Miss Mary Landon, a professor at Vassar College, who, together with his daughter, Mrs. Sterling Carter, of Poughkeepsie, survive him.

Mr. Sague joined the A.S.M.E. in 1887, and was vice-president of the Society in 1914–1916.

JOHN JOSEPH SCOLLAN

John Joseph Scollan, whose death occured on January 5, 1930, was a native of Elizabeth, N. J., where he was born on September 24, 1870. He attended St. Henry's School in that city and then served an apprenticeship in the shops of the Central Railroad of New Jersey.

From 1896 to 1903 Mr. Scollan was employed by the Crescent Shipyard Company at Elizabeth, a year each as machinist and foreman machinist, and five years as chief engineer. He spent seven years at sea, first as junior and subsequently as chief engineer, and for a year and a half was in the employ of the Japanese government in charge of the design, installation, and trials of war vessels.

Mr. Scollan was first located in Canada as superintendent of mechanical erection for the Canada Foundry Company, Ltd., at Toronto. He was advanced to the position of mechanical engineer in this company, and had charge of the manufacture of boilers and general machinery.

After leaving the employ of the Canada Foundry Company, Mr. Scollan became general superintendent for the Canadian Allis-Chalmers Company at the Niagara Shipyards, at Bridgeburg, Ontario.

He returned to the United States about 1919 to accept a position with the Submarine Boat Corporation, Newark, N. J.

Mr. Scollan became a member of the A.S.M.E. in 1910. He was also an Elk.

MICHAEL JACOB SHAMRAY

Michael Jacob Shamray, son of Jacob and Anna (Shulova) Shamray, was born at Kremenchug, Russia, on July 23, 1862. He attended the classical gymnasium at Kherson, Russia, receiving the degree of Academic Maturity in 1880. He also studied at the Petrograd Technological Institute, and received an M.E. degree from the Royal Saxon Polytechnikum, Dresden, Germany, in 1886.

During the next few years Mr. Shamray worked on the design of special machinery for paper mills, water turbines, and steam engines in Dresden, and design and construction of railway shops for the Libau-Romen Railroad, Russia. In 1889 he accepted a position as superintendent of car repair shops for the Bulgarian State Railway, Sofia, and he was engaged in municipal work in Bulgaria from then until 1902. He was classed by the Ministry of Public Works as first grade mechanical engineer and was in responsible charge of the following works: city survey and planning, including water supply, public buildings, reconstruction of dams, and power development, City of Stanimaka; revising and checking of city plan and construction of public buildings, City of Kustendil; correction and flood regulation of Maritsa River, water supply, and city survey, City of Philippople; and general municipal work in the Province of Tatar-Bazardjik. A number of inventions by him during these years were patented in Germany and Bulgaria.

Mr. Shamray came to the United States in 1902 and spent the first year in standardizing parts of special machinery for the International Postal Supply Company, New York. For the next three years he was engaged in the design of railroad cars for the Goodwin Car Company, New York. Since 1906 he has been associated with George F. Hardy, of New York, in consulting engineering practice. His work dealt particularly with reinforced concrete and hydraulic engineering in connection with the design of more than fifty paper mills and water-power developments in the United States and Canada. He had contributed a number of articles to the technical press.

Mr. Shamray became a member of the A.S.M.E. in 1923. He also belonged to the Russian Engineering Association in the United States and the American Society of Civil Engineers. He was active in charitable work, being a member of the Jewish Federation of Charities, Jewish Consumptive Relief Society, Welfare League Association, National Home for Jewish Children at Denver, New York Association for the Blind, Inc., National Society for the Prevention of Blindness, and New York Guild for the Jewish Blind. He was also a member of the Boy Scouts Foundation of Greater New York. He was interested in astronomy and mathematics and belonged

to the Amateur Astronomers of the American Museum of Natural History.

Surviving Mr. Shamray are his widow, Pauline Ortman Shamray, whom he married in 1906, and one son, Peter Leo Shamray. Mr. Shamray was killed by an automobile in New York on December 23, 1930.

WILLIAM MILLER SHAW

William Miller Shaw, president of the Benj. F. Shaw Co., Wilmington, Del., died suddenly of heart trouble at his home there on September 3, 1930.

Mr. Shaw was a native of Wilmington, having been born there on October 8, 1882, the son of Benjamin F. and Helen Shaw. He was educated in the Wilmington public and high schools and attended the Wilmington Military Academy. He entered the shops of the Benjamin F. Shaw Company, of which his father was president, and was soon promoted to office work, and then to the mechanical office, and in 1908 was elected first vice-president and general manager of the company. In 1927, upon the death of his father, he succeeded to the presidency of the company, which position he retained until his death. He was also well known in Atlantic City, where he had a home.

Mr. Shaw became a member of the A.S.M.E. in 1915. He also belonged to the Masonic fraternity.

He is survived by his widow, Clara E. Rotthouse Shaw, and four children, Benjamin F. Shaw, 2nd, Miss Elizabeth Shaw, W. Miller Shaw, Jr., and Robert Frederick Shaw.

THOMAS SHIPLEY

Thomas Shipley, president of the York Ice Machinery Corporation, York, Pa., died on January 22, 1930. Mr. Shipley had been a member of the A.S.M.E. since 1891, was a charter member and president in 1912 of the American Society of Refrigerating Engineers, and also belonged to the National Association of Practical Refrigerating Engineers and the American Association of Ice and Refrigeration. He had presented papers on refrigeration at meetings of these and other societies and through both his society and business affiliations was very well known in the refrigeration industry.

Mr. Shipley was born at Jersey City, N. J., on June 30, 1861. He attended Cooper Institute, from which he was graduated as a mechanical engineer in 1882. During his years at Cooper Institute and for several years thereafter he was employed as a draftsman by the Morris & Cummings Dredging Co. of Jersey City, and the Babcock & Wilcox Boiler Co. and the firm of Wood and Richmond in New York, N. Y. In 1885 and 1886 he was associated with Wm. H. Wood in the firm of Wood & Shipley, designing and building ice machinery. Mr. Wood, likewise a prominent figure in refrigeration and a member of the A.S.M.E., died in July, 1930.

From 1887 to 1893 and again from 1895 to 1897 Mr. Shipley was identified with the Frick Company of Waynesboro, during the latter period as manager of the ice and refrigerating machinery department. During the intervening period he was president and general manager for a year of the Steubenville Ice Manufacturing Company, at Steubenville, Ohio, and operating engineer for two years of the Chautauqua Lake Ice Company at Pittsburgh, Pa.

Mr. Shipley became vice-president and general manager of the York Manufacturing Company in 1897. Other firms which he had served either as president or treasurer included the York Milk Machinery Company and York Oil & Chemical Co., York, Pa.; Bay State Construction & Supply Co., Boston, Mass.; Shipley Construction & Supply Co., Brooklyn, N. Y.; Central Construction & Supply Co., Philadelphia, Pa.; Southern Construction & Supply Co., Atlanta, Ga.; Greenwood Construction & Supply Co., Pittsburgh, Pa.; and York-Ohio Ice Machine Company, Cleveland, Ohio.

GEORGE MARSHALL SINCLAIR

George Marshall Sinclair, whose death occurred on August 21, 1930, was born at Milwaukee, Wis., on June 10, 1861. He secured the degrees of A.B. in 1881 and A.M. in 1884 from Princeton University, and an M.E. degree from Stevens Institute of Technology in 1884.

Following the completion of his college work Mr. Sinclair became assistant to the chief engineer of the Midvale Steel Works, Philadelphia, Pa., where he remained for three years. After spending some time in Germany and England, visiting iron and steel works, and working for two years in the ordnance and marine forging department of the Bethlehem Steel Company, he returned to the Midvale Steel Works in 1890 to work on design.

In 1893 Mr. Sinclair opened an office as consulting engineer. From 1895 to 1905 he served as secretary and treasurer of the Philadelphia Machine Tool Company and its successor, the Falkenau-Sinclair Machine Company. Since that time he had maintained an office as consulting engineer in Philadelphia, served as director in a few small manufacturing companies, and given a large portion of his time to selling engineering equipment.

Mr. Sinclair became a junior member of the A.S.M.E. in 1887 and a full member in 1890.

BRONSON HASBROUCK SMITH

Bronson Hasbrouck Smith died in Los Angeles, Calif., on June 6, 1930, after a long illness. He is survived by his widow, Florence Merwin Smith.

Mr. Smith was born in Brooklyn, N. Y., on May 9, 1880. After studying mechanical engineering for two years at Cornell University he became assistant to the general manager of the Perth Amboy Shipbuilding Company, Perth Amboy, N. J. From this company he went in 1902 to the employ of the Holland Submarine Torpedo Boat Company as machinist and in 1903 and 1904 was designer and assistant to the superintendent of the F. H. Lovell Mfg. Co.

For about ten years Mr. Smith was identified with Westinghouse, Church Kerr & Co., as draftsman and designing engineer. He had charge of the construction of railway stations in New York, Toronto, and Chicago, power plants in Worcester and Meriden; railway shops for the Canadian Pacific Railway and the Central Railroad of New Jersey; and power houses for several other railways and companies. He also made appraisals on several hydroelectric plants.

Mr. Smith left the Westinghouse company in 1913 to become general superintendent in charge of maintenance and operation of railroad and steamboat lines for the Jamestown, Chautauqua & Lake Erie R. R. After two years with that road he accepted a position with the United Gas & Elec. Corp., part of his work being the design and construction of steel motor cars for railways. As engineer for Henry E. Kent & Co. from 1915 to 1920 he designed and supervised the construction of power plants and factory buildings for a large number of companies including the Spicer Manufacturing Corporation, American Brass Company, and National Analine & Chemical Co. Following a period as chief mechanical engineer for the American Cotton Oil Company, New York, N. Y., Mr. Smith went to Los Angeles, where he was managing engineer for Meyer & Holler, Inc., for some years. He had charge of the construction of the Petroleum Securities Building, the Chinese Theater in Hollywood, and many other large buildings.

Mr. Smith had been a member of the A.S.M.E. since 1921.

PETER E. SMITH

Peter E. Smith, designing engineer for Louis T. Klauder, of Philadelphia, Pa., at the time of his death on January 28, 1930, was born in Washington, D C., on July 31, 1888. Following his high school work he entered Drexel Institute, from which he was graduated in 1908. All of his business connections were with Philadelphia companies. During the four years following graduation he was employed by the American Heating & Ventilating Co., the latter part of the time being spent in laying out installations for public buildings. He next spent a year each with the Philadelphia Electric Company, working on piping layout for one of its stations, and with the American Engineering Company, making setting drawings for stoker installations.

In 1914 Mr. Smith took a position as designing draftsman with the Pennsylvania Flexible Metallic Tubing Company; his work included the supervision of foundry and machine shop and the erection of machinery and new buildings. Three years later he became design engineer for the Roach Stoker Company, in complete charge of design and drawing room, and also new equipment for the plant. Prior to his association with Mr. Klauder he was field engineer for a time for the United Gas Improvement Contracting Company.

Mr. Smith became an associate-member of the A.S.M.E. in 1922.

STEPHEN RAYMOND SMITH

Stephen Raymond Smith, tool designer for the Victor Talking Machine Company, Camden, N. J., died suddenly on June 10, 1930.

Mr. Smith was born at Windber, Pa., on August 19, 1898. Prior to the World War he worked in the machine shop and foundry of the Marion Steam Shovel Company, Marion, Ohio. He enlisted in the U. S. Army in 1916 and saw overseas service. Following the War he worked for two years as detail draftsman in the maintenance department of the Baldwin Locomotive Works at Philadelphia.

From 1920 to 1922 Mr. Smith attended the Brown College Preparatory School at Philadelphia, and after a summer school course in mathematics at the University of Pennsylvania, entered Rens-

selaer Polytechnic Institute, where he took three years' work in mechanical engineering.

Mr. Smith returned to the employ of the Baldwin Locomotive Works in 1925 and remained there for two years, engaged in design work. In 1927 and 1928 he was connected with the Edw. G. Budd Mfg. Co., on the design of dies, etc., for steel automobile bodies, and the John Warren Watson Company, manufacturers of the Watson stabilators, on tool and machine design. He had been with the Victor Talking Machine Company since 1928.

Mr. Smith was a new member of the Society, having joined as a junior member only about six months before his death. He is survived by his widow, Dorothea C. Smith.

WILLIAM GAGE SNOW

William Gage Snow, manager of the Middlesex Products Company, Boston, Mass., died on February 14, 1930. He had been a member of the A.S.M.E. since 1905.

Mr. Snow was born at Watertown, Mass., on Feburary 16, 1866. Following his receipt of an S.B. degree from the Massachusetts Institute of Technology in 1889 he spent two years in the drawing room of the B.F. Sturtevant Co., at Jamaica Plain, Mass., and then for two more years was in charge of installation work throughout New England for the Company.

For five years beginning in 1894 Mr. Snow was employed by the Walker & Pratt Mfg. Co., Boston. He designed heating and ventilating systems for schools and other public buildings and laid out the steam power plant and blower system for a new plant for the company. A treatise on Furnace Heating written by him during these years was published by the David Williams Company.

After leaving the Walker & Pratt Co., Mr. Snow engaged in heating and ventilating work, particularly in investigations and reports, for the S. Homer Woodbridge Co., Boston. In 1901 he went to Philadelphia as chief heating and ventilating engineer for Francis Bros. & Jellett, Inc. Among the heating, ventilating, and mechanical plants for which he made plans and specifications were those at the Bellevue-Stratford Hotel in Philadelphia, the U. S. Court House and Post Office at Indianapolis, and the Camden County Court House.

Mr. Snow prepared heating and ventilation courses for two correspondence schools and while in Philadelphia lectured on this subject at the University of Pennsylvania.

Mr. Snow returned to Boston as New England manager of Warren Webster & Co., of Camden, N. J. Prior to his connection with the Middlesex Company he was for about six years treasurer of the Reversible Collar Company in Boston.

ELMER AMBROSE SPERRY

Elmer Ambrose Sperry, past-president of the A.S.M.E., engineer and inventor, whose name will always be associated with the development of devices involving the gyroscope, died at St. Johns Hospital, Brooklyn, N. Y., on June 16, 1930, as a result of complications which set in after he had practically recovered from an operation.

Mr. Sperry was born at Cortland N. Y., on October 12, 1860. He was the son of Stephen Decatur and Mary Burst Sperry, and a descendant of Richard Sperry, who emigrated from England in 1634 and who, in 1666, at New Haven Colony in Connecticut, secreted on his farm in what is now known as Judges Cave, Whalley, Goffe, and Dixwell, three of the regicide judges who had condemned King Charles I to death.

Mr. Sperry attended the State Normal School at Cortland, and spent the college year of 1879-1880 at Cornell University. In 1876, through arrangements made possible by the Y.M.C.A. of Cortland, N. Y., he visited the Centennial Exposition in Philadelphia, and here received an imperishable inspiration for a career of invention. To this experience, which introduced him to engineering and determined his life's work, he paid magnificent tribute by leaving in his will the sum of $1,000,000 to the Y.M.C.A.

One of Mr. Sperry's early contributions to the electrical industry was an improved form of Gramme dynamo for arc lighting and an arc lamp for use with the machine. He secured the adoption of lamp and dynamo, and in 1880 founded the Sperry Electric Company of Chicago in order to manufacture these and other electrical appliances.

In 1883 he erected on Lake Michigan an electric beacon 350 ft. high, the highest in the world, and equipped it with 40,000 candlepower of arc lights.

In 1888 he was the first to build electrical mining machinery. His machines have been widely used, and started a distinct advance in mining.

About 1890, he became a designer of electric street-railway cars and soon founded the Sperry Electric Railway Company of Cleveland, Ohio, to build them. In 1894 the patents were purchased by the General Electric Company. He then designed electric carriages and manufactured them for several years. With a storage battery invented by him he was able to drive an electric carriage the remarkable distance of 100 miles. In 1896 he drove the first American-built automobile in Paris. A number of his electric carriages were sold there.

Electrochemistry also interested Mr. Sperry. He originated a process for caustic soda and bleach which still continues to be used extensively because a second large plant has recently been put into operation. Under other Sperry patents the National Battery Company was organized. He invented a detinning process for recovering tin from old cans and scrap, and an electrolytic process for producing white lead from wastes of copper mines. He invented machinery for producing fuse wires. On this invention the Chicago Fuse Wire Company was established.

In 1918 Mr. Sperry announced his high-intensity arc searchlight, having a brightness 500 per cent greater than that of any light previously made. It has high actinic value and has made possible indoor photographing of motion pictures without the sun. It is a great aid in the navigation of air and water, and is the standard searchlight for the principal armies and navies of the world.

Mr. Sperry devoted much thought, energy, and money to the development of compound internal-combustion engines using low-grade fuel oil. His compound Diesel engine, for a given horsepower, has about one-fifth the size and weight of the ordinary types.

About 1896, Mr. Sperry turned his attention to making practical use of the principles underlying the toy known as the gyroscope. This amazing device appears to have been invented some time in the eighteenth century. It was studied scientifically by Foucault, a French physicist, about 1851. The gyroscope is a wheel with a heavy rim, so mounted that it can spin very rapidly on its axis. When friction is reduced to a minimum and the method of mounting and suspending eliminates restraint by other objects or external forces, the gyroscope tends to point its axis in a definite direction and to return to that direction if disturbed. Possibilities of great usefulness were perceived. By diligent, tedious, and expensive investigation and great ingenuity, overcoming many obstacles, Mr. Sperry skilfully combined electrical and mechanical elements into successful gyroscopic compasses and stabilizers for ships and airplanes.

The gyroscopic compass was completed in 1910 and was first tried out on the United States Battleship *Delaware* at the Brooklyn Navy Yard. Soon after this it was adopted by the U. S. Navy and during the War it was used in the allied navies and subsequently by more than sixty steamship lines. In 1913 the gyroscopic stabilizer for ships appeared. The following year Mr. Sperry entered the field of aeronautics, and on June 14, 1914, his airplane stabilizer was awarded a first prize of 50,000 francs by the French government in a contest for safety devices for airplanes. The winning machine was piloted by the inventor's son, Lawrence B. Sperry.

These inventions have been great contributions to safety and comfort of navigation of the seas and the air. In some respects they are the most distinctive productions of a remarkably prolific inventor.

Another of Mr. Sperry's inventions is a device for detecting flaws in steel rails. The detector is mounted upon a car which runs along the track at the rate of 6 to 8 m.p.h. Any flaw in the rail is detected, recorded in ink on a moving chart, and its location automatically marked on the rail with white paint.

Mr. Sperry possessed a rare combination of business and inventive ability. Prior to 1910 six companies had been founded to manufacture his inventions with an aggregate annual business in excess of five million dollars. In 1910 he organized the Sperry Gyroscope Company, New York, to manufacture the gyrocompass, ship and airplane stabilizers, high-intensity searchlights, fire-control apparatus, internal-combustion engines, and other products invented by him. In January, 1929, this company was sold to the North American Aviation Company. At the time of death he was chairman of the board of the Sperry Products, Inc., successor to the Sperry Development Company and the Sperry Rail Service Corporation.

Mr. Sperry obtained more than four hundred patents. For nearly fifty years he was an unusually productive worker in a surprisingly wide area of science and engineering. Many honors were conferred upon him for his achievements. In 1914, as already noted, he was awarded the first prize of the Aero Club of France for his airplane stabilizer. In that year he also received the John Scott Legacy Medal and Premium awarded by the Franklin Institute. Other awards include the Collier Trophy in 1915 and 1916; the John Fritz Medal, 1927; the Holley Medal, 1927; the Elbert H. Gary Medal of the American Iron and Steel Institute, 1929; the Elliott Cresson Medal of the Franklin Insitute, 1929; two decorations from the Emperor

of Japan, the Order of the Rising Sun and the Order of the Sacred Treasure; two decorations from the last Czar of Russia; and the Grand Prize, Panama Exposition.

Mr. Sperry was a member of the United States Naval Consulting Board and chairman of the Division of Engineering and Industrial Research of the National Research Council. He was a founder member of the American Institute of Electrical Engineers and the American Electrochemical Society; a life member of the A.S.M.E., which he joined in 1910 and which he served as president in 1928-1929; and past-president of the New York Electrical Society. He was also a member of the American Chemical Society, the Society of Naval Architects and Marine Engineers, Society of Automotive Engineers, American Petroleum Institute, American Association for the Advancement of Science, National Academy of Sciences, Edison Pioneers, National Aeronautic Association, Franklin Institute, and other technical and scientific organizations in this country. He was an honorary member of the Japanese Society of Mechanical Engineers, the Japanese Society of Naval Architects, the Japanese Society of Electrical Engineers, the Illuminating Engineering Society of Japan, and the Engineering Association of Hawaii. He was a member of the Engineers' Club of New York and numerous other social organizations as well.

Mr. Sperry has been credited with having originated the World Engineering Congress in Japan in 1929. He was elected chairman of the American Committee, of which President Hoover was honorary chairman. At the Congress he was elected an honorary vice-president and, as leader of the American delegation, took a very active part in the program.

Stevens Institute of Technology and Lehigh University conferred the degree of Doctor of Engineering upon Mr. Sperry and Northwestern University the degree of Doctor of Science.

Mr. Sperry was married in 1887 to Miss Zula A. Goodman, recently deceased, of Chicago. He is survived by his daughter, Helen Marguerite (Mrs. Robert Brooke Lea), his sons, Edward Goodman and Elmer A. Sperry, Jr., and five grandchildren. Another son, Lawrence Burst, lost his life flying over the English Channel in 1923 in a plane of his own design.

JOHN STRACHAN

John Strachan was born at Govan, Glasgow, Scotland, on July 24, 1872, and belonged to one of the most prominent families connected with shipbuilding in Scotland. Following the completion of grammar school, he acquired a technical education at the Andersonian Institute, Glasgow, of which he was a graduate. He next served a six years' apprenticeship with Dunsmuir & Jackson, Govan, Glasgow, four years of which were spent in the shops and the last two years in the drawing office. For the next two years he worked in the engine drawing office of Alex. Stephen & Sons, Linthouse, Glasgow.

Mr. Strachan's sea experience comprised fifteen year's service with the Allan and State Line, Glasgow, Scotland, during which time he served in all grades from junior to chief engineer, and the latter part of the time as assistant superintendent engineer, and five years with the United Fruit Company as chief engineer. During his service with the United Fruit Company he spent the greater portion of the time at Belfast, Ireland, supervising the construction of vessels for the passenger and fruit trade.

In 1913 Mr. Strachan left the United Fruit Company to join the Babcock & Wilcox Company, with whom he remained four years doing testing and experimental work on coal, pulverized coal, and oil fuel. For some time he was in charge of the shell shop at Barberton, Ohio, which was engaged in making 9.2 shells for the British government. When the United States entered the World War Mr. Strachan left the Babcock & Wilcox Company and joined the American International Shipbuilding Corporation, Hog Island, Pa., where he served two and a half years as general superintendent of machinery installation and outfitting, and in charge of all floating equipment.

In 1919 he joined the International Products Steamship Company as operating manager and during his connection with that company had charge of the building of two refrigerator ships for the carrying of frozen meats. He spent a large portion of his time while with this company in Buenos Aires and Paraguay, South America.

In 1922, on his return from South America, he joined A. H. Bull & Company as operating manager, and in 1924 he became connected with the Black Diamond Steamship Corporation in a similar capacity.

In 1925 Mr. Strachan left the Black Diamond Company to practice as a consulting engineer and surveyor, in which business he was still actively engaged at the time of his death.

He became a member of the A.S.M.E. in 1920. He was also a member of the Society of Naval Architects and Marine Engineers. His death occurred on February 2, 1930.

JOHN T. TAYLOR

John T. Taylor, who had been a member of the A.S.M.E. since 1891, was born in England on July 31, 1855. At the age of fifteen he began an apprenticeship as machinist, following the completion of which he worked as a journeyman until 1878. He had six years' experience as a locomotive engineer and six as chief engineer for W. & J. Sloane, New York, N. Y. He attended Cooper Institute, from which he was graduated in 1890, subsequent to which he did consulting work for the Oldham Mills Company. For many years he had been superintendent and building manager for Horace S. Ely & Company, New York, N. Y.

Surviving Mr. Taylor is a daughter, Miss Alice Taylor, of New York.

WILLIAM MASON TOWLE

William Mason Towle, professor emeritus of industrial engineering, Clarkson College of Technology, Potsdam, N. Y., died suddenly at his home at Enosburg Falls, Vt., on October 21, 1930. He was a life member of the A.S.M.E., which he joined in 1887.

Professor Towle was born at Franklin, Vt., on December 21, 1851, the son of John Johnson and Mercy A. (Mason) Towle. He attended the normal school there and subsequently the Montpelier (Vt.) Seminary. He was graduated from Worcester Polytechnic Institute with a B.S. degree in mechanical engineering in 1877.

For some years following the completion of his college work Professor Towle engaged in the manufacture of sashes, doors, etc., as a partner in the firm of Manley & Towle in Enosburg Falls. In 1884 he went to Terre Haute, Ind., as superintendent of the Bramble Lock Works, and during the next two years was draftsman for the United Brass Company, Lorain, Ohio. He then became instructor in machine toolwork at Rose Polytechnic Institute at Terre Haute, where he remained until 1888. For the next year he was employed by the Buckeye Engine Company, Salem, Ohio, and the Straight Line Engine Company, Syracuse, N. Y.

Professor Towle returned to the teaching profession in 1889 as instructor in mechanical engineering and foreman of the machine shop at Sibley College, Cornell University, and with the exception of a year (1891-1892) as mechanical engineer for the Mansfield (Ohio) Machine Works, devoted the remainder of his active life to that profession. He was assistant professor in charge of shops at Pennsylvania State College from 1892 to 1902, associate professor in charge of shops at Smith College, Syracuse University, during the next two years, and from 1907 until his retirement in 1917 professor of industrial engineering at Clarkson.

Professor Towle was a Methodist Episcopalian. He belonged to the Society for the Promotion of Engineering Education, the Vermont Society of Engineers, the Vermont Historical Society, the Royal Society of Arts, and the Potsdam Club, and was a fellow of the American Association for the Advancement of Science.

CARL EDWARD TRUBE

Carl Edward Trube, who died on March 11, 1930, as the result of burns suffered during some experimental work, was born in New York, N. Y., on February 22, 1901. He attended the Horace Mann High School and Stevens Institute of Technology, from which he was graduated with an M.E. degree in 1922.

Following his graduation Mr. Trube was employed for a time at the Jersey City branch of the Mengel Company, in charge of the development and production of radio apparatus. Later he took up consulting work in New York and at Ossining, N. Y. He became a junior member of the A.S.M.E. in 1923.

CHARLES PRENTICE TURNER

Charles Prentice Turner, who died on October 25, 1930, was born at Oxford, N. Y., on March 30, 1862.

After his graduation from Oxford Academy he entered Lehigh University, from which he received a M.E. degree in 1889.

His first work was with the Cambria Steel Company, Johnstown, Pa., making physical tests of iron and steel, and doing drafting and general construction work until 1892. After a year as draftsman on engines and boilers for the Stearns Manufacturing Company, Erie, Pa., and about six months' work on special engine research for Professor J. F. Kline of Lehigh University, he returned to the steel industry as draftsman for the Johnson Company (now Lorain Steel Company) at Lorain, Ohio. In addition to drafting he made estimates and checks on the design of steel plants and mills.

In 1895 and 1896, and from 1897 to 1901 Mr. Turner wrote and edited textbooks for the International Correspondence School of Scranton, and was principal of its school of mechanical engineering.

In 1896 and 1897 he was employed by the Carnegie Steel Company, Braddock, Pa., as draftsman at the Edgar Thomson Works.

Mr. Turner severed his connection with the International School in 1901 to take charge of the construction of the Clairton Steel Works and furnaces, Clairton, Pa., for the Garrett-Cromwell Engineering Company of Cleveland, Ohio. After completing this job he installed furnaces at the Delray, Michigan, plant, and was chief draftsman for the company's furnaces and steel works.

From 1903 to 1906 Mr. Turner was associated with the National Tube Company of McKeesport, Pa., in charge of the design and construction of new rolling mills, power plants, etc., for the company.

Mr. Turner went to the Steelton, Pa., plant of the Pennsylvania Steel Company in 1906, and his first duties were the design and construction of a new open-hearth unit of five 70-ton furnaces. As soon as the work was well under way at Steelton, he was transferred temporarily to the plant of the Maryland Steel Company at Sparrow's Point, Md., which was under the same financial control as the Pennsylvania Steel Company, to start the design and construction of the first open-hearth plant there.

In 1908 he was made chief engineer of the Steelton plant and continued in this capacity until the latter part of 1926, although in 1916 the ownership of the plant had been acquired by the Bethlehem Steel Company.

In 1926 Mr. Turner was transferred to the central office of the Bethlehem Steel Company at Bethlehem as an engineer in the development and research department, a position for which his long and intimate contact with the steel plant's operations eminently qualified him. He continued in this capacity until ill health compelled his retirement in 1929.

During his long period of service as chief engineer of the Steelton plant the program of improvements was continued beyond the construction of the open-hearth unit, the engineering of which first drew him there. In all the successive development and reconstruction of coke ovens, blast furnaces, rolling mill, and additional departments, Mr. Turner had a large share of the responsibility.

Mr. Turner became a member of the A.S.M.E. in 1912. He is survived by his widow, Laura V. Turner.

GEORGE CHRISTIAN UGGLA

George Christian Uggla died on January 12, 1930, as the result of an automobile accident a few days before.

Mr. Uggla was born at Westerias, Sweden, on May 26, 1885, and secured his education in that country. For a time he was connected with the Atlas Machine Company in Sweden, in machine shop work, and also had some experience in shipbuilding and in engine operation at sea. He came to the United States in 1905 and had been naturalized. His first position here was with the Midland Steel Company, on general machine work and as erecting and steam engineer in charge of the power house.

Since 1907, Mr. Uggla had been connected with the Seneca Iron & Steel Co., of Buffalo, N. Y., with the exception of from 1927 to 1929, when he was with the Michigan Steel Company. He served the Seneca company in various positions, and at the time of his death was its chief engineer.

Mr. Uggla became a member of the A.S.M.E. in 1927.

VERNER R. VELANDER

Verner R. Velander was born at Stanton, Iowa, on May 16, 1888. After completing high school he entered Iowa State College, at Ames, Iowa, from which he was graduated in 1909.

For the first year following his graduation, he was employed by the Crane Company of Chicago, as machine hand and foreman in the coupling department. He then spent three years with the Underfeed Stoker Company of America, at Chicago, two and a half years as draftsman of forced draft systems and boiler settings. From 1913 to 1914 he was working on the designing of boiler settings, piping systems, etc., for power stations for Sargent & Lundy of Chicago. During the next year he was responsible for the field inventory of mechanical equipment in connection with buildings in Detroit, as an employee of the Detroit United Railways. Subsequently for a short time he did similar work for the Public Service Corporation of Northern Illinois, in the employ of Sanderson & Porter. In 1916 Mr. Velander became associated with the Gas Machinery Company of Cleveland, Ohio, as a designer of mechanical equipment and structures for gas plants. After two years, he resigned this position to take charge of the drawing room of the Willis E. Holloway Co., Cleveland, Ohio, but left this company shortly to become connected with the Marion Machine Foundry & Supply Co., of Scottdale, Pa. His work for the latter firm included the design of coal handling machinery, crushing equipment, and other machinery. About 1924 Mr. Velander went to Pittsburgh, Pa., as district representative of the Stearns Conveyor Company. In 1926 and 1927 he was connected with the United States Arsenal in that city. He then removed to Chicago, where he founded the Verner Steel Products Company, with which he was identified at the time of his death.

Mr. Velander's death occurred at Chicago on May 22, 1930. He had been an associate member of the A.S.M.E. since 1921. He also belonged to the Swedish Engineers' Society of Chicago, Ill.

CHARLES MARSHALL WALES

Charles Marshall Wales, New York representative of the Wheeling Mold & Foundry Co., died of pneumonia at his home in Englewood, N. J., on November 1, 1930.

Mr. Wales was born at Elkhorn, Wis., on May 2, 1862, the son of Charles and Eliza A. (Crandall) Wales. After his graduation in 1885 from the University of Wisconsin, with a B.M.E. degree, he worked as a machinist in Providence, R. I., and Hartford, Conn., for Thurston, Stearns & Co., the Waterhouse Electric & Mfg. Co., and the Paige Typesetter Company until 1866. He then went to Cleveland as a designer and draftsman for the Prospect Machine & Engine Co. Following a year with this company, he became associated with the Cleveland City Forge & Iron Co. He designed and superintended the construction of furnaces and machinery at the Cleveland office for several years, following which he was made manager of the New York office of the company, a position which he retained until his death. In addition to his work as representative of the Wheeling Company and the Cleveland Forge Company, Mr. Wales engaged in consulting engineering.

Mr. Wales became a member of the A.S.M.E. in 1890. He also belonged to the Society of Naval Architects and Marine Engineers. For more than twelve years he was treasurer of the Engineers' Club (New York) and a member of its board of governors for nearly thirty years. He belonged to the New England Historical and Genealogical Society, the Western University Club, and the Knickerbocker Country Club. For more than twenty years he had belonged to the first Panel Sheriff Jury of New York.

Surviving Mr. Wales are his widow, Mrs. Catherine M. (Gillet) Wales, whom he married in 1894, and three daughters, Mrs. Roland B. Haines, Mrs. Walt Thomas, and Miss Elisabeth Crandall Wales.

CHARLES BOSS FRANKLIN WALLER

Charles Boss Franklin Waller, the son of William Henry Herron and Harriet Boss Waller, was born at Drifton, Pa., October 14, 1868.

His early education was obtained at the old Episcopal Academy in Philadelphia. After graduation he entered commercial life, first with the Pennsylvania Railroad and later with his father in the stock brokerage firm of W. H. H. Waller & Co. His inclinations however, were toward things mechanical, so leaving his father he studied engineering and its associated lines, taking a night course at the Franklin Institute and later the Scranton Course. In 1901 he entered the employ of the City of Philadelphia, in the Bureau of Water, where he remained until his death on January 22, 1930.

His long experience in testing boilers and pumping engines made him a valued employee, and for years he was responsible for the efficiency and upkeep of the entire water pumping system of the city.

He became an associate member of the A.S.M.E. in 1917 and also belonged to the Engineers and West Philadelphia Clubs.

JAMES T. WALLIS

James T. Wallis, associated for nearly forty years with the motive power department of the Pennsylvania Railroad and since 1927 assistant vice-president in charge of operation, died at his home in Philadelphia, on November 7, 1930.

Mr. Wallis was born in New Orleans, La., on June 11, 1868, and attended the University of Louisiana, Georgetown College, and Stevens Institute of Technology, from which he received an M.E. degree in 1891. The same year he began his service with the Pennsylvania Railroad as an apprentice in the West Philadelphia shops, and after a year's experience as superintendent of the Altoona Manufacturing Company, Altoona, Pa., returned to the drafting room of the Pennsylvania. For a time he was assistant road foreman of the Maryland Division of the P. W. & B. Railroad, then assistant master mechanic of the Meadows Shops of the P. R. R., and of its Altoona Shops, and master mechanic of the Baltimore Shops. For several years he was superintendent of motive power of the Erie Division and Northern Central Railway.

He became superintendent of the West Jersey & Seashore Railroad in 1911 and in the following year was made general superintendent of motive power of the Pennsylvania Railroad, with headquarters at

Altoona. Nine years later he was promoted to be chief of motive power with supervision over the power department of the entire system. He was in direct charge of the locomotive and car shops at Altoona and became widely known in the design and construction of railway cars and locomotives.

Mr. Wallis was a trustee of The Pennsylvania State College from 1913 to 1922. He also was interested in and cooperated with instruction in railroad mechanical engineering through tests conducted jointly by the Pennsylvania Railroad and The Pennsylvania State College.

Mr. Wallis became a member of the A.S.M.E. in 1901 and had served in its committee work on iron and steel.

HAROLD ASHLEY WELCOME

Harold Ashley Welcome, general manager of the American Mason Safety Tread Company, Lowell, Mass., died on October 27, 1930.

Mr. Welcome was born at Lowell, Mass., on March 26, 1894. He attended the Lowell High School and secured his training in mechanical drawing and machine shop practice at the Lowell Textile Institute, where he attended evening classes for five years. From 1912 to 1915, Mr. Lowell was shop foreman at the Saco-Lowell Shops. During the next five years he was connected with the U. S. Cartridge Co. in a similar capacity. He was in charge of the purchasing and testing of tool steel for the company at three different plants.

Mr. Welcome became identified with the American Mason Safety Tread Company as factory superintendent and mechanical engineer in 1920, and was made its general manager in 1922. He was in charge of factory production and sales, covering branch offices throughout the United States, Canada, and other countries. He devoted considerable time also to the experimental and patent departments of the company.

Mr. Welcome became an associate member of the A.S.M.E. in 1925 and was promoted to full membership three years later. He also belonged to the American Society of Safety Engineers and the Society of American Military Engineers.

OTTO H. L. WERNICKE

Otto H. L. Wernicke, president of Wernicke Engineers, Inc., Pensacola, Fla., was born in Calumet County, Wis., on June 18, 1862, the son of Carl F. G. and Sophia (Fricke) Wernicke.

His first employment was with O. C. Steenburg, manufacturers of sashes and doors, Fond du Lac, Wis., and the Nobridge Foundry of Fond du Lac. From 1881 to 1892 he was employed by Altman Miller & Co., manufacturers of harvesters and threshers, also the McCormick Harvester Company of Chicago, as well as by the Singer Sewing Machine Company, of New Brunswick, N. J. He entered the furniture manufacturing business in 1893 as a member of the firm of Wernicke Company at Minneapolis, Minn., and Grand Rapids, Mich. Among other concerns with which he was connected during the remainder of his life, serving as an executive, were the Globe Wernicke Company of Cincinnati, Ohio, the Wernicke Hatcher Laboratories, the Wernicke Hatcher Pump Company, the Wernicke Timber Land Company, the Wernicke Chemical Company, the Wernicke Mariner Company, the Pensacola Tar and Turpentine Co., and the Macey Company of Grand Rapids, Mich. He invented and developed the Wernicke record and business systems, sectional book cases and furniture, gas engines, air compressors, pumps, safes, kilns, sawing machinery, and other articles in the wood, metal, and chemical industries. He also contributed articles on subjects in these fields to the scientific and trade press.

Mr. Wernicke had served as a member of the Michigan National Guard, was chairman of the Michigan State Penology Commission from 1911 to 1917, and was a collaborator in the U. S. Forest Service. He became an associate member of the A.S.M.E. in 1918. He also belonged to the National Association of Manufacturers, the Furniture Association, the Florida Engineering Society, and the Masonic fraternity, as well as to a large number of clubs.

Mr. Wernicke married Loula Abbey in 1889, and is survived by her and a son, Julius F. Wernicke.

HAROLD WILSON WIKLE

Harold Wilson Wikle died at a private hospital in Atlanta, Ga., on April 24, 1930, after a major operation. Mr. Wikle was born in Atlanta, on February 15, 1902, the son of Mr. and Mrs. J. T. Wikle. He was a graduate with a B.S. degree in Mechanical Engineering from the Georgia School of Technology, Class of 1922. Technical experience which he had secured during summer vacations in the boiler room and power house of the Fulton Bag & Cotton Mills of Atlanta, where his father was chief engineer, was supplemented by the factory test course of the General Electric Company at Schenectady, N. Y., and Lynn, Mass., which he completed in December, 1923. Since that time he had been connected with the Southeastern District of the General Electric Company, and at the time of his death was one of its most capable and promising industrial salesmen.

Mr. Wikle became a junior member of the A.S.M.E. in 1924, and was also a member of the American Institute of Electrical Engineers. His widow, Helen (Macon) Wikle, survives him.

WILLIAM WILKE

William Wilke, whose death occurred on April 4, 1930, was born in Darmstadt, Germany, on September 9, 1855, the son of William and Charlotte Catherine (Seippel) Wilke. His father, who resided in the United States in 1848-1849, was a manufacturer of machine tools and special machinery in Darmstadt; and his mother was a daughter of John Seippel of Darmstadt, who came to Baltimore, Md., in 1845.

William Wilke attended the preparatory schools of his native city, served an apprenticeship of two years (1869–1871) in his father's shop, and was graduated with an M.E. degree at the Darmstadt Engineering College in 1877.

Immediately after his graduation he entered the employ of the Imperial Railways of Germany. He came to the United States in 1881 and for five years was assistant chief engineer of the Midvale Steel Company, Philadelphia, Pa. In this position he made the acquaintance of Frederick Winslow Taylor, who became his intimate friend, and to whom he gave valuable assistance in research work, particularly in perfecting the art of cutting metals.

During the years 1886–1893, Mr. Wilke was chief engineer of the Gray's Ferry Chemical Works, owned at that time by Harrison Bros. & Co., Philadelphia (now owned by the du Pont de Nemours Company) devoting his attention principally to construction work, remodeling antiquated chemical works, and improving chemical processes. Since 1893 he had an extensive practice as a consulting and construction engineer.

His principal contributions to the American chemical industry were the introduction into the United States in 1902 of the first Mannheim sulphur-trioxide process and the first Mannheim salt cake furnace and hydrochloric acid process; the design, construction, and inauguration of some of the largest fertilizer and sulphuric acid plants in the western hemisphere, as well as the development of new processes for the manufacture of white lead and lead oxide.

Mr. Wilke's white lead process consists in the reduction of metallic lead to a very fine powder which is charged into revolving cylinders, in which it is brought into intimate contact with acetic acid, steam or water vapors, and carbonic acid gas and transformed into carbonate of lead or white lead within seven days, whereas in the most prevalent system it requires 100 days. This idea had been tried in a similar crude way by the Adams White Lead Company, Baltimore, Md., in 1871–1880, and by Harrison Brothers in Philadelphia for more than ten years until Mr. Wilke developed the processes for the latter company in 1886, producing a capacity of 30,000 tons of white lead of the best quality within five years. The lead oxide process is similar and is carried out in various types of mechanical furnaces.

During the years 1886–1893, he superintended the reconstruction of the entire works of Harrison Bros. & Co., building twelve new factories for the manufacture of alum, acetic acid, white lead, lead oxide, nitric, muriatic and sulphuric acids, color making and grinding, varnish and oil treating, and other departments of chemical manufacture.

In 1893 he built the large sulphuric-acid and fertilizer plant at Pinner's Point, Va., and played an important part in organizing the Virginia & Carolina Chemical Co. In later years he built fertilizer and sulphuric acid plants for the Richmond Guano Company and the Phosphate Mining Company of Savannah, Ga., the large sulphuric acid plants for the American Smelting & Refining Co. at Garfield, Utah, and extensive plants for the Standard Oil Company, Richmond, Calif., the Dupont Powder Company, Pinola, Calif., the Pennsylvania Salt Manufacturing Company, Natrona, Pa., the Naugatuck Chemical Company, Naugatuck, Conn., the Merrimac Chemical Company and the Cochran Chemical Company, Boston, Mass., the Butterworth-Judson Company, Newark, N. J., the McDougall White Lead Plant and the Contract-Process Company, Buffalo, N. Y., and with his sons erected a large lead oxide plant for the Metals Refining Company, Inc., Hammond, Ind.

During the World War, Mr. Wilke rendered important service to the Government in inspecting factories and preparing exhaustive reports on their condition and industrial possibilities.

He became a member of the A.S.M.E. in 1893 and also belonged to the American Electro-Chemical Society, the American Institute of Mining and Metallurgical Engineers, the Society of American

Military Engineers, the Society of Chemical Industry of England, and the Verein deutscher Ingenieure of Germany. He was a 32nd degree Mason and a member of the University Club of Buffalo, N. Y., where he resided for many years. Mr. Wilke was twice married. His first wife, Catherine (Nax) Wilke, died in 1895, leaving three children, William Lewis, Erwin L., and Charlotte Wilke. In 1896 he married Mary Nax, sister of his first wife, and is survived by her and their son, Henry Phillip Wilke, as well as by his other children.

JOHN T. WILKIN

John T. Wilkin, president of The Connersville Blower Company, died at his home in Connersville, Ind., on December 27, 1930, of paralysis of the heart.

He was born on July 29, 1863, at Danville, Ind., the son of William and Susan Wilkin. He received his early education in the Danville and Plainfield schools and was graduated from the Rose Polytechnic Institute with a B.S. degree in 1886. He received an M.S. degree in 1893 and his M.E. two years later.

Mr. Wilkin went to Connersville in 1886 as draftsman for the P. H. & F. M. Roots company. He married Hortense Riley of Connersville in 1889.

A few years later Mr. Wilkin was instrumental in organizing The Connersville Blower Company. He was first chief engineer of the Blower Company, later vice-president, and upon the death of E. W. Ansted, became president, which position he occupied for more than ten years.

During his career with the Blower Company he was credited with a number of important inventions and perfections relating to his business and had recently completed a new gearing arrangement which is considered one of his most important inventions.

Mr. Wilkin became a member of the A.S.M.E. in 1898, and had a keen interest in its activities. He served as a member of its Publications Committee from 1921 to 1925.

Mr. Wilkin was also a member of the Franklin Institute and a charter member of the Old Colony Club and of the Columbia Club in Indianapolis.

He was a trustee of Western College for Women at Oxford, Ohio, and of the First M.E. Church of Connersville, and belonged to the Masonic fraternity.

D. CURTIS WILLIAMS

D. Curtis Williams, connected with the engineering department of the National Tube Company, Pittsburgh, Pa., for 28 years, died on February 27, 1930. Mr. Williams was born at Shaftsbury, Vt., on September 2, 1860, and attended Lehigh University and Stevens Institute of Technology.

His early experience was as draftsman and assistant superintendent in the steel mill of William Whitely, Springfield, Ohio, and as draftsman and assistant master mechanic in the Gautier Steel Department of the Cambria Iron Company, Johnstown, Pa.

Mr. Williams became a member of the A.S.M.E. in 1891. He also belonged to the Western Society of Engineers. He was a member of the First Unitarian Church of Pittsburgh. He is survived by his widow, Mrs. Ida M. Williams, and a daughter, Lorna N. Williams.

LAWRENCE PERRY WOLFE

Lawrence Perry Wolfe, whose death occurred on September 16, 1930, was born at Kittaning, Pa., on July 25, 1881. He completed the steam engineering course of the International Correspondence School and also studied at the Hays School of Combustion. From 1911 until his death, he was assistant chief engineer of the Covington Plant of the West Virginia Pulp & Paper Co. His main duties were those of promoting and maintaining efficiency in the production and use of steam and other power at this and other plants of the company, and he also conducted tests of boilers, furnaces, and other plant equipment. He designed an automatic flue gas collector and a system of cost accounting and record keeping, and also assisted in the design and construction of other furnace and stoker equipment.

Mr. Wolfe became an associate member of the A.S.M.E. in 1921.

EDWARD RANDOLPH WOOD, JR.

Edward Randolph Wood, Jr., who died in Paris, France, on March 5, 1930, was born at Philadelphia, Pa., on March 25, 1876, the son of Edward Randolph and Mary (Kneas) Wood. He was graduated from the Episcopal Academy in that city in 1893 and five years later secured his M.E. from Cornell University.

His first position was with the Camden Iron Works, Camden, N. J., and he remained in the employ of that company for some time, being promoted to the position of erecting engineer. From 1900 to 1914 he was engineering salesman and machinery sales manager for R. D. Wood & Co. of Philadelphia. Since 1914 he had been executor and trustee of the estate of Stuart Wood, president and treasurer of the Tampa Water Works Company, director of the Market Street National Bank, and president of the Cotiga Development Company.

Mr. Wood was commissioned a Captain of Field Artillery in 1917 and served with the 18th F. A. in the Second Battle of the Marne, St. Mihiel Salient, Argonne Forest, and Heights of the Meuse.

Mr. Wood was a life junior member of the A.S.M.E., which he joined in 1900. He also belonged to the Franklin Institute, American Academy of Natural Sciences, Iron and Steel Institute of Great Britain, American Society for Testing Materials, and a number of clubs in Philadelphia and New York.

WILLIAM HEAWORD WOOD

William Heaword Wood died at Media, Pa., on July 12, 1930. He was a native of England, having been born at Stockport, Cheshire, on November 26, 1844. He secured his early engineering training under his father, James Wood, a prominent engineer and millwright in England. After coming to the United States, where he later became a citizen, he worked for a time as draftsman for Ribon and March, Jersey City, N. J. In the early eighties he established an office in New York as a member of the firm of Wood and Richmond. At this time he designed and patented the first refrigerating and ice machinery in America. In 1885 he formed a partnership with Thomas Shipley, who had been connected with the firm of Wood and Richmond. Mr. Shipley, who later became well known in the refrigeration industry and was also a member of the Society, died about six months before Mr. Wood. Their partnership was dissolved in 1886 when Mr. Wood became connected with B. W. Payne & Sons of Elmira, N. Y., and also with Bement, Miles & Co., of Philadelphia.

In 1891 Mr. Wood established his own business at Media, Pa., as a hydraulic engineer, and designer and builder of special hydraulic machinery. He conducted this business until a few months before his death, when he sold it to the Reading Iron Company, which had previously built these machines according to his specifications.

Mr. Wood was the inventor of corrugated locomotive fire boxes and tube plates which several years ago were tried out by some of the largest railroads in the United States.

Mr. Wood became a member of the A.S.M.E. in 1889. He also belonged to the Western Railroad Club and the New York Railroad Club. Mr. Wood is survived by his widow, Bertha A. Wood, and a daughter, Miss Katharine H. Wood, of Media.

VOLLIE RICHARD YATES

Vollie Richard Yates, associate professor of mechanical engineering at the University of Vermont, Burlington, Vt., died of acute nephritis at the Mary Fletcher Hospital in that city on May 31, 1930.

He was born at Richford, Vt., on June 30, 1889, son of Richard and Flora (Dew) Yates. When he was six months old his parents moved to Fairfield, where he attended the local schools until he entered the St. Albans High School. He entered the University of Vermont in 1911, and received the degree of B.S. in mechanical engineering in 1915, winning Phi Beta Kappa honors.

Immediately after graduation he was made instructor in the department of mechanical engineering. In 1921 he was promoted to an assistant professorship in the same department and last year received a further promotion to an associate professorship. Since the death of Professor Edward Robinson in 1929 he was acting head of the department.

He was an untiring student of his subject. The summers of 1915 and 1917 were spent at the Jones & Lamson works in Springfield, acquiring practical experience. In 1925 he attended the summer school of the Westinghouse plant in Philadelphia, specializing in turbine design. The academic year 1926–1927 he spent at the University of Michigan, doing graduate work, principally in automotive and aeronautic engineering. He had acquired considerable proficiency in the mathematics and mechanics of turbine and aeroplane design. The summer of 1929 he spent at the S.P.E.E. School of Engineering at Purdue University, specializing in scientific management, a subject in which he was growing much interested.

Professor Yates might be truly called a born teacher, a calling which appealed to him very strongly. He was himself a thorough student and a master of his subject, and this, combined with a most likable personality and a deep personal interest in each student, always secured close attention and hearty cooperation from the class.

He became a member of the A.S.M.E. in 1923 and also belonged

to the Phi Mu Delta Fraternity, the Vermont Society of Engineers, the Society for the Promotion of Engineering Education. He was a communicant of the First Church of Burlington.

JOHN JAMES YORK

John James York, general works manager of the St. Lawrence Sugar Refineries, Ltd., Montreal, Canada, died on April 10, 1930. He is survived by a son, J. Aleck York, who is chief engineer of the company.

Mr. York was born at Lacadie in the Province of Quebec, on June 12, 1861. Through private tutorship and two years' study at the Council of Arts and Manufacturing he secured fundamental engineering training, and then served an apprenticeship in steam heating and ventilation.

All of his professional life from that time, with the exception of two years with The Garth Company, was devoted to the St. Lawrence Sugar Refining Company, now the St. Lawrence Sugar Refineries, Ltd. He designed and erected both buildings and machinery for the company, introducing new systems of heating feedwater, insulating underground steam lines, weighing and piling goods, etc. Mr. York had been a member of the A.S.M.E. since 1910.

LESLIE I. ZIEGLER

Leslie I. Ziegler died of heart disease on June 6, 1930, while returning to Indianapolis from a trip to Buffalo. Surviving him are three sisters and three brothers.

Mr. Ziegler was born at Sterling, Ohio, on September 22, 1864. He was with Millwright & Miller of Cincinnati, at Sterling, as apprentice from 1883 to 1891, and for the following year with the Bradford Mill Company, Cincinnati, Ohio, as superintendent of design and manufacturing of cereal machinery.

From 1900 to 1925, Mr. Ziegler was associated with the Nordyke & Marmon Co., at Indianapolis. For five years he was sales engineer of cereal milling machinery and for four years superintendent of installation plans. He then became general manager of the milling machinery department. Since his resignation from the company he had practiced as a consulting engineer.

Mr. Ziegler had been a member of the A.S.M.E. since 1914.

Depositories for Transactions

BOUND copies of the complete Transactions of The American Society of Mechanical Engineers will be found in the libraries in the United States and other countries which are listed on the following pages.

UNITED STATES AND POSSESSIONS

Alabama

Auburn	Engineering Library, Alabama Polytechnic Institute
Birmingham	Public Library

Arkansas

Fayetteville	Engineering Library, Arkansas University

California

Berkeley	Library, University of California
Long Beach	Public Library
Los Angeles	Public Library
	University of Southern California
